Transient diabetes insipidus during pregnancy can occur in patients with acquired or hereditary latent diabetes insipidus. Patients with limited vasopressin-secreting capacity (latent-central defect) may be unable to sustain the increased production rates necessary during gestation. Clinically, transient diabetes insipidus manifests in the latter part of gestation coinciding with peak vasopressinase levels, and subsequent pregnancies may involve many recurrences. History of prior insult to the area, such as histiocytosis X or Sheehan syndrome, may be obtained. Classic hereditary nephrogenic diabetes insipidus is caused by an X-linked recessive mutation of the renal vasopressin receptor gene, and symptomatic diabetes insipidus in female carriers is rare. Some carriers, however, do have defects in renal concentrating ability, and it has been hypothesized that nonrandom X-chromosome inactivation in the kidneys could be responsible for the variable expression. Unmasking of a mild defect in vasopressin action (i.e., nephrogenic diabetes insipidus) may occur. The increased disposal of vasopressin could lead to decompensation. Lowering of the osmotic threshold for thirst, which occurs normally in pregnancy (see Fig. 48-4), causes polydipsia and unacceptable polyuria in a patient with previously compensated nephrogenic diabetes insipidus.⁸⁴

Diabetes insipidus can occur after a complicated delivery. This is often associated with severe blood loss leading to some degree of pituitary apoplexy or Sheehan syndrome.

Transient de novo nephrogenic diabetes insipidus may be resistant to AVP and DDAVP. During pregnancy, the concentration of prostaglandin E₂ in the kidney physiologically increases. Ford and Lumpkin⁸⁵ found high prostaglandin E₂ concentrations. Reduced renal sensitivity to vasopressin has been proposed⁸⁶ to explain this.

Treatment. The treatment of choice for central diabetes insipidus is DDAVP or desmopressin acetate, a synthetic analogue of vasopressin, administered intranasally or orally. Clinical experience with DDAVP, in a study involving many infants exposed during gestation, has confirmed its safety.^{87,88} Dosages range from 10 to 20 μg given once or twice daily intranasally or 0.05 to 0.1 mg administered twice daily orally, titrating up if needed. In a study by Burrow and coauthors,⁸⁹ the drug was administered and DDAVP concentrations were measured

as vasopressin by radioimmunoassay in maternal serum and breast milk. Whereas maternal serum concentrations rose about sevenfold, breast milk concentrations showed little change. This suggests that, given the low levels of DDAVP in milk, these mothers may breastfeed. DDAVP has little pressor or uterotonic action, and it is not affected by vasopressinase.

PRIMARY POLYDIPSIA DURING GESTATION

Primary polydipsia has rarely been reported during gestation.⁹⁰ Pregnancy was merely incidental and had no role in the polydipsia.

Adrenal Glands

The adrenal cortex plays an important and essential metabolic role in humans. Adrenal steroidogenesis leads to the production of three types of steroids. Mineralocorticoids are produced by the zona glomerulosa, glucocorticoids produced primarily in the zona fasciculata, and sex steroids produced in the zona reticularis. Figure 48-7 depicts the biosynthetic pathways.

Control of Adrenocortical Hormones

Aldosterone is primarily under the control of the renin-angiotensin system, although ACTH and hyperkalemia also have a stimulatory role. Renin, which is secreted by the juxtaglomerular apparatus of the kidney, converts angiotensinogen (an α_2 -globulin produced by the liver) to angiotensin I, which is converted to angiotensin II. Angiotensin II, in addition to its pressor action, stimulates aldosterone secretion. Although an increase in angiotensin II suppresses renin production, volume and sodium depletion stimulate its release.

Cortisol secretion is controlled by the hypothalamic-pituitary axis. CRH is secreted by the paraventricular nucleus of the hypothalamus.

It is a 1-41-NH₂ polypeptide that binds to the corticotroph membrane, activating the adenyl cyclase system. ACTH is a 1-39 polypeptide derived from a much larger precursor, pro-opiomelanocortin (POMC). This precursor is processed mainly into ACTH. Cortisol secretion has a diurnal rhythm; the main secretory phase occurs during the late hours of sleep and early morning. Long- and short-loop negative feedback mechanisms are operating. In the long loop, the adrenal inhibits the anterior pituitary through the plasma cortisol by inhibiting ACTH release and by inhibition of the genome responsible for POMC synthesis. In the short loop, ACTH regulates its own secretion by inhibiting CRH release.

ACTH has a stimulatory effect on adrenal androgen synthesis, and production declines with age. The major androgens are androstenedione, dehydroepiandrosterone, and dehydroepiandrosterone sulfate. Androstenedione is converted peripherally to testosterone and to estrone and estradiol.

Physiologic Changes during Pregnancy

The plasma level of CRH increases progressively during the second and third trimesters, peaking at delivery. It has been isolated from the placenta, which is its likely source.^{91,92} ACTH concentrations increase threefold from the first to third trimester, and its production by the placenta has been demonstrated.⁹³ The diurnal variation of cortisol and ACTH, although blunted, is maintained. Corticosteroid-binding globulin concentrations increase by three times during pregnancy, resulting in an increase in the total plasma cortisol and a decrease in its metabolic clearance. The unbound fraction also increases (free cortisol elevations of twofold to fourfold have been shown), and this is reflected by a rise in urinary free cortisol. These changes are depicted in Figure 48-8. In the third trimester, the 9 AM plasma cortisol level ranges between 25 and 46 $\mu\text{g}/\text{dL}$, and the mean urinary free cortisol excretion is elevated at least 180% during gestation. Neither placental

Extra-adrenal conversion of sex steroids is denoted by *double arrows*. Numbers indicate enzymatic steps as follows: 1, 20 α -hydroxylase, 22-hydroxylase, 20,22-desmolase; 2, 17 α -hydroxylase; 3, 3 β -hydroxysteroid dehydrogenase, Δ^5 -4-isomerase; 4, 21-hydroxylase; 5, 11 β -hydroxylase; 6, C17,20-lyase; 7a, 18-hydroxylase; 7b, 18-dehydrogenase; 8, 17 β -hydroxysteroid dehydrogenase; 9, aromatase; 10, sulfatase.

FIGURE 48-8 Distribution of bound and free cortisol ($\mu\text{M/L}$) pregnancy plasma. Corticosteroid-binding globulin concentrations increase during pregnancy, resulting in increased total plasma cortisol and decreased metabolic clearance. The unbound fraction also increases and is reflected by an increase in the urinary free cortisol level. (From Rosenthal HE, Slaunwhite WR, Sandberg AA: Transcortin: A corticosteroid-binding protein of plasma X. Cortisol and progesterone interplay and unbound levels of these steroids in pregnancy. *J Clin Endocrinol Metab* 29:352, 1969. Copyright © The Endocrine Society.)

ACTH nor CRH are suppressible in vitro with exogenous glucocorticoids. In the future, salivary assays of free cortisol may become more widely available. The normal response to ACTH has been evaluated.⁹⁴

Renin activity increases early, peaking at 12 weeks' gestation, with a decline in the third trimester.⁹⁵ The decline is probably related to the rise in angiotensin II that occurs at this time. Plasma aldosterone concentrations reach values up to 20 times that of the nonpregnant state by the third trimester. The activation of the renin-angiotensin-aldosterone axis may result from the fall in blood pressure, which in itself results from decreased vascular responsiveness to angiotensin II and decreased vascular resistance. High levels of serum progesterone block aldosterone action, preventing kaliuresis.

Total testosterone increases in pregnancy because of an increase in sex hormone-binding globulin with a reduction in the percentage unbound; although the amount of free testosterone is low to normal in the first 28 weeks, it increases thereafter, with values often exceeding the normal range for nonpregnant women.⁹⁶ Mean levels of androstenedione also increase in the latter part of pregnancy, whereas dehydroepiandrosterone sulfate concentrations decrease because of a major increase in the metabolic clearance rate.

Fetal Adrenal Development

Fetal adrenal development has been reviewed by Keller-Wood and Wood.⁹⁷ The fetal adrenal can synthesize cortisol in vitro by 8 weeks' gestation. In vivo, placental 5-pregnenolone and 4-progesterone are used to synthesize steroids.⁹⁸ Two adrenal cortical zones can be identified in the fetus. The inner, or fetal, zone, which accounts for about

Rights were not granted to include this figure in electronic media. Please refer to the printed publication.

80% of the cortex in utero, involutes in the first few months of extrauterine life. The outer zone becomes the adult adrenal cortex. The fetal zone lacks 3β -hydroxysteroid dehydrogenase and is therefore unable to synthesize glucocorticoids or mineralocorticoids. The most abundant product is dehydroepiandrosterone, which forms the substrate for placental estrogen synthesis. During most of gestation, most cortisol in the fetal circulation is supplied by the mother through transplacental passage, although fetal cortisol concentrations are lower than maternal because of placental cortisol metabolism.

Disorders of the Adrenal Cortex during Pregnancy

Disorders of the adrenal cortex during pregnancy have been reviewed by Lindsay and Nieman.⁹⁹ Disrupted reproductive function commonly accompanies significant genetic or acquired abnormalities of adrenal cortical function. These abnormalities are usually diagnosed before conception. In patients with previously recognized adrenal disorders, replacement hormone therapy is continued throughout gestation, and the patient is monitored. The pregnancy-associated changes in normal values must be borne in mind.

Primary Adrenocortical Insufficiency: Addison Disease

Atrophy of the adrenals on an autoimmune basis is the most common cause of adrenal failure, accounting for 83% of cases.¹⁰⁰ Other causes include hemorrhage (usually associated with sepsis and burns), infections (viral, fungal, or tuberculous), and infiltrative disorders, including metastases, lymphoma, and amyloidosis. With the

availability of hormone replacement, pregnancy is no longer contraindicated.

DIAGNOSIS DURING PREGNANCY

In a review of 40 cases of Addison disease in pregnancy about 5 decades ago, 18 died during pregnancy; 12 of 22 who delivered had a crisis in the puerperium, and 7 of these died.¹⁰¹ The diagnosis of Addison disease in pregnancy is uncommon and may be related to the fetal contribution to maternal steroids. The symptoms include weakness, lassitude, nausea with or without vomiting, pigmentation, weight loss, anorexia, and abdominal pain. Some of these symptoms are also common in normal pregnant women. Suspicion should be heightened when a thin pregnant woman complains of prolonged nausea and vomiting, weakness, postural hypotension, and personality changes. A history of polyendocrine autoimmune disorders, type 1 diabetes, adrenogenital syndrome, tuberculosis, and acquired immunodeficiency syndrome (AIDS) places the pregnant woman at increased risk for adrenocortical insufficiency.

The signs, symptoms, and laboratory findings for primary adrenal insufficiency during pregnancy are outlined in Table 48-4. In acutely ill patients, replacement therapy must be initiated immediately and the diagnosis of primary adrenocortical insufficiency during pregnancy confirmed retrospectively by a pretreatment serum or plasma sample for measuring electrolytes, cortisol, and ACTH. In patients whose illness is less severe, a rapid ACTH stimulation test using synthetic ACTH may be performed; 250 µg is administered intravenously and blood samples are obtained at baseline, 30 minutes, and 60 minutes. Although a cortisol level exceeding 18 µg/dL and an increment exceeding 7 µg/dL are considered normal in the nonpregnant state, the mean increments have been reported as 18, 23, and 26 µg/dL in the first, second, and third trimester of pregnancy, respectively.¹⁰² Responses to 1 µg of ACTH have shown mean peak cortisol levels of 44 µg/dL in normal pregnant women.¹⁰³ It has been suggested that adrenal insufficiency may be excluded if the basal or ACTH stimulated (250 µg) cortisol exceeds 30 µg/dL in the third trimester.

TABLE 48-4 DIAGNOSIS OF PRIMARY ADRENAL INSUFFICIENCY DURING PREGNANCY

Signs and Symptoms

Nausea with or without vomiting, anorexia
Systolic blood pressure < 100 mm Hg with postural decrease
Increased pigmentation
Abdominal pain
Personality changes
Weakness, fatigue
Muscle and joint pain
Salt craving

Laboratory Findings

Decreased sodium concentration
Increased potassium, BUN, and creatinine levels
Hypoglycemia
Plasma cortisol level below normal pregnancy level
Urinary-free cortisol: 24-hour excretion below normal pregnancy level
Increased plasma level of ACTH
Abnormal cortisol response to rapid ACTH stimulation test

ACTH, adrenocorticotropic hormone; BUN, blood urea nitrogen.

TREATMENT

Replacement regimens are similar to those used in nonpregnant women. This is usually accomplished by hydrocortisone (cortisol) at a dose of 20 mg in the morning and 10 mg in the evening, along with 0.05 to 0.1 mg of 9α-fludrocortisone administered daily. The dose of 9α-fludrocortisone is increased if postural hypotension or hyperkalemia persists and is decreased if hypertension or hypokalemia occurs. The dose of cortisol should be doubled or tripled in any situation associated with stress, including systemic illness or trauma. Breastfeeding has been discouraged because of the potential hazard of corticosteroids passing into the maternal milk, but some investigators disagree.¹⁰⁴ Less than 0.5% of the absorbed dose is excreted per liter of breast milk. Labor should be managed with stress doses of 300 mg of hydrocortisone over 24 hours, with subsequent tapering.

ACUTE ADRENAL INSUFFICIENCY DURING PREGNANCY, LABOR, DELIVERY, OR THE PUERPERIUM

Addisonian crisis is a rare but life-threatening event in pregnant women.¹⁰⁵ The onset can be confused with an abdominal surgical emergency because of the prominence of abdominal pain, nausea, vomiting, and shock. After necessary blood samples are obtained for electrolytes, cortisol, and ACTH determinations, intravenous therapy should be started immediately with 100 mg of hydrocortisone sodium succinate along with an infusion of normal saline and 5% glucose. During the first 24 hours, 300 to 400 mg of intravenous hydrocortisone sodium succinate should be given continuously, and this can conveniently be added to the replacement fluids administered.

Recovery occurs quickly, and by 24 hours, the patient may be able to return to oral feedings and replacement doses of oral hydrocortisone and 9α-fludrocortisone. If not, hydrocortisone may be continued intravenously, usually at a diminished dosage. An effort should be made to determine the cause of the adrenal crisis, and the patient should receive careful post-pregnancy supervision. Patients with mild deficiency are especially at risk during labor, delivery, and the immediate postpartum period.¹⁰⁴

EFFECT OF MATERNAL ADDISON DISEASE ON THE NEWBORN

Infants born to mothers with Addison disease usually do not have any recognizable defects. Fetal growth, however, can be suboptimal, with lower-than-normal birth weights, especially if the diagnosis is confirmed late in pregnancy or during the postpartum period.¹⁰⁶ Fetal death has also been reported.⁹⁷ Maternal antibodies to the adrenal cortex do cross the placenta but do not significantly affect neonatal adrenal function.

Cushing Syndrome

Cushing syndrome results from an excess of glucocorticoids and is rare during pregnancy. Hypothalamic and pituitary disorders were discussed previously and have been reviewed by Buescher¹⁰⁷ and Lindsay and colleagues.⁴⁶

Primary Hyperaldosteronism

Primary hyperaldosteronism has been reviewed by Lindsay and Nieman.⁹⁹ The autonomous secretion of aldosterone in primary hyperaldosteronism may result from an adrenal adenoma, bilateral hyperplasia, or, rarely, an adrenocortical carcinoma. In pregnancy, the clinical picture of hyperaldosteronism is similar to that of the nonpregnant patient with hypertension, hypokalemia, and often, kaliuresis and elevated serum bicarbonate.¹⁰⁸ The electrolyte disturbances and hyperten-

sion may first be apparent in the peripartum period, coinciding with the removal of the protective antialdosterone effect of progesterone. Of 31 patients reported, most have harbored adenomas.¹⁰⁹

DIAGNOSIS

After standardizing the patient for dietary sodium (100 to 150 mEq daily) and posture (i.e., recumbent) and the replacement of plasma potassium, the physician measures renin activity and aldosterone concentrations. The renin activity is lower and the aldosterone concentration higher than those found in normal pregnancy.¹⁰⁸ Suppression of the aldosterone axis can also be attempted with salt loading (200 to 300 mEq/day for 3 to 5 days); the hallmark of primary hyperaldosteronism is a lack of suppression of serum aldosterone concentration. If surgery is contemplated, MRI may be used to localize the adenoma. The course of pregnancy is one of difficult-to-treat hypertension. Neonatal morbidity and mortality are related to placental insufficiency.

TREATMENT

Medical treatment with standard antihypertensive drugs should be provided, along with potassium supplements. Surgery in the second trimester may be required if medical treatment fails; surgery has gained wider acceptance since the advent of laparoscopic adrenalectomy. Spironolactone is contraindicated in pregnancy, especially in the first trimester, because of its possible feminizing effects. In the first case report of a pregnant patient with hyperaldosteronism associated with bilateral hyperplasia, documented by Neerhof and colleagues,¹¹⁰ enalapril maleate, an angiotensin-converting enzyme inhibitor, successfully lowered blood pressures in a patient unresponsive to other medications. However, later reports of adverse effects preclude the use of angiotensin-converting enzyme inhibitors in pregnancy.¹¹¹

Congenital Adrenal Hyperplasia

The congenital adrenal hyperplasias (CAHs) involve inherited enzymatic defects of adrenal steroidogenesis. The most severe and life-threatening disorders occur early in the biosynthetic cascade and are usually fatal or incompatible with successful reproduction. Deficiency of 21-hydroxylase is the most common defect (see Fig. 48-7), accounting for 90% to 95% of cases with an incidence of about 1 in 14,000, although in some areas, such as Alaska, it is more common.¹¹² The second most common form is 11-hydroxylase deficiency. CAH in pregnancy and its prenatal treatment was reviewed in 2001 by New.¹¹³

GENETICS

All CAHs are autosomal recessive disorders. The parents of an affected child have at least one haplotype for the defect, giving each subsequent offspring a 25% chance of having the condition and a 50% chance of being a carrier. An affected individual produces 100% carriers if her partner is not affected; if her partner is a carrier, 50% of the offspring are affected, and the other 50% are carriers. Siblings or spouses who want to know whether they are heterozygotes for 21-hydroxylase deficiency can be tested by undergoing measurements of adrenal steroids (notably 17-hydroxyprogesterone) before and after ACTH stimulation.¹¹⁴

21-HYDROXYLASE DEFICIENCY

21-Hydroxylase deficiency arises because of genetic mutations of the 21-hydroxylase gene located at a site linked to the human leukocyte antigen (HLA) histocompatibility complex on the short arm of the sixth chromosome. The variation in severity of the deficiency can be accounted for by allelic variation at the gene locus.¹¹⁵ The enzyme

block results in inadequate synthesis of 11-deoxycortisol and cortisol; the resulting excess ACTH stimulates adrenal precursors, notably 17-hydroxyprogesterone. Shunting of these excess precursors results in excess androgens, leading to masculinization of genitalia of the female fetus and excess masculinization of the male infant.

If the defect is severe, mineralocorticoid deficiency occurs with salt wasting. Diagnosis is confirmed by the finding of excess basal 17-hydroxyprogesterone concentrations; in milder forms, ACTH stimulation is necessary and shows an excessive increase in 17-hydroxyprogesterone. Physiologic replacement doses of glucocorticoids (usually cortisol) are used as therapy, and the dosage is based on surface area. Concentrations of 4-androstenedione, testosterone, and 17-hydroxyprogesterone are used to monitor adequacy of suppression. Fludrocortisone is indicated in salt-losing forms and in non-salt-losing forms with increased plasma renin activity. Virilized females may require surgical reconstruction of the genitalia to provide for normal appearance, intercourse, and pregnancy.

MATERNAL AND FETAL CONSIDERATIONS

Although poor control of CAH results in irregular or absent menses, patients in whom the condition is well controlled may achieve pregnancy, although less often than expected, possibly because of postnatal intervals of excess androgen exposure. Usually, the same dose of cortisol can be continued through gestation, with additional amounts given during labor, delivery, and the immediate postpartum period. Cesarean section rates may be higher because of abnormal maternal external genitalia or a small bony pelvis from premature closure of the epiphyses.¹¹⁶ Most children of mothers with CAH are normal, although women receiving suboptimal doses of replacement therapy have elevated circulating androgens, which may cross the placenta and virilize the fetus.

Free testosterone levels do not change significantly during gestation and can be used as a marker for monitoring therapy. Conversely, excessive glucocorticoid therapy of the mother with CAH may result in suppression of fetal adrenals with resulting transient adrenocortical insufficiency of the neonate.

PRENATAL DIAGNOSIS AND TREATMENT

Prenatal diagnosis of 21-hydroxylase deficiency for offspring of known heterozygotes first became possible with the finding of elevated levels of 17-hydroxyprogesterone in amniotic fluid obtained by amniocentesis.¹¹⁷ By the time amniocentesis is performed in the second trimester, it is too late to prevent virilization. Dexamethasone is administered in a pregnancy at risk before the end of the seventh week from conception (9 weeks' gestation). This treatment results in suppression of 17-hydroxyprogesterone and renders it unreliable for diagnosis. After HLA profiles were found to be linked to CAH, diagnoses were made with HLA linkage marker analysis using amniotic cells. To avoid errors resulting from recombination or haplotype sharing, however, direct DNA analysis of the 21-hydroxylase gene (*CYP21*) with molecular genetic techniques is recommended. Chorionic villus sampling should preferably be used to obtain fetal tissue sooner (9 to 11 weeks' gestation) for diagnosis by molecular genetic analysis.¹¹⁸

Prenatal treatment of the mother with high-dose glucocorticoids has been effective in preventing virilization of the affected female fetus; the glucocorticoid crosses the placenta and suppresses ACTH secretion from the fetal pituitary.¹¹⁷ The current approach is to treat all such mothers with glucocorticoids. Dexamethasone (20 µg/kg of pre-pregnancy weight) is given orally in divided daily doses after pregnancy has been confirmed. This treatment must be given before the end of the seventh week from conception. Chorionic villus sampling is then

performed. If the fetus is male, maternal treatment is discontinued; if female, the treatment is continued until the results of DNA analysis of the 21-hydroxylase gene are available. The glucocorticoids are discontinued only if the female fetus is considered unaffected.

A review of 532 pregnancies prenatally diagnosed using amniocentesis or chorionic villus sampling between 1978 and 2001 was reported by New and associates.¹¹⁸ Of these 532 pregnancies, 281 were treated prenatally for congenital adrenal hyperplasia because of the risk of 21-hydroxylase deficiency. Of 116 babies affected with CAH, 61 were female, and 49 of them were treated prenatally with dexamethasone. If given in proper dosage, dexamethasone administered at or before week 9 of gestation was effective in reducing virilization. With the exception of striae, weight gain, and edema, there were no other differences in the symptoms of treated and untreated mothers. Prenatally treated newborns had weights that matched untreated and unaffected newborns, and no enduring side effects were observed. Prenatal diagnosis and treatment of 21-hydroxylase deficiency is possible and effec-

tive. An algorithm showing prenatal management of pregnancies in families at risk for a fetus affected by 21-hydroxylase deficiency is provided in Figure 48-9. An updated review has been provided by Nimkarn and New.¹¹⁹ However, there are few data on long-term risks. A study based on a maternal survey showed that 174 children (48 had CAH) who received dexamethasone did not differ in cognitive or motor development from 313 unexposed children.¹²⁰ However, a later study showed impaired cognitive function in at-risk children who were treated prenatally.¹²¹ A consensus conference recommended that only an experienced team direct this therapy, preferably under a research protocol, with consent and with prospective and long-term follow-up of the children.¹²²

11-HYDROXYLASE DEFICIENCY

11-Hydroxylase deficiency, an enzyme defect that is not HLA linked, results in blocked production of cortisol and aldosterone with resulting excess precursors, 11-deoxycortisol and deoxycorticosterone.¹¹⁷ A

FIGURE 48-9 Algorithm for prenatal management of pregnancy in families at risk for a fetus with 21-hydroxylase deficiency. Prenatal diagnosis and treatment of 21-hydroxylase deficiency are possible and effective. (From New MI, Carlson A, Obeid J, et al: Extensive personal experience: Prenatal diagnosis for congenital adrenal hyperplasia in 532 pregnancies. *J Clin Endocrinol Metab* 86[12]:5651-5657, 2001. Copyright © The Endocrine Society.)

shunt toward excess androgens occurs, and the presentation is that of androgen excess and hypertension. Diagnosis is based on elevated 11-deoxycortisol and deoxycorticosterone concentrations determined basally or after ACTH stimulation. Heterozygotes have no demonstrable biochemical abnormality, even with ACTH stimulation. Treatment is with glucocorticoid replacement. Prenatal diagnosis is confirmed by measuring amniotic fluid 11-deoxycortisol concentrations.¹²³ Prenatal treatment of the mother with dexamethasone, as in 21-hydroxylase deficiency, has been reported, resulting in a female without virilization or ambiguous genitalia who was genetically affected.¹²⁴ Mutations in the 11-hydroxylase gene that may facilitate prenatal diagnosis have been reported.¹²⁵

OTHER CONGENITAL ADRENAL HYPERPLASIA ENZYME DEFICIENCIES

There are a few other rare forms of CAH (see Fig. 48-7). In 17-hydroxylase deficiency, the sex steroid pathway is blocked in the adrenal cortex and gonad, resulting in a hypogonadal state and primary amenorrhea. Deficiency of 3 β -hydroxysteroid dehydrogenase, if severe, manifests as lack of pubertal development. Milder forms manifest pubertally with hyperandrogenism.¹²⁶

Long-Term Therapy with Pharmacologic Doses of Steroids

The occurrence of congenital anomalies in animal experiments—cleft palate in particular—raised concerns about pregnant women receiving glucocorticoids during pregnancy. In a review involving 260 pregnancies in which glucocorticoids had been administered to women in pharmacologic doses, only two infants had cleft palate.¹²⁷ Both mothers had received steroids in large doses early in pregnancy. Because closure of the palatal process occurs by the 12th week of gestation, it is possible that the anomaly was related to the medication. Although other, smaller studies have not supported this association,¹²⁸ a prospective cohort study and meta-analysis of epidemiologic studies concluded that prednisone increases the risk of oral clefts by an order of 3.4-fold.¹²⁹

The hypothalamic-pituitary-adrenal axis is suppressed with long-term supraphysiologic doses of glucocorticoids, and abrupt withdrawal should be avoided because it can precipitate maternal adrenocortical insufficiency. Glucocorticoids are excreted in breast milk and have the potential to cause growth restriction in the neonate. Neonatal adrenal insufficiency, although rare, can occur in infants born to mothers being treated with exogenous glucocorticoids.¹²⁷

Disorders of the Adrenal Medulla during Pregnancy

Pheochromocytoma

Pheochromocytomas have been reviewed by Lindsay and Nieman.⁹⁹ Pheochromocytomas are tumors of chromaffin cells. These cells cluster predominantly in the adrenal medulla, and 90% of pheochromocytomas are found in this location. Sites of extra-adrenal tumors range from the carotid body to the pelvic floor. They occur sporadically or as part of the familial multiple endocrine neoplasia type 2 syndrome. Approximately 12% are malignant, although this percentage is higher in pheochromocytomas occurring in extra-adrenal sites.

SYMPTOMS

Pheochromocytoma is a rare but potentially lethal cause of hypertension in pregnancy. Its possibility should be considered in women with intermittent, labile hypertension or paroxysmal symptoms such

as anxiety, diaphoresis, headache, and palpitations. Other symptoms include chest or abdominal pain, unusual reactions to drugs affecting catecholamine release and actions, visual disturbances, convulsions, and collapse. Symptoms tend to be similar in pregnant and nonpregnant women. The occurrence of symptoms during pregnancy only, with recurrence in subsequent pregnancies, has also been described. Increased vascularity of the tumor in pregnancy and the mechanical effect of an enlarging uterus may explain this phenomenon. In many cases, severe symptoms develop in the peripartum and postpartum periods. At least 200 cases have been diagnosed in pregnancy, with an estimated prevalence of 1 in 54,000 at term.

LABORATORY DIAGNOSIS

Laboratory diagnosis involves biochemical demonstration of elevated levels of vanillylmandelic acid, catecholamines, and fractionated metanephrines in the 24-hour urine specimen. Plasma catecholamine and metanephrine levels can also be determined. Values in pregnant women are similar to those in nonpregnant subjects, but they are elevated for 24 hours after eclamptic seizures. Because methyl dopa interferes with catecholamine measurements, it should be discontinued before testing. If necessary, the tumor may be localized during pregnancy by means of ultrasonography¹³⁰ or MRI.¹³¹

TREATMENT

Treatment of pheochromocytoma in pregnancy is somewhat controversial. Most physicians agree that when the diagnosis is confirmed in the second half of pregnancy, α -adrenergic blockade with phenoxybenzamine is the treatment of choice. This drug is given orally, starting with 10 mg twice daily and gradually increasing by 10 to 20 mg daily until hypertension is controlled. When fetal maturity is achieved, cesarean section should be performed, with simultaneous or subsequent excision of the tumor^{132,133} during adrenergic blockade. Phentolamine (1 to 5 mg) can be used for a hypertensive crisis.

In tumors detected before 24th weeks' gestation, surgery during pregnancy has been advocated¹³³ to avoid fetal wasting. Laparoscopic adrenalectomy can be performed.¹³⁴ However, a number of such cases have been managed successfully during pregnancy with α - and β -blockade with good fetal outcome.^{135,136} The arguments against medical therapy are the unknown effects of α -blockade and β -blockade on the fetus in the long term, the teratogenic potential of phenoxybenzamine, and the risk of a malignant lesion. β -Blockade alone should not be used without prior α -blockade because unopposed α -adrenergic activity can lead to generalized vasoconstriction and a steep rise in blood pressure. Anesthetic management of pheochromocytoma resection during pregnancy requires special consideration.¹³⁷

PROGNOSIS

Pheochromocytoma constitutes a life-threatening disease for the mother and the fetus, although with better management and the availability of α -adrenergic and β -adrenergic blockade, the prospects for both have improved. Table 48-5 shows the changes in maternal and fetal mortality rates over the past few decades and indicates the improved prognosis when the diagnosis is made during pregnancy.^{133,138} However, a 36-year-old woman died at 27 weeks' gestation from an autopsy-diagnosed pheochromocytoma.¹³⁹ Fetal growth restriction can result from reduced uteroplacental perfusion, and fetal death may occur during acute hypertensive crises.

Four cases of malignant pheochromocytomas in pregnancy were reviewed by Ellison and associates¹⁴⁰ and another by Devoe and coworkers;¹⁴¹ α -methyl paratyrosine, a dopamine synthesis inhibitor, was used in the latter case. Several cases of pregnancy with pheochro-

mocytoma as part of type 2 multiple endocrine neoplasia have been reported.^{133,142,143}

Hirsutism and Virilization in Pregnancy

Hirsutism and virilization in pregnancy have been reviewed by McClamrock and Adashi.¹⁴⁴ Women and their female fetuses are protected from the increased concentrations of androgens by the enhanced binding to sex hormone-binding globulin, competition by progestins for binding to the androgen receptor or for disposition of androgens to more biologically potent compounds, and placental aromatization of androgens. Nevertheless, maternal hirsutism and virilization can occur in pregnancy and usually results from ovarian disease or iatrogenic insult. The female fetus can be affected by elevated circulating maternal androgens. Differentiation of the female external genitalia occurs between 7 and 12 weeks' gestation, and exposure to excess androgens can result in partial or complete labial fusion and clitoromegaly. Clitoromegaly may still occur after 12 weeks' gestation. The approach to maternal hirsutism and virilization in pregnancy is outlined in Table 48-6.

The two major causes of gestational hyperandrogenism are luteomas and hyperreactio luteinalis (i.e., gestational ovarian theca-lutein cysts). Luteomas are benign, solid tumors of the ovary; they are often multinodular and bilateral, and they are usually yellow to tan. Regardless of their virilizing effect, luteomas have been associated with elevated levels of circulating maternal androgens.

Not all luteomas cause maternal virilization (overall incidence is 35%); it depends on the amount of androgen secreted, the end-organ sensitivity, and the degree of aromatization by the placenta to nonandrogenic steroids. Approximately 80% of female infants born to mothers with virilizing luteomas are virilized and usually exhibit clitoromegaly. Although luteomas are considered intrapartum lesions that regress after delivery, this concept has been challenged and could

account for recurrence of virilization in subsequent pregnancies as shown in a case of severe maternal virilization.¹⁴⁵ In contrast with hyperreactio luteinalis, luteomas occur more frequently in black multiparas and are not associated with toxemia, erythroblastosis, or multiple gestation.

Hyperreactio luteinalis is characterized by ovarian enlargement with many large-follicle cysts or corpora lutea, or both, with marked edema of the stroma. It usually is bilateral, affects white primigravidas, and is often associated with conditions resulting in increased human chorionic gonadotropin (hCG), such as molar pregnancies and multiple gestation. Maternal hirsutism or virilization has been documented in approximately 30% of reported cases. There are no reported cases of fetal masculinization, even if the mother is virilized. The condition may represent an excessive ovarian sensitivity to hCG. The lack of fetal virilization in this condition is intriguing and has been attributed to androgen aromatization in the placenta. As with luteomas, recurrence of hyperreactio luteinalis in consecutive pregnancies has been reported.¹⁴⁶ Recurrent, severe hyperandrogenism during pregnancy has also been reported without the presence of luteomas or hyperreactio luteinalis.¹⁴⁷

Placental aromatase deficiency is a rare cause of maternal and fetal virilization, which may be suspected if maternal hyperandrogenism is associated with low maternal estrogen levels.¹⁴⁸ Only 1% enzyme activity appears necessary to prevent virilization.

Another rare cause of maternal and fetal virilization is¹⁴⁹ cytochrome P450 oxidoreductase (POR) deficiency; it is an autosomal recessive disorder caused by mutations in the gene encoding an electron donor of all P450 enzymes.^{149,150} This enzyme is an essential redox partner for CYP17 and CYP21 hydroxylases. Abnormal function of these enzymes can lead to maternal virilization and virilization of the female fetus together with low estriol secretion in pregnancy. Variable clinical manifestations include skeletal malformations referred to as the Antley-Bixler syndrome with insufficient glucocorticoids and increased 17-hydroxyprogesterone in both sexes.

In a few cases,^{151,152} insulin-resistant polycystic ovary syndrome patients who achieve pregnancy may become extremely androgenized

during pregnancy. Metformin was used in one of these cases.¹⁵¹ Other ovarian lesions that can cause maternal virilization include Sertoli-Leydig cell tumors (i.e., arrhenoblastomas), Krukenberg tumors, Brenner tumors, lipoid cell tumors, dermoid cysts, and mucinous and serous cystadenocarcinomas. Most Sertoli-Leydig cell tumors coexisting with pregnancy are associated with maternal virilization, and virilization of the female fetus can occur. The malignancy rate for these tumors is high (44%), with substantial maternal (31%) and perinatal (50%) mortality rates. Krukenberg tumors, which are gastrointestinal tumors metastatic to the ovary, are often bilateral and have caused maternal and fetal virilization in all reported cases.

Adrenal tumors, including adrenocortical carcinoma, can cause maternal and fetal virilization.¹⁵³ Masculinization of the female fetus has been associated with the gestational administration of progestins and androgens and can be unaccompanied by maternal virilization.

Parathyroid Glands and Calcium Metabolism

Maternal and Fetal Physiology and Lactation

The serum calcium level is tightly regulated and maintained within normal limits by parathyroid hormone (PTH) and vitamin D. Vitamin D can be synthesized in the skin under the influence of ultraviolet irradiation or can be absorbed from dietary sources through the gastrointestinal tract. The 25(OH)D form of vitamin D (i.e., 25-hydroxycholecalciferol or vitamin D₃) is 25-hydroxylated in the liver and then 1-hydroxylated in the kidney. The physiologically active form of vitamin D is 1,25(OH)₂D (i.e., 1 α ,25-dihydroxycholecalciferol, calcitriol, or vitamin D₂), which is responsible for increasing intestinal absorption of calcium and for bone resorption. The parathyroid glands, which produce PTH, are stimulated by hypocalcemia and suppressed by high concentrations of calcium, magnesium, and 1,25(OH)₂D and by hypomagnesemia. PTH influences calcium metabolism by directly resorbing bone and by stimulating 1,25(OH)₂D formation. There are three major forms of circulating calcium: ionized, protein-bound, and chelated fractions. The ionized fraction is physiologically active and homeostatically regulated.

Calcium homeostasis in pregnancy was reviewed by Kovacs¹⁵⁴ and Kovacs and Fuleihan.¹⁵⁵ Large amounts of calcium and phosphorus are transferred against a concentration gradient from the mother to the fetus,¹⁵⁶ with the net accumulation of calcium being 25 to 30 g by term (mostly in the third trimester). Maternal calcium absorption doubles during pregnancy to meet these demands. Doubling of 1,25(OH)₂D synthesis of placental and maternal renal origin (from increased 1 α -hydroxylase, itself resulting from increased prolactin, estrogen, human placental lactogen, and parathyroid related peptide) leads to the opening of voltage-gated calcium channels in the enterocyte membrane, increasing calcium absorption.¹⁵⁷ In the maternal circulation, there is little change in ionized calcium,¹⁵⁸ whereas total serum calcium concentrations fall during gestation, paralleling a decline in serum albumin.

In addition to placental calcium transfer, an expanding extracellular volume and increased urinary calcium losses place further stress on maternal calcium homeostasis. Studies of PTH using traditional radioimmunoassays have supported a concept of physiologic hyperparathyroidism in pregnancy.¹⁵⁸ The advent of newer immunoradiometric assays for intact PTH have shown a decline in PTH during pregnancy

to 10% to 30% of pre-pregnancy values, increasing toward term.¹⁵⁹ This decline, however, appears to be offset by increased parathyroid-related protein (PTHrP) of fetal origin. This peptide shares considerable homology with PTH and a common receptor. It appears that PTHrP is produced by the fetal parathyroid glands and by the placenta and is the predominant regulator of active placental calcium transport. Transtrophoblastic calcium transfer also depends on an increase in calcium-binding protein, which reaches maximal concentrations in the third trimester when fetal growth is most rapid. Serum calcitonin concentrations have been variously reported as showing a rise or no consistent change during pregnancy.¹⁶⁰ The level of PTHrP also increases during pregnancy and is produced by fetal and maternal tissues. It likely contributes to increased 1,25(OH)₂D and decreased PTH concentrations, and it regulates placental calcium transport to the fetus. Urinary calcium excretion is also increased.

Fetal parathyroid tissue has been identified by 6 weeks' gestation, and skeletal mineralization is apparent by the eighth week. Total and ionized calcium concentrations are elevated in the fetus at term and decrease to normal in the newborn period. PTH levels are low in the fetus and increase after birth.¹⁵⁶ PTHrP is produced by fetal parathyroid glands and is the main regulator of fetal serum calcium. The calcitonin level is elevated in the fetus. These events are summarized in Table 48-7. During lactation, the average daily loss of calcium in human milk is 220 to 340 mg. There is a small drop in serum calcium accompanied by a rise in PTH and 1,25(OH)₂D concentrations. The ionized calcium concentration increases a little, remaining within the normal range; the serum phosphorus level increases. Intact PTH is reduced 50%, rising to normal with weaning. In contrast to the high levels in pregnancy, serum 1,25(OH)₂D concentrations fall to normal within days of parturition. PTHrP levels (of mammary origin) are significantly higher in lactating women, and the protein plays a key role during lactation in regulating demineralization of the skeleton, stimulating resorption of bone, and in renal tubular reabsorption of calcium and suppression of PTH. Higher PTHrP levels correlate with greater losses of bone.¹⁵⁵ Calcitonin levels are high in the first 6 weeks of lactation and may modulate the rate of skeletal resorption. Figure 48-10 depicts maternal calcium homeostasis during pregnancy and lactation, contrasting the mechanisms at work in these two situations.

TABLE 48-7 LEVELS OF MINERALS AND HORMONES INVOLVED IN CALCIUM HOMEOSTASIS

Mineral or Hormone	Mother	Fetus	Newborn
Total calcium*	Low	High	Decreases [†]
Ionized calcium*	Low normal	High	Decreases

PTH, parathyroid hormone; PTHrP, parathyroid hormone-related protein; 1,25(OH)₂D, 1 α ,25-dihydroxycholecalciferol calcitriol, or vitamin D₂, the physiologically active form of vitamin D; 25(OH)D, 25-hydroxycholecalciferol, calcidiol, or vitamin D₃.

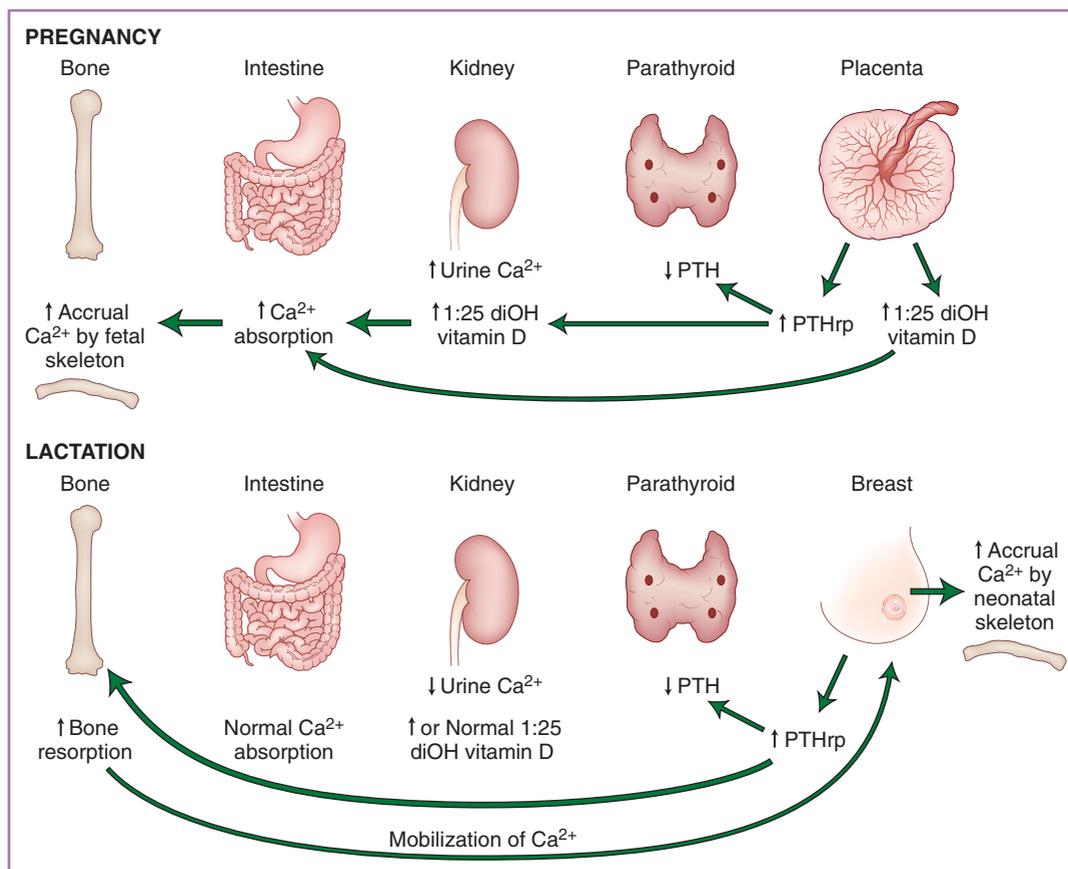

FIGURE 48-10 Factors regulating maternal calcium metabolism during pregnancy and lactation. Calcium (Ca^{2+}) accretion by the fetus and neonate is achieved during pregnancy and lactation, but the mechanisms are different. In pregnancy 1,25-dihydroxycholecalciferol (1:25 diOH vitamin D)-mediated increased calcium absorption plays the dominant role, whereas in lactation, parathyroid hormone–related peptide (PTHrP)-mediated bone resorption makes calcium available to the neonate. (Adapted from Kovacs CK, Fuleihan GEH: Calcium and bone disorders during pregnancy and lactation. *Endocrinol Metab Clin North Am* 35:21, 2006.)

Disorders of the Parathyroid Glands

Primary Hyperparathyroidism and Hypercalcemia

Hyperparathyroidism is rare in pregnancy. Of 750 cases of parathyroid surgery performed over a 21-year period,¹⁶¹ only 6 occurred in pregnant women (0.8%). The topic of parathyroid disorders in pregnancy was reviewed by Mestman.¹⁶² As in nonpregnant women, the histopathology of hyperparathyroidism involves a single adenoma in most reported cases in pregnant women, although hyperplasia and carcinoma have also been reported.^{163,164} Although many patients are asymptomatic, clinical features of the associated hypercalcemia are summarized in Table 48-8.

In the 102 pregnancies (in 73 women) reported by Kristofferson and coauthors,¹⁶³ the clinical history was known in 45. Abdominal symptoms, including nausea, vomiting, pain, and renal colic, were the most common, followed by muscular weakness, mental symptoms, and polyuria; 20% were asymptomatic. The diagnosis of hyperparathyroidism during pregnancy is suggested by hypercalcemia. The decline in total serum calcium during pregnancy may mask the diagnosis or be associated with a postpartum flare-up, and ionized serum calcium should be measured in patients suspected of having primary

TABLE 48-8 MATERNAL FEATURES OF HYPERCALCEMIA

Affected System	Clinical Features
Urinary	Nephrolithiasis Nephrocalcinosis Polyuria
Neuromuscular	Weakness
Gastrointestinal	Peptic ulcer disease Constipation Anorexia Nausea and vomiting
Cardiovascular	Hypertension Arrhythmias
Skeletal	Osteitis fibrosa cystica Osteopenia and fractures
Neuropsychiatric	Depression Psychosis Obtundation
Miscellaneous	Coma Thirst Pruritus

hyperparathyroidism. The physician then confirms the diagnosis by finding inappropriately elevated PTH concentrations and an increase in urinary nephrogenic cyclic adenosine monophosphate levels (cAMP).

The differential diagnosis of hypercalcemia includes malignant disease, granulomatous disease, thyrotoxicosis, hypervitaminosis D or A, milk-alkali syndrome, immobilization, and familial hypocalciuric hypercalcemia (FHH), which is an autosomal dominant, inherited form of mild, benign hyperparathyroidism associated with low urinary calcium excretion. Affected neonates of mothers with FHH can manifest symptomatic hypercalcemia; if unaffected, they can develop severe neonatal hypocalcemia because of suppression of fetal parathyroid function. Severe neonatal hypercalcemia may be the homozygous variant of FHH. An altered calcium ion-sensing receptor gene, changing the set point for PTH secretion, is the underlying defect in FHH.

Hypercalcemia associated with increased production of PTHrP has been described during pregnancy and after delivery.¹⁶⁵ In one case, production of PTHrP by hypertrophied breast tissue led to hypercalcemia.¹⁶⁶ In another, hypercalcemia developed after delivery in a hypoparathyroid woman on vitamin D.¹⁶⁷

During pregnancy, calcium transport across the placenta provides a degree of protection in the mother against hypercalcemia, and this protection is greatest during the third trimester. Loss of this protection with delivery can cause acute postpartum maternal hypercalcemia. In many patients, the diagnosis is confirmed after delivery by the occurrence of neonatal tetany. Ten of 15 cases of hyperparathyroidism reported by Gelister and colleagues¹⁶⁴ manifested in this way, and the others manifested with hyperemesis, hypertension, and a jaw fracture in a patient who turned out to have a parathyroid carcinoma.

COMPLICATIONS

Complications of hyperparathyroidism affect the mother and infant. Maternal complications include hyperemesis, renal calculi (36%), pancreatitis (13%), hypertension (10%), bone disease (19%), hypercalcemic crises (8%), and psychiatric problems. The overall maternal mortality rate remains low (1 of 73 in the collected series of Kristofferson and colleagues¹⁶²).

Fetal morbidity and mortality rates are significant. A 30% rate of spontaneous abortion or stillbirth, 50% rate of tetany, and 25% rate of neonatal death have been reported.¹⁶⁸

Although neonatal hypocalcemia with tetany is usually a transient phenomenon related to suppression of fetal parathyroid glands resulting from maternal-fetal hypercalcemia, it can be more prolonged in less mature infants or in infants with birth asphyxia. Hypercalcemic crisis also can occur during pregnancy or after delivery with high serum calcium level (>14 mg/dL), generalized weakness, vomiting, and altered mental status. Aggravation of hypercalcemia can occur because of an increase in placental production of 1,25(OH)₂D by the end of gestation and the removal of the placenta, with the loss of the shunt that transfers calcium from mother to fetus.

TREATMENT

For hyperparathyroidism presenting during pregnancy, standard practice favors surgical treatment. In the collected series of Kristofferson and colleagues,¹⁶³ there were 79 pregnancies among 50 women who did not undergo surgery; there were complications in 41 of the pregnancies (52%), and neonatal tetany occurred in 21 (26.6%). This contrasts with the more favorable outcome in 23 pregnancies involving 23 women who underwent surgical treatment during pregnancy; 5 (22%) had complications, and there were three cases of neonatal tetany

TABLE 48-9 TREATMENT OF HYPERCALCEMIA

Treatment	Adverse Effects
General Approach	
Hydration	
Discontinue offending drugs	
Restrict calcium	
Increase Renal Calcium Excretion	
0.9% Saline, 200-500 mL/hr	Volume overload
Furosemide, 20-60 mg IV every 2-4 hr	Volume depletion, hypokalemia
Dialysis	
Calcium Chelation with Phosphates	
Oral: Neutra-phos, 500-750 mg every 6-8 hr	Extraskeletal calcification
Rectal: Phospho-soda, 5 mL every 6-8 hr	
IV: 50 mM phosphate over 8-12 hr	
Decrease Bone Resorption	
Calcitonin, 4-8 IU/kg IM or SC every 6-12 hr*	Allergic reaction, nausea
Pamidronate (bisphosphonate), 30-60 mg IV as a single infusion over 24 hr	Renal toxicity
Mithramycin, 25 µg/kg IV [†] every 48-72 hr	Low platelet count, renal toxicity, hepatotoxicity

*No reports of congenital defects; does not cross placenta.

†No reports on use in pregnancy; antineoplastic.

IV, intravenously; IM, intramuscularly; SC, subcutaneously.

(13%). Ideally, surgery should be performed in the second trimester, when fetal organs are developed and the uterus is less likely to undergo labor.¹⁶⁹ Conservative treatment of mildly affected, asymptomatic patients has also been suggested.¹⁷⁰

In a case reported by Haenel and Mayfield,¹⁷¹ oral phosphate and parenteral saline were used to sustain the patient during the third trimester. However, even milder forms have adverse fetal effects and risk.¹⁷²

The treatment of life-threatening hypercalcemia can be problematic and may require hydration, furosemide, phosphates, and even hemodialysis.¹⁷³⁻¹⁷⁵ Treatment is summarized in Table 48-9. Calcitonin inhibits bone resorption; its effects are generally short lived, and it does not cross the placenta. It has been used briefly in pregnancy in the third trimester in one case.¹⁷⁶ In life-threatening situations, Mithramycin (plicamycin) lowers calcium by inhibiting bone resorption. It is an antineoplastic agent and toxic to the fetus. In nonpregnant patients, bisphosphonates (e.g., pamidronate) given intravenously are also effective in lowering calcium levels. Transplacental passage has been shown in animal studies. For a patient with milk-alkali syndrome who presented with severe hypercalcemia related to excessive use of calcium carbonate, a single dose of the bisphosphonate etidronate was given, with prompt reduction of serum calcium and subsequent hypocalcemia.¹⁷⁷

PARATHYROID CARCINOMA IN PREGNANCY

Four cases of parathyroid carcinoma during pregnancy were reviewed by Montoro and associates.¹⁷⁸ Severe hypercalcemia, hypertension, and a palpable neck mass were consistent features, whereas palpable masses were found in only 5% and hypertension in 10% of pregnant

TABLE 48-10 CLASSIFICATION OF HYPOPARATHYROID DISORDERS

Defect	Cause
Absence of parathyroid hormone (PTH) or insufficiency	Previous thyroid or parathyroid surgery Idiopathic hypoparathyroidism (familial or sporadic) DiGeorge syndrome Iron overload (rare) Previous irradiation with ¹³¹ I (rare)
Absence of and resistance to PTH PTH resistance	Magnesium depletion Pseudohypoparathyroidism

patients with parathyroid adenomas. Because survival depends on complete initial resection, early surgical intervention is important.

Hypoparathyroidism

Hypoparathyroidism has been reviewed by Mestman.¹⁶² Hypoparathyroidism in pregnancy usually occurs in patients who have previously undergone neck surgery, but it can occur in less common circumstances (Table 48-10). The diagnosis is confirmed by the combination of hypocalcemia with low PTH, 1,25(OH)₂D, and nephrogenous cAMP concentrations. Other hypocalcemic states that need to be differentiated from hypoparathyroidism include vitamin D deficiency (with a finding of a high PTH level), excessive chelation (after blood transfusion), pancreatitis, and septic states.

Clinical features include tetany, which may be elicited in latent form by the Chvostek test (i.e., tapping of the facial nerve) and the Trousseau test (i.e., occurrence of tetany within 3 minutes of the induction of ischemia in the upper extremity). Other symptoms include paresthesia, stridor, muscle cramps, and mental changes, including frank psychosis. The electrocardiogram may reveal prolongation of the QT interval.

COMPLICATIONS

Neonatal hyperparathyroidism may result from maternal hypocalcemia. It can cause fetal bone demineralization and growth restriction.¹⁷⁹ Although this condition is transient, death from the complications of skeletal fractures can occur. Loughhead and colleagues¹⁸⁰ reviewed 16 cases of congenital hyperparathyroidism resulting from maternal hypocalcemia; bone features of hyperparathyroidism were documented in 13 cases. Six of the neonates died within the first 3 months of life. The investigators concluded that the presentation varied greatly, ranging from clinically and radiologically silent cases to neonates with severe skeletal disease and bone demineralization.

TREATMENT

The maternal serum calcium level should be maintained within normal limits. Vitamin D (50,000 to 100,000 units/day or more) and calcium salts (1.0 or 1.5 g of elemental calcium per day) may be given to maintain normocalcemia. Alternatively, calcitriol (1,25[OH]₂D), which has a more rapid onset of action and a shorter half-life, can be used. The usual dose is 0.5 to 1.0 μg/day.¹⁸¹

The normal replacement dose of vitamin D in a hypoparathyroid woman may need to be increased, possibly because of increased binding of vitamin D to vitamin D-binding protein. In a patient treated with calcitriol, the dose had to be doubled during pregnancy to maintain normocalcemia, similar to the physiologic twofold rise in 1,25(OH)₂D during pregnancy.¹⁸² The aim should be serum calcium concentrations

in the range of 8 to 9 mg/dL, with avoidance of hypercalciuria (>250 mg/24 hr), which can lead to nephrolithiasis. In late pregnancy, the dose of calcitriol may need to be reduced, and this is likely to be related to the increased PTHrP levels in late pregnancy. In limited reports of pseudohypoparathyroidism (i.e., resistance to PTH), pregnancy has normalized serum calcium, decreased PTH, and increased 1,25(OH)₂D levels. The presence of PTHrP cannot explain these changes, because they are resistant to PTH and PTHrP. The mechanism is unclear but may include increased placental secretion of 1,25(OH)₂D.¹⁸³ In the hypoparathyroid patient, a prompt decrease to pre-pregnancy doses of vitamin D is necessary after delivery so that hypercalcemia can be avoided.¹⁸⁴ Although lactating women usually require continuation of pregnancy doses of vitamin D, hypercalcemia has been reported,¹⁸⁴ and close monitoring is prudent. This finding may be related to the production of PTHrP by the breasts^{167,185} or to induction of 1α-hydroxylase by prolactin.

Acute symptomatic hypocalcemia is a medical emergency. It should be treated with intravenous calcium (e.g., 10 mL of 10% calcium gluconate over 10 minutes, followed by an infusion of 0.5 to 2.0 mg/kg/hr of elemental calcium, diluted with dextrose to avoid irritation to veins).

Infants receiving breast milk from mothers consuming large doses of vitamin D should undergo periodic calcium determinations, because the breast milk will have higher-than-normal levels of vitamin D.¹⁸⁶ The elevated levels of vitamin D can cause hypercalcemia and impaired linear growth in the infant.

Pregnancy-Related Osteoporosis

Osteoporosis is a disorder characterized by loss of bone mass and microarchitectural deterioration, resulting in an increased risk of fracture. Normally, bone formation and resorption are coupled. Bone loss because of reduced formation or increased resorption may occur in estrogen-deficiency states, glucocorticoid-excess syndromes, thyrotoxicosis, and other circumstances.

The effect of pregnancy on bone turnover was evaluated by Black and colleagues,¹⁸⁷ Oliveri and coworkers,¹⁸⁸ and Karlsson and associates.¹⁸⁹ In a detailed study using biochemical markers of bone formation and resorption and dual-energy x-ray absorptiometry (DEXA) before, during (i.e., in the forearm), and after pregnancy (i.e., in the hip, spine, and forearm), Black and colleagues¹⁸⁷ reported increased markers of bone resorption by 14 weeks' gestation and further by 28 weeks, whereas markers of bone formation did not increase significantly until 28 weeks. Lumbar spine and hip bone mineral density decreased significantly during pregnancy. It appeared that bone remodeling became uncoupled, with an increase in resorption during the first two trimesters, and the increase in formation became evident only in the third trimester. In a study of 34 women during pregnancy, peripheral computed tomography measurements showed no change in cortical bone but tremendous variability in loss of trabecular bone. Fast losers had high serum levels of osteocalcin (a marker of bone formation), and it was suggested that this could be used as a marker of the change.¹⁹⁰

In 1955, Nordin and Roper¹⁹¹ described four young women with backache and vertebral compression fractures diagnosed with idiopathic osteoporosis. Their symptoms developed during or shortly after pregnancy and improved with follow-up. These investigators suggested that the association between osteoporosis and pregnancy might not have been fortuitous. Since that time, sporadic cases and small series of patients with osteoporosis in relation to pregnancy and lactation have been reported.^{192,193} Smith and coworkers¹⁹⁴ suggested that failure of calcium accretion by the maternal skeleton, normally facilitated by increased calcium absorption in response to higher 1,25(OH)₂D concentrations, might explain this occurrence; these vitamin concentra-

tions were low in several patients with osteoporosis. They suggested failure of the calcitonin response to pregnancy as another mechanism; calcitonin has anti-resorptive properties, and levels may increase during pregnancy.

In a study of 29 women with idiopathic osteoporosis associated with pregnancy,¹⁹⁵ it was observed that pain occurring late in the first full-term pregnancy was the most common presentation and that the natural history was improvement over time. Adult-related fractures occurring at an earlier age were more prevalent in the mothers of these women, suggesting possible genetic factors in the cause of osteoporosis. Low 1,25(OH)₂D concentrations were demonstrated in a case by Khan and colleagues;¹⁹⁶ the abnormality reversed over time. Subsequent pregnancies are not necessarily affected.

During lactation, a substantial part of the calcium demand is mobilized from the maternal skeleton because of low estrogen and high PTHrP levels from the breasts.¹⁹⁷ In a study of 18 exclusively breastfeeding women, compared with 18 women in whom lactation was inhibited by bromocriptine, there was a significant decrease in lumbar spine and distal radius and in bone density, and there was biochemical evidence of increased bone turnover during breastfeeding, with an incomplete recovery 6 months after breastfeeding cessation.¹⁹⁸ In the bromocriptine-treated women, bone mineral density did not change. Overall, it appears that healthy young women have significant early losses of bone mineral density at the axial spine and hip during 6 months of lactation.¹⁹⁹ Loss, however, does not continue beyond 6 months despite continuing lactation, and bone mineral density loss usually is restored with the return of normal menses. In a study of 60 women, 47% of breastfeeders lost more than 5% of bone at the lumbar spine, and the bottle-feeders maintained bone mineral density. At 1 year after delivery, all but seven had returned to within 5% of preconception values at the spine, but recovery of the total hip loss was less complete. Several women became transiently osteoporotic.²⁰⁰

The calcium demands of late pregnancy and lactation are about 0.3 g per day. There are limited long-term data on the effects of extended and repeated lactation. Whereas some studies have shown an adverse effect,²⁰¹ parity and lactation have not been associated with low bone mineral density or osteoporotic fracture risk in epidemiologic or case-control cohort studies.²⁰² In a study of 11 women with pregnancy and lactation-associated osteoporosis, 10 of whom had vertebral fractures and one a nonvertebral fracture, at least one recognized risk factor (e.g., low body weight, smoking, family history, vitamin D deficiency) was present in 9 patients. Nine patients received bisphosphonates for a median of 24 months, with increase in bone mineral density of 23% after 2 years. Of five women who had subsequent pregnancies, one sustained a fracture after delivery, and two patients followed for more than 10 years sustained fractures outside pregnancy.²⁰³ The study authors concluded that bisphosphonate therapy administered soon after presentation substantially increased spine bone density. However, because bisphosphonates can have an extremely long half-life and stay in bone for a long period, caution should be exercised if the patient wishes to conceive again, because the effects of bisphosphonates on the developing fetal skeleton has not been well studied, and the long-term safety as far as the fetus is concerned is unknown. In cases of severe osteoporosis it is reasonable to discourage lactation.

Chapter 49

Gastrointestinal Disease in Pregnancy

Thomas F. Kelly, MD, and Thomas J. Savides, MD

Pregnancy alters the anatomy and physiology of the gastrointestinal tract. These changes result in significant maternal symptoms that are experienced even in uncomplicated gestations. Difficulty arises in differentiating normal pregnancy complaints from those associated with pathology. The workup of suspected gastrointestinal disease is hampered by the potential risks of radiation or endoscopy to the fetus. Similarly, therapy for many gastrointestinal disorders must be altered because of the adverse or unknown effects of medical or surgical treatment. In this chapter, we review the common gastrointestinal disorders occurring in pregnancy and describe how pregnancy affects the presentation, diagnosis, and treatment of these disorders.

Alterations in Normal Gastrointestinal Function in Pregnancy

Esophagus

The esophagus normally maintains an alkaline pH, mainly by peristalsis of orally produced saliva and the lower esophageal sphincter preventing reflux of gastric contents.¹ Van Thiel and colleagues^{2,3} found decreased tone of the gastroesophageal sphincter during pregnancy and with the use of progesterone-containing oral contraceptives. However, Fisher and associates⁴ found no change in lower esophageal pressure in early pregnancy, but the sphincter's responses to hormonal and physiologic stimuli were reduced.⁴ These investigators observed in opossums decreased responses of the lower esophageal sphincter circular muscle to gastrin and acetylcholine.⁵ Whether arising from reduced sphincter tone or response to stimuli during pregnancy, the potential for gastrointestinal reflux appears to increase compared with nonpregnant individuals.

Stomach

The stomach receives, mixes, and propels food. It has mechanical and secretory properties. Peristaltic contractions are triggered by the gastric pacemaker located between the fundus and the corpus on the greater curvature with a normal frequency of three cycles per minute. Gastric emptying is difficult to measure in pregnancy because the typical use of radioisotopes in test meals must be avoided during human pregnancy. Measuring serial blood levels of acetaminophen, an agent that is poorly absorbed from the stomach, but quickly absorbed from the

small intestine, Macfie and coworkers⁶ found that gastric emptying was not delayed in pregnancy. Another study found no differences in pregnant compared with nonpregnant individuals, with the exception of delayed emptying 2 hours after delivery.⁷ Using hydrogen breath testing, there were no delays in gastric emptying, but there were increases in orocecal transit time as pregnancy advanced.⁸ Results of indirect studies suggest that gastric motility is not altered in pregnancy. Studies of gastric acid secretory function during pregnancy have produced conflicting results, with suggestions that acid production is decreased, unchanged, or increased.⁹⁻¹¹

Small Intestine

Small intestinal transit time is prolonged during pregnancy¹² and during the luteal phase in nonpregnant women. It may be caused by elevated progesterone levels during pregnancy and their relaxing effect on smooth muscle.¹³ The teleologic advantage is presumed to be increased nutrient absorption. Vitamin B₁₂ absorption and transluminal transport of some amino acids in animals are increased during pregnancy.^{14,15} The weight of the small intestine is increased during pregnancy in animals and is probably accounted for by the larger mucosal surface, supporting the theory of increased absorptive surface.

Colon

The functional changes of the colon in human pregnancy are inadequately studied. In pregnant animal models, colonic transit time is increased, and the smooth muscle is less responsive to stimulation.^{16,17} Because progesterone is known to inhibit colonic smooth muscle activity,¹⁸ it appears plausible that colonic motor activity is diminished during human pregnancy.

Nausea and Vomiting

Epidemiology

Up to 80% of pregnant women experience nausea and vomiting during pregnancy.¹⁹ Annually, 4 million women in the United States and 350,000 in Canada are affected.¹ Symptoms usually occur between 4 and 10 weeks' gestation and resolve by week 20. Nausea and vomiting usually occur in the first trimester, but they occur only in the third trimester in 3% of patients. One half of pregnant women experience

nausea in the morning, whereas nausea peaks in the evening in 7% of patients, and 36% experience symptoms constantly.²⁰

The term *morning sickness* is somewhat misleading in that a prospective study suggested that nausea occurring only during the morning affected 2% of patients, whereas 80% of symptomatic patients had nausea or vomiting throughout the day.²¹ Demographic factors associated with vomiting include first pregnancy, younger age, fewer than 12 years of education, nonsmoking status, and obesity.²² Nausea and vomiting are more common in the Western countries and Japan and rare in Africa, Asia, and Alaska among Native Americans,²³ indicating that factors other than pregnancy contribute to the pathogenesis.

Etiology

The cause of nausea and vomiting is unknown. Genetic influences have been suggested by the concordance of frequency in monozygotic twins²⁴ and the fact that family members are more likely to be affected.^{25,26}

Human chorionic gonadotropin has been implicated in causing nausea and vomiting. The close temporal association of peak human chorionic gonadotropin levels and nausea and vomiting symptoms and the fact that conditions associated with elevated levels, including female fetal sex, twins, and hydatidiform moles, have higher rates of hyperemesis tend to confer a causal relationship.²⁶⁻³³ Fifteen prospective comparative studies have been published since 1990, and 11 have shown a significantly higher level of human chorionic gonadotropin in women with hyperemesis.³⁴ Estrogens also can cause nausea and vomiting. Women who experience nausea after oral contraceptive use have a higher incidence of nausea and vomiting during pregnancy.²⁰ In the past 29 years, there have been 17 studies of the relationship between nonthyroid hormones and nausea and vomiting, and only human chorionic gonadotropin and estrogen have shown a consistent association.³⁵

Prostaglandin E₂ may contribute to this disorder, in that levels are elevated during symptomatic episodes.³⁶ *Helicobacter pylori* has been implicated as an etiologic agent for hyperemesis gravidarum,³⁷⁻³⁹ although later studies have not confirmed this.⁴⁰

Physiologic causes of nausea and vomiting of pregnancy historically have been underemphasized compared with the psychosocial factors, although these issues do have an association.⁴¹ Some authorities have proposed that nausea and vomiting of pregnancy is an evolutionary adaptation, protecting the woman and fetus from potentially harmful foods, and is therefore a healthy adaptive response.⁴²

Physiologic studies suggest that gastric dysrhythmias may have a role. Electrogastrographic recordings during pregnancy indicate that women with nausea and vomiting of pregnancy have alterations of the typical nonpregnant frequency of three cycles per minute and that these altered peristaltic contractions correlate temporally with the symptoms.⁴³ Altered gastric motility and gastroesophageal reflux appear to contribute to the mechanisms of nausea and vomiting in pregnancy, but the exact details are unknown.

Diagnosis of Nausea and Vomiting

Evaluation of the patient is based mainly on history. The nausea usually lasts all day. Pain is usually absent unless recurrent retching leads to painful abdominal and rib muscles. Similarly the physical exam is unremarkable unless the patient is severely dehydrated, a picture more consistent with hyperemesis gravidarum. Laboratory studies usually are not indicated or helpful. However, they are impor-

TABLE 49-1 EFFECTIVENESS OF THERAPIES FOR NAUSEA AND VOMITING DURING PREGNANCY COMPARED WITH PLACEBO

Therapy	Number of Trials	Odds Ratio	95% Confidence Interval
Bendectin	3	0.23	0.007 to 0.70
Antihistamines	6	0.20	0.06 to 0.63
Phenothiazines	2	0.09	0.00 to 1.88
Vitamin B ₆	2	0.64	0.18 to 2.26
Ginger	1	0.31	0.12 to 0.85
Acupuncture	2	0.35	0.12 to 1.06

tant in evaluating other potential causes that may mimic the condition, including hepatitis, pancreatitis, pyelonephritis, and uncontrolled diabetes.

Treatment of Nausea and Vomiting

Therapy can be instituted before the development of symptoms. Two studies have suggested that multivitamin therapy at the time of conception may reduce the incidence of nausea and vomiting.^{44,45} Non-pharmacologic treatment may include ginger (500 to 1500 mg in divided doses daily).^{46,47} Six randomized, controlled trials of vitamin B₆ have suggested superior or equivalent efficacy in improving symptoms over placebo, with no reports of adverse events. Acupressure or electrical stimulation on the P6 point of the wrist has shown conflicting results. The bulk of the literature suggests a benefit, but many of the studies have methodologic flaws or reveal no improvement over sham stimulation.⁴⁸⁻⁵¹

Pharmacologic therapy may be effective for nausea and vomiting of pregnancy (Table 49-1). Vitamin B₆ in doses of 10 to 25 mg taken three times daily is likely the best initial treatment, and it has a low likelihood of side effects.^{48,52,53} Doxylamine (10 mg) and vitamin B₆ were used until the early 1980s with apparent good effect. The compound Bendectin was removed from the market in 1983, and there was a subsequent increase in hospital admissions for nausea and vomiting.⁵⁴ For other pharmacologic treatments, including antihistamines and phenothiazines, there are no well-controlled trials.¹ Phenothiazines such as promethazine, prochlorperazine, chlorpromazine, and trimethobenzamide have shown some clinical efficacy, but their safety in pregnancy has not been proved.¹ Metoclopramide improves gastric emptying and corrects gastric dysrhythmias, and it has been safe and effective in small series.⁵⁵⁻⁵⁷ Droperidol and ondansetron have been used for postoperative nausea and vomiting, but their use in pregnancy has been limited to case reports.¹

Hyperemesis Gravidarum

Epidemiology

A more severe form of nausea and vomiting in pregnancy is hyperemesis gravidarum, which occurs in approximately 0.5% of live births.^{34,58} It is responsible for increased hospitalization and disability, and it can result in weight loss, electrolyte imbalances, and nutri-

tional deficiencies.^{59,60} Maternal factors shown to increase the rate of hospitalization because of hyperemesis gravidarum include hyperthyroidism, psychiatric disorders, diabetes, gastrointestinal disorders, and asthma. Multiple gestations and singleton female fetuses were also associated with a higher risk.⁶¹ Infants born to women with poor weight gain due to hyperemesis frequently have low birth weights.^{60,62}

Severe rare complications of hyperemesis include Wernicke encephalopathy, a neurologic manifestation of thiamine deficiency, and pneumomediastinum and esophageal rupture.^{34,63} This disorder leads to elective pregnancy termination in approximately 2% of affected pregnancies.²⁰ Hyperemesis gravidarum is more likely in multiple gestations, gestational trophoblastic disease, hydrops fetalis, and fetal karyotypic abnormalities, including triploidy and trisomy 21.¹ Although it typically begins in the first trimester, 10% of patients continue with symptoms throughout the pregnancy.¹⁹

Diagnosis

Symptoms of hyperemesis gravidarum include dry mouth, sialorrhea, hyperolfaction, and altered taste. Physical examination usually reveals dry mucous membranes, poor skin turgor, and hypotension.¹ Unlike standard nausea and vomiting of pregnancy, electrolyte abnormalities and ketonuria are identified in patients with hyperemesis gravidarum. Severely affected individuals may have elevated levels of hepatic transaminases and abnormalities in renal function.

Management

Intravenous fluid resuscitation is the initial treatment for hyperemesis gravidarum. Up to 2 L of Ringer's lactate should be infused over 3 to 5 hours, and continuing infusion subsequently is adjusted to maintain urine output above 100 mL/hr. Thiamine (100 mg) should be given intravenously before the infusion of dextrose to avoid Wernicke encephalopathy. Electrolyte levels, including magnesium and ionized calcium, should be monitored regularly.

Pharmacologic treatment includes the various antiemetics previously discussed. Pulsed steroids have been used in refractory cases. Methylprednisolone and hydrocortisone have been used in refractory cases with conflicting results. A randomized trial of oral methylprednisolone (initial doses of 16 mg three times daily followed by a 2-week taper) resulted in a reduction in readmission to the hospital when compared with oral promethazine.⁶⁴ Intravenous hydrocortisone 300 mg daily for 3 days followed by a taper over a week reduced vomiting episodes and subsequent readmission when compared with a regimen of metoclopramide.⁶⁵ Another study compared the use of intravenous methylprednisolone followed by an oral prednisone taper plus promethazine and metoclopramide with the use of only the latter drugs and found no difference in the rates of rehospitalization (35%).⁶⁶ Another randomized trial using oral prednisolone that was converted to intravenous hydrocortisone for no response was inconclusive, with a trend toward reduced vomiting, but patients had an improved sense of well-being and weight gain.⁶⁷

The mechanism by which steroids affect nausea is not clear. The nuclei of the solitary tract, area postrema, and raphe have glucocorticoid receptors and are known to participate in the regulation of nausea and vomiting responses.⁶⁸ Corticosteroid exposure in the first trimester may be weakly associated with an increased rate of facial clefting, potentially accounting for one or two cases per 1000 treated women.⁶⁹⁻⁷¹ Steroids therefore should be used with caution and should be avoided if possible during the period of fetal organogenesis.⁴⁸

Total parenteral nutrition has been used for hyperemesis gravidarum with reportedly improved outcomes.⁷² Significant complications of lipid emulsions have been reported, primarily with the use of cottonseed oil, and they have included placental infarction, ketonemia, and increased uterine activity. Subsequent case reports using soybean- or soybean and safflower oil-based emulsions have not shown the same adverse events.⁷³ However, there is an increased risk of complications directly related to therapy, including infusion catheter sepsis (25%) and venous thrombosis (3%).^{74,75} Centrally placed venous catheters have higher morbidity rates (50%) compared with peripherally inserted lines (9%).⁷⁶ One series of 52 patients receiving peripherally inserted central catheters had a complication rate of 50%.⁷⁷ The use of total parenteral nutrition should be considered as a last resort.

Adverse outcomes for women with hyperemesis and low maternal weight gain compared with those for patients without hyperemesis include higher rates of small-for-gestational-age fetuses, low birth weight, prematurity, and 5-minute Apgar scores less than 7.⁶⁰ Among women who experienced hyperemesis gravidarum in their first gestation, 15% to 19% will be affected in the second pregnancy, compared with 0.7% who had unaffected first pregnancies.^{60,78}

Gastroesophageal Reflux Disease

Epidemiology

Heartburn is the most common gastrointestinal complaint in Western populations, with up to 20% of the population having heartburn symptoms on a weekly basis. During pregnancy, up to 80% of women experience heartburn at some point, and 25% have daily heartburn.^{79,80} The prevalence and severity of heartburn progressively increase during pregnancy and resolve after delivery.^{81,82} One large study found the prevalence of heartburn symptoms to be 22% for patients in the first trimester, 39% for those in the second trimester, and 72% for patients in the third trimester.⁸² Factors associated with increased risk of heartburn symptoms were increasing gestational age, pre-pregnancy heartburn, and parity.⁸²

Pathogenesis

The exact cause of gastroesophageal reflux disease (GERD) during pregnancy is unknown. The resting lower esophageal sphincter (LES) pressure is decreased during pregnancy, and progesterone seems to mediate LES relaxation in the setting of elevated estrogen levels.⁸³ Other possible mechanisms for gastroesophageal reflux during pregnancy include increased intra-abdominal pressure causing gastric fluid reflux, ineffective esophageal motility to clear esophageal acid reflux, and decreased gastric emptying, which can result in reflux of gastric contents.

Diagnosis

The symptoms of gastroesophageal reflux in pregnancy are the same as in the general adult population. They can include substernal burning, epigastric discomfort, dyspepsia, mild dysphagia, and regurgitation. Patients may have extraesophageal manifestations, such as hoarseness, chronic cough, chronic laryngitis, and asthma. Complications of GERD, such as gastrointestinal bleeding and esophageal strictures, are rare during pregnancy.

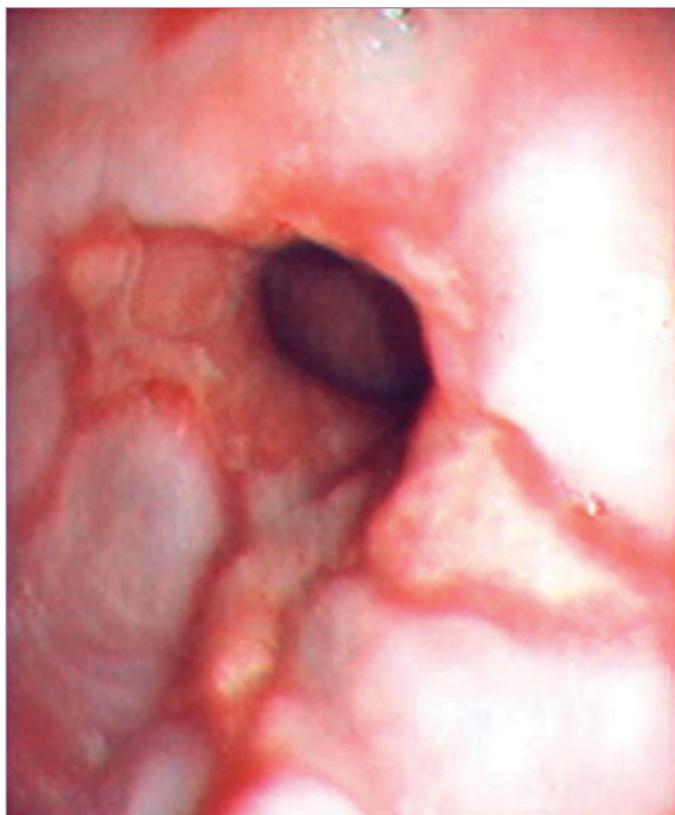

FIGURE 49-1 Endoscopic image of severe erosive esophagitis.

The diagnosis usually is made by clinical symptoms only. There is rarely reason to do invasive diagnostic tests such as barium radiographs, esophageal pH studies, or esophageal manometry studies. Upper gastrointestinal endoscopy is rarely needed, except in exceptional cases of symptoms refractory to medical management. The endoscopic appearance of GERD ranges from no mucosal breaks to severe ulceration of the distal esophagus (Fig. 49-1).

Management

For mild to moderate symptoms, lifestyle and dietary changes may help. Patients should avoid eating late at night or within a few hours of bedtime, elevate the head of the bed 6 inches, sleep on the left shoulder, and avoid things that can make GERD worse, including alcohol, cigarette smoking, caffeine, chocolate, and peppermint.

Medication is commonly used as first-line therapy for GERD in the general adult population, but in pregnancy, therapeutics are complicated by the small potential risk of teratogenicity from GERD medications. Most medications for GERD are not routinely or rigorously tested in pregnant women, and recommendations therefore come from small case series. The risks and benefits of medications for GERD, as well as the limited knowledge of the effects of these medications during pregnancy, must be discussed with the patient by the provider. Because the risk of teratogenicity is greatest in the first 10 weeks, efforts should be made to avoid all unnecessary medications during that period. Table 49-2 shows the U.S. Food and Drug Administration (FDA) classification of drug therapy for GERD and peptic ulcer disease during pregnancy. Most drugs are FDA class B.

TABLE 49-2 FETAL SAFETY OF MEDICATIONS USED TO TREAT GASTROESOPHAGEAL REFLUX DISEASE OR PEPTIC ULCER DISEASE

Drug	FDA Pregnancy Category*	Comments
Antacids	Unrated	Generally safe
Simethicone	C	
Sucralfate	B	
Histamine ₂ (H ₂) receptor antagonists		
Cimetidine	B	
Ranitidine	B	
Famotidine	B	
Nizatidine	B	
Proton pump inhibitors		
Omeprazole	C	
Lansoprazole	B	
Rabeprazole	B	
Pantoprazole	B	
Esomeprazole	B	
Misoprostol	X	Abortifacient
<i>Helicobacter pylori</i> treatments		
Amoxicillin	B	
Clarithromycin	C	
Bismuth subsalicylate	C	
Tetracycline	D	
Metronidazole	B	

*U.S. Food and Drug Administration (FDA) classification of teratogenic drug risk:

- A:** Well-controlled studies in pregnant women have failed to demonstrate an increased risk of fetal abnormalities.
- B:** Animal studies show no fetal risk, and no human data are available, or animal studies show a risk, but well-controlled studies in pregnant women have failed to show a risk to the fetus.
- C:** Risk cannot be ruled out because animal studies have shown an adverse effect, and there are no adequate, well-controlled studies in pregnant women, or no animal studies have been conducted, and there are no adequate, well-controlled studies in pregnant women.
- D:** Well-controlled or observational studies in pregnant women have demonstrated a risk to the fetus, but the benefits of therapy may outweigh potential risk.
- X:** Well-controlled or observational studies in animals or pregnant women have demonstrated positive evidence of fetal abnormalities, and the product is contraindicated in women who are or may become pregnant.

Antacids are considered safe to use during pregnancy and can be expected to relieve symptoms in 30% to 50% of pregnant women.⁸⁴ Sucralfate is a mucosal protectant that can help relieve GERD symptoms in pregnancy. Proton pump inhibitors such as metoclopramide can also be used to help gastric emptying and increase LES pressure, although these drugs are infrequently used because of poor tolerance to their side effects.

Histamine type 2 (H₂) receptor antagonists are apparently safe and effective in pregnancy.^{85,86} Proton pump inhibitors are more effective than H₂-blockers for healing esophagitis and treating GERD, but they are less well studied in pregnancy than H₂-blockers. Omeprazole is categorized as a class C drug by the FDA because of embryotoxicity and fetotoxicity in animals and because of a few case reports

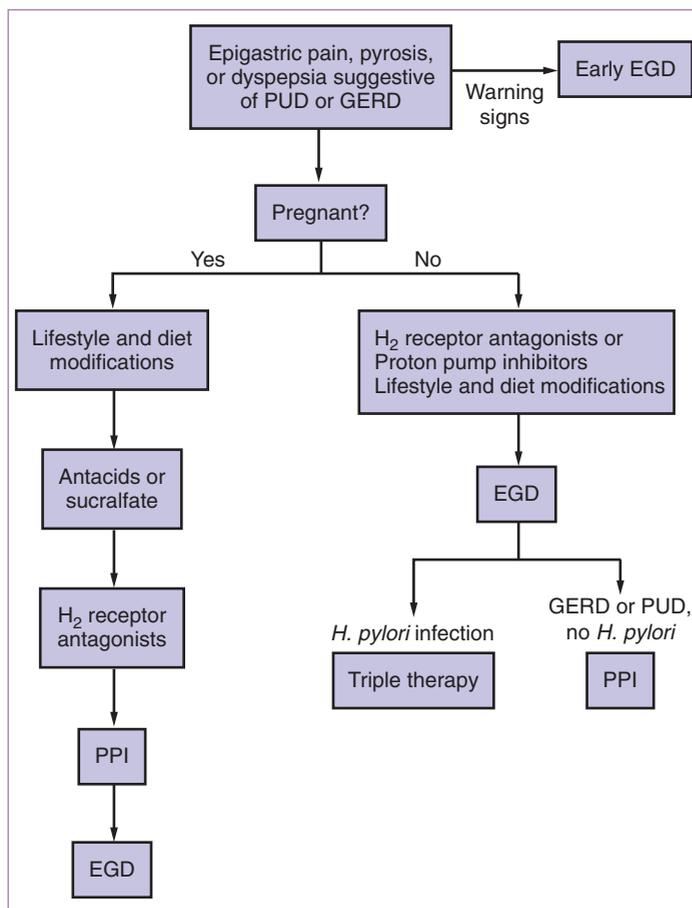

FIGURE 49-2 Stepwise management of gastroesophageal reflux disease (GERD) or peptic ulcer disease (PUD). EGD, esophagogastroduodenoscopy; PPI, proton pump inhibitor. (Modified from Cappell MS: Gastric and duodenal ulcers during pregnancy. *Gastroenterol Clin North Am* 32:263-308, 2003.).

of fetal birth defects in humans.⁸³ However, a meta-analysis of the risk of fetal malformations during the first trimester found no increase with the use of proton pump inhibitors in general and with omeprazole specifically by pregnant women.⁸⁷ A large study from Europe comparing several proton pump inhibitors, including omeprazole, also found no increase in major fetal anomalies compared with patients not exposed to proton pump inhibitors.⁸⁸

A recommended algorithm for treating GERD in pregnancy is shown in Figure 49-2. Patients should initially be reassured and treated with lifestyle modifications. If these are unsatisfactory, use of antacids or sucralfate should be considered. Persistent symptoms, especially after the first trimester, can be treated with H₂-blockers. If symptoms persist despite H₂-blockers, consideration can be given to using proton pump inhibitors or undergoing upper endoscopy to assess the cause of GERD.

Peptic Ulcer Disease

Epidemiology

Because the incidence of peptic ulcer disease (PUD) during pregnancy is estimated from case reports and retrospective studies, it may be

FIGURE 49-3 Endoscopic image of a deep gastric ulcer.

unreliable.⁸⁹ Epidemiologic studies suggest a decreased incidence of PUD during pregnancy, and there appears to be an improvement in patients with PUD during pregnancy. Clark⁹⁰ found that in 313 pregnancies occurring after a diagnosis of PUD, 45% had no symptoms, 44% improved, and 12% experienced no improvement. Hypotheses for this improvement include physiologic changes, including increased plasma histaminase or estrogen levels leading to reduced gastric acid; increased gastric mucosal protection induced by progesterone; immunologic tolerance allowing *H. pylori* colonization without injury; and elevated epidermal growth factor levels stimulating mucosal growth. Maternal alterations such as avoidance of alcohol, smoking, and nonsteroidal anti-inflammatory drugs; increased rest; and improved nutrition have also been postulated.⁸⁹

Diagnosis

Symptoms of PUD are similar to those in the nonpregnant population and include epigastric pain, anorexia, postprandial nausea, and vomiting. Duodenal ulcer pain can occur several hours after a meal or at nighttime, and pain usually improves with eating.⁹¹ Gastric ulcers may not follow the classic pattern of symptoms (Fig. 49-3), and older patients who use antiulcer medication and NSAIDs may be asymptomatic.⁹² Gastrointestinal reflux disease, which is more common in pregnancy, differs in that there may be a sense of substernal chest burning and fluid reflux, and it can often be worse after meals. Results of the physical examination are nonspecific, and they essentially are helpful in ruling out complicated ulcer disease or other causes of abdominal pain, including pancreatitis, cholecystitis, and appendicitis.

In the nonpregnant population, esophagogastroduodenoscopy (EGD) is preferable mainly because of its ability to accurately diagnose ulcers and to obtain histologic specimens that are tested for *H. pylori* infection.⁸⁹ EGD is relatively safe in pregnancy.⁹³ In the largest study, there were no maternal complications in 83 procedures, and EGD did not induce preterm delivery. Despite its presumed safety, most cases of PUD can be managed without imaging. EGD should be reserved for cases refractory to medical management.

Management

Management begins with empiric treatment (see Fig. 49-2). Because PUD and GERD therapies are similar, a stepwise scheme should be followed before considering EGD. Dietary and lifestyle alterations include avoidance of fat-laden foods, acidic drinks, caffeine, chocolate, NSAIDs, and alcohol. Smoking, stress, anxiety, and nighttime snacks should be avoided.⁸⁹

Antacids should be used as first-line medical therapy because they have been effective in approximately 75% of duodenal ulcers.^{94,95} Dosages range from 15 to 30 mL taken 1 hour after meals and at bedtime. Extra doses may be taken 3 hours after meals.⁸⁹ Aluminum- and magnesium-containing antacids have little systemic absorption and appear to be safe in pregnancy. Sucralfate, an aluminum-based polysaccharide complex, attaches to the surface of an ulcer, protecting the mucosa from further injury, and it may suppress *H. pylori* infection.^{96,97} Seventy-five percent of duodenal ulcers heal with 4 weeks of sucralfate therapy.⁹⁷ Because of its minimal systemic absorption, it is a preferred drug for treating PUD in pregnancy.⁹⁸

H₂-receptor antagonists are an effective treatment for PUD; about 80% of duodenal ulcers heal with this therapy in the general population.⁹⁹ Before the discovery of *H. pylori* and the introduction of proton pump inhibitors, H₂-blockers were the mainstay of treatment. Their safety profile in pregnancy has not been adequately demonstrated. H₂-receptor antagonists cross the placenta, but their use is justifiable if significant clinical conditions warrant.¹⁰⁰ Cimetidine and ranitidine have had considerable use over the past 20 years. In animal studies, cimetidine has caused a reduction in the size of fetal testes, prostate, and seminal vesicles, presumably by means of a weak antiandrogenic effect.¹⁰¹ Ranitidine has no such effects in animals, and neither drug has had reports of genital malformations in humans.^{84,102} More than 2000 pregnancies in database studies with exposure to cimetidine or ranitidine have been assessed, and there has not been an associated risk of congenital malformations.⁸⁴ There is less information reported for famotidine and nizatidine. Because of nizatidine's conflicting animal data, it is preferable to use more extensively studied H₂-receptor antagonists as first-line agents.⁸⁴

Proton pump inhibitors suppress gastric acid secretion at the level of the H⁺,K⁺-ATPase on the parietal cell surface.⁸⁹ These agents are highly effective in the treatment of esophagitis and gastroduodenal ulcers, and they are often used in combination therapy for eradication of *H. pylori* infection. Omeprazole, the first agent in the class, produced dose-related embryonic and fetal death in animal studies. Because of these concerns and cases reported to the FDA, it has remained an FDA category C drug.⁸⁴ However, a meta-analysis comprising 593 infants suggested a nonsignificant risk for congenital malformations.⁸⁷ A multicenter, prospective, controlled study involving proton pump inhibitors in 295 pregnancies also suggested no increased teratogenic risk.⁸⁸ Although the other proton pump inhibitors are category B drugs, omeprazole is the only one available over the counter, and it is less expensive than the others.⁸⁴

In the nonpregnant population, proton pump inhibitors are usually the initial treatment for suspected or documented reflux esophagitis and PUD. H₂-receptor antagonists, sucralfate, and antacids are used as secondary medications and for symptomatic relief.⁸⁹ During pregnancy, therapy should be modified to avoid fetal harm and because PUD usually improves during gestation. EGD is usually avoided unless the patient is failing empiric therapy with H₂-receptor antagonists. There appears to be little benefit in diagnosing *H. pylori* infection during pregnancy, because treatment involves triple drug therapy, including antibiotics, and it is usually deferred until after delivery.⁸⁹

Appendicitis

Epidemiology

Acute appendicitis is one of the most common causes of an acute abdomen in pregnancy. It occurs in 1 in 1500 pregnancies¹⁰³ and has an approximate incidence of 0.15 to 2.10 per 1000 gestations.¹⁰⁴ Previous studies suggested similar incidences for nonpregnant adults, but a large case-control study indicated a lower incidence than among nonpregnant individuals, particularly in the third trimester.¹⁰⁵ Overall incidence rates in the first trimester range between 19% and 36%, and rates increase in the second trimester to between 27% and 60%.¹⁰⁵⁻¹⁰⁷ The incidence decreases in the third trimester, with rates ranging from 15% to 30%. Appendiceal perforation rates in pregnancy are higher when compared with those for nonpregnant populations (55% versus 4% to 19%).¹⁰⁷⁻¹⁰⁹ This is likely explained by confounding variables leading to the delay of diagnosis and therapy.

Fetal and maternal morbidity and mortality rates increase when appendicitis occurs during pregnancy, particularly if perforation occurs.^{110,111} The fetal loss rate associated with appendectomy is higher (2.6%) than for other surgical procedures (1.2%) during pregnancy, and the rate approximates 10% if peritonitis is present.¹¹² There is a high rate of appendicitis-induced delivery (4.6%), and if preterm labor occurs, it is usually within 5 days of the surgery.^{110,112} The advancing pregnancy appears to impair the ability of making an accurate diagnosis. Cunningham and McCubbin¹¹¹ identified delays in diagnosis of 18% and 75% in the second and third trimester, respectively, which corresponded to the higher rates of complications, including perforation and peritonitis, found in other series.¹⁰⁷ Hee and Viktrup¹⁰⁶ found the ratio of perforated appendicitis to nonperforated appendicitis to be 1.0, 2.1, and 1.6 in the first, second, and third trimesters, respectively, and they found the overall rate of appendicitis confirmed by pathologic analysis to be 50%.

Diagnosis

Right lower quadrant pain appears to be the most common symptom of appendicitis, regardless of gestational age, and it occurs in about 80% of patients.^{103,106,110} Right upper quadrant pain varies, and it occurs in about 10% to 55% of patients.^{103,107} Nausea and vomiting may be absent in approximately 20% of patients, and anorexia is not a reliable marker. Objective findings are similarly confusing. Fever, tachycardia, a dry tongue, and localized abdominal tenderness are common in nonpregnant individuals, but they are less reliable findings during pregnancy.¹¹³ The Rovsing and psoas signs have not been shown to have clinical significance.¹¹⁰

Laboratory evaluation of patients with appendicitis is important, primarily for its ability to exclude alternative diagnoses (Table 49-3). Urinalysis and chest radiography should be strongly considered because urinary tract infection and right lower lobe pneumonia may manifest with lower abdominal pain. However, pyuria may occur in 40% of pregnant patients with appendicitis.¹¹⁴ White blood cell (WBC) counts are not predictive, mainly because of the physiologic leukocytosis of pregnancy. Mean WBC counts in acute appendicitis are in the range of 16,000 cells/mm³.¹⁰³

Imaging modalities help to make the diagnosis of acute appendicitis (Table 49-4). Abdominal plain film radiography should be avoided, unless there is concern about bowel obstruction or visceral perforation. Ultrasound with a graded compression technique is

usually available in most hospitals, and it avoids ionizing radiation. However, ultrasound detection of appendicitis is operator dependent. Studies assessing the accuracy of ultrasound for the diagnosis of appendicitis have been of insufficient quality or fraught by small numbers or selection bias.¹¹⁵ The utility of the graded compression technique diminishes as the uterus enlarges, or the appendix is often not visualized.

Helical computed tomography (CT) in the nonpregnant population is highly sensitive and specific (approximately 98% each) for appendicitis.¹¹⁶ CT scans are considered abnormal if there is an enlarged appendix (>6-mm maximal diameter) or if there are periappendiceal inflammatory changes, such as fat stranding, phlegmon, fluid collection, and extraluminal gas.¹¹⁷ Radiation exposure is 300 mrad with a limited helical CT scan, which is one third of the amount of the average abdominopelvic CT scan.¹¹⁸ Unfortunately, published experience with this technique in pregnancy is limited. Magnetic resonance imaging (MRI) during pregnancy has no known adverse fetal effects, and its use has been advocated in patients for whom the diagnosis has not been confirmed by other techniques.^{119,120} Two reports have suggested that MRI is an excellent modality for use in the diagnosis of appendicitis in pregnancy.^{121,122} A normal appendix was suggested by a diameter of less than or equal to 6 mm or if it was filled with air or oral contrast. Conversely, a fluid-filled appendix greater than 7 mm in

diameter was considered abnormal.¹²² However, these studies were small and retrospective.

Treatment

Prompt surgical intervention remains the standard treatment. Appendectomy may be delayed during active labor, but it should be performed immediately after delivery or if labor is abnormally prolonged or perforation is suspected.¹²³ If an open procedure is chosen, a muscle-splitting incision is made over the point of maximal tenderness. If diffuse peritonitis is present, a midline incision is usually performed. A periappendiceal abscess can be treated with percutaneous drainage followed by an interval appendectomy 2 to 3 months later.¹²³ Perioperative antibiotics should be administered, usually a second-generation cephalosporin, expanded-spectrum penicillin, or even triple-agent therapy.

Laparoscopic appendectomy was first performed in 1980, and it spawned controversy about its use in pregnancy that continues to the present.¹²⁴ Its use in pregnancy has been documented with a good safety record,¹²⁵ and it has a complication rate similar to that for nonpregnant laparoscopy.¹²⁶ It may have advantages over open appendectomy of less abdominal wall trauma, less pain and narcotic use, and faster return to normal activity.^{124,127} However, the presence of the enlarged uterus does increase the risk of inadvertent puncture with a trocar or Veress needle.¹²⁸ In the second half of pregnancy, pen laparoscopy may be preferred to avoid such complications. Unlike nonpregnant laparoscopy, no instrument should be applied to the cervix. The primary trocar is inserted after determining the height of the uterus, and the secondary trocars are inserted under direct visualization. Consideration of supraumbilical, subxiphoid insertions may be necessary. Limiting intra-abdominal pressure to less than 12 mm Hg and reducing operative time can reduce concerns about maternal hypercarbia and subsequent fetal acidosis.^{127,129}

Inflammatory Bowel Disease

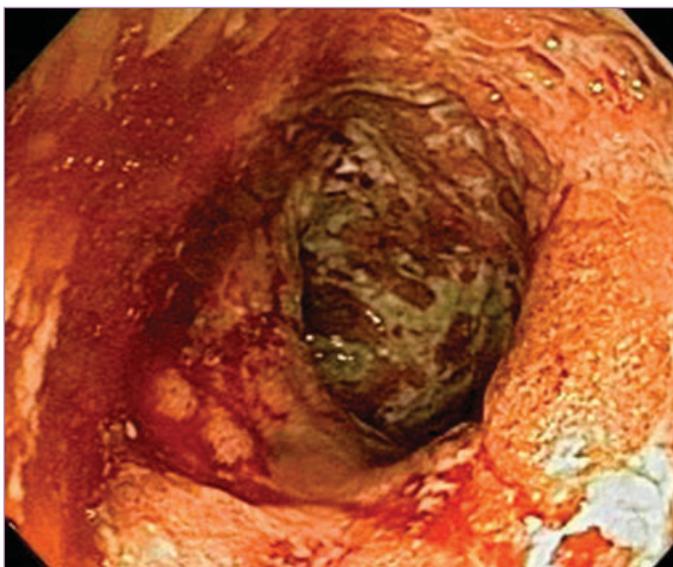

Inflammatory bowel disease (IBD) refers to ulcerative colitis and Crohn disease. Their similarities and differences are outlined in Table 49-5. These entities are similar in that both are inflammatory conditions of the luminal gastrointestinal tract. They differ in terms of the layer of involvement of the intestinal wall, the anatomic location of involvement within the gastrointestinal tract, and the response to surgical resection. Both are treated with similar medications. The cause of ulcerative colitis and Crohn disease is unknown. There seems to be a genetic component in some patients, but there is also the possibility of an environmental trigger such as an infection. The final common

Evaluation	Alternative Diagnosis
Surgical	Acute cholecystitis Pancreatitis Mesenteric adenitis Diverticulitis Intestinal obstruction Meckel's diverticulum
Medical	Gastroenteritis Pneumonia Inflammatory bowel disease Lupus serositis Diabetic ketoacidosis Porphyria
Gynecologic	Ruptured adnexal cyst Torsion
Urologic	Uterine myoma degeneration Ureteral colic Pyelonephritis Urinary tract infection

Modality	Diagnostic Criteria	Evidence
Plain radiography	None	No role in the diagnosis of acute appendicitis
Ultrasound ¹¹⁵	Aperistaltic and noncompressible structure with a diameter >6 mm	Sensitivity of 67-100%, specificity of 83-96%
Computed tomography ¹¹⁸	Abnormal appendix identified or calcified appendicolith seen in association with periappendiceal inflammation or a diameter >6 mm	Sensitivity of 94%, specificity of 95%
Magnetic resonance imaging ¹²²	Appendix diameter >7 mm or 6-7 mm with periappendiceal inflammation	Sensitivity 100%, specificity 94%

TABLE 49-5 COMPARISON OF ULCERATIVE COLITIS AND CROHN DISEASE

Feature	Ulcerative Colitis	Crohn Disease
Extent of inflammation Intestine involved	Limited to mucosa Colon only	Involves all layers (transmural) Throughout the gastrointestinal tract, especially the terminal ileum
Rectal involvement	Always	Sometimes
Pattern of spread	Contiguous	Skip lesions
Granulomas	No	Yes (sometimes)
Fistula	No	Yes
Strictures	No	Yes
Abscess	No	Yes
Perianal disease	No	Yes
Bloody diarrhea	Yes	Maybe
Ileal disease on computed tomography	No	Yes
Increased colon cancer risk	Yes	Maybe (if colonic involvement)
Cure with surgery	Yes	No
Percent of patients who will require surgery	20%	70%

**FIGURE 49-4** Endoscopic image of severe ulcerative colitis.

pathology is an increased inflammatory response against the tissues of the gastrointestinal tract.

Ulcerative colitis is characterized by inflammation limited to the mucosal surface of the colon (Fig. 49-4). It always starts at the dentate line of the rectum and extends proximally but only involves the colon. Patients usually present with bloody diarrhea. Patients usually are managed with medical therapy consisting of 5-aminosalicylates, prednisone, 6-mercaptopurine or azathioprine, and occasionally infliximab. Surgery, which is occasionally performed for refractory disease, results in complete cure of the ulcerative colitis.

Crohn disease is characterized by inflammation that can be transmural, involving all wall layers. It often involves the terminal ileum, but it can involve any part of the luminal gastrointestinal tract. Transmural inflammation may result in intestinal strictures or intestinal fistulas or abscesses. Patients are usually managed medically with 5-aminosalicylates, prednisone, 6-mercaptopurine or azathioprine, and infliximab. They also can benefit from antibiotics such as metronidazole and ciprofloxacin.

Effect of Inflammatory Bowel Disease on Pregnancy

If a woman has quiescent IBD, the pregnancy can be expected to proceed without increased complications.^{130,131} Patients with ulcerative colitis and Crohn disease usually have healthy deliveries at the same rate as the general population, although some studies have suggested a greater incidence of preterm births and low-birth-weight infants.¹³²⁻¹³⁸ However, it is unclear from these studies whether the degree of disease activity correlated with the differences in outcomes.

Effect of Pregnancy on Inflammatory Bowel Disease

Active ulcerative colitis or Crohn disease at the time of conception tends to remain active, and inactive disease tends to remain inactive.^{136,139,140} Pregnant patients with active ulcerative colitis or Crohn disease have the same risks for complications from IBD as nonpregnant women.

Diagnostic Testing for Inflammatory Bowel Disease during Pregnancy

Patients with known IBD can be managed based on their history, physical examination findings, and blood test results. It is important to determine whether a patient with IBD who is having a flare of diarrhea during pregnancy has an intestinal infection, especially with *Clostridium difficile*, before starting any new immunosuppressive therapy (Fig. 49-5). In selected pregnant IBD patients, stool studies for infectious causes are needed. Flexible sigmoidoscopy appears to be safe during pregnancy, and it is usually the only endoscopic procedure needed in selected IBD patients. Abdominal CT or MRI may be used in carefully selected cases if the benefits outweigh potential risks.

Safety of Inflammatory Bowel Disease Medications during Pregnancy

Pregnant patients with IBD should stay on the medications that are maintaining them in remission. Stopping the medications can induce a relapse or flare of disease. Table 49-6 shows the safety of various IBD medications during pregnancy.

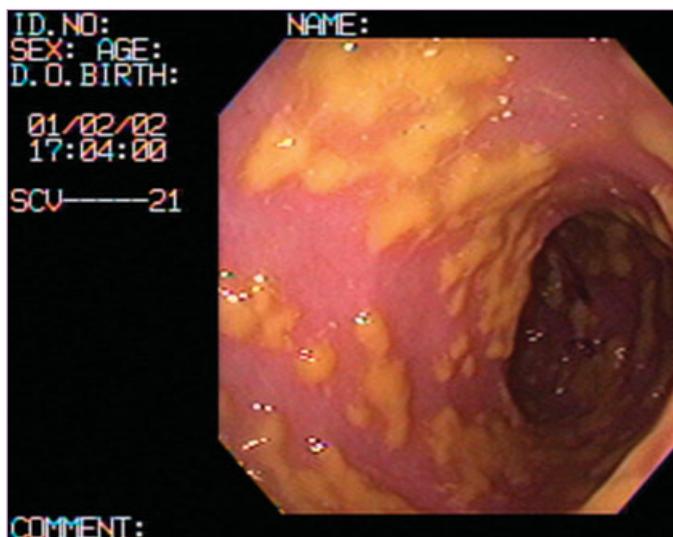

FIGURE 49-5 *Clostridium difficile* colitis.

TABLE 49-6 SAFETY OF INFLAMMATORY BOWEL DISEASE MEDICATIONS DURING PREGNANCY		
Safe to Use	Probably Safe but Limited Data	Contraindicated
Sulfasalazine 5-Aminosalicylates Corticosteroids	Azathioprine 6-Mercaptopurine Cyclosporine Metronidazole Ciprofloxacin Infliximab Loperamide	Methotrexate Diphenoxylate

Antidiarrheal Medications

Loperamide (Imodium) appears to be safe during pregnancy because it has not been associated with increased rates of fetal malformations, spontaneous abortions, low birth weight, or prematurity.¹⁴¹ In contrast, there have been reports of fetal malformations in patients exposed to diphenoxylate with atropine (Lomotil) during the first trimester, and it should be avoided.¹⁴² It is probably best to avoid antidiarrheal drugs, if possible, during pregnancy and instead rely on supplemental fiber or psyllium seed.

Antibiotics

Metronidazole and ciprofloxacin are occasionally used in the management of patients with Crohn disease. Several studies have shown that short-term use of metronidazole is safe during pregnancy.^{143,144} Some animal studies suggested that musculoskeletal abnormalities resulted from ciprofloxacin, but small clinical series have not reported any fetal malformations or arthropathies.^{145,146}

Sulfasalazine and 5-Aminosalicylate Drugs

Sulfasalazine and 5-aminosalicylate drugs are often used for long-term maintenance of mild or moderately active IBD. These drugs appear to be safe to use in pregnancy.^{88,147-150}

Corticosteroids

Oral corticosteroids such as prednisone are commonly used to manage active ulcerative colitis and Crohn disease. They are typically used for short periods to induce remission but are not used for maintenance of remission. The use of prednisone for IBD appears to be relatively safe in pregnancy, although an increased incidence of low-birth-weight neonates has been reported.^{149,151}

Immunomodulators

Azathioprine and 6-mercaptopurine are increasingly used to maintain remission in patients with ulcerative colitis or Crohn disease. Azathioprine and 6-mercaptopurine cross the placenta. The largest experience with azathioprine in pregnancy comes from the renal transplant literature, which suggests it is safe to use.¹⁵² There is less information on 6-mercaptopurine in pregnancy, but it also appears safe to use in pregnant IBD patients to keep them in remission.^{153,154}

Methotrexate is occasionally used in challenging cases of IBD. Methotrexate is associated with fetal malformations and fetal demise, and it should not be used during pregnancy and ideally for at least 3 months before conception.

Biologic Agents

Infliximab (Remicade) is increasingly being used for induction and maintenance of remission of Crohn disease and occasionally for ulcerative colitis. Infliximab inhibits tumor necrosis factor. There are only small case series of infliximab being continued intentionally during pregnancy for Crohn disease, but the limited data show no obvious adverse effects.¹⁵⁵ Because patients who are taking maintenance infliximab usually have been refractory to other treatments, it is likely that their Crohn disease will flare during pregnancy if infliximab is stopped. The unknown risks and benefits must be discussed with the patient.

Surgery for Inflammatory Bowel Disease during Pregnancy

Surgery for IBD during pregnancy is done for emergencies such as intestinal obstruction, perforation, abscess, or fulminant colitis. In these cases, the surgery is required for the mother's health.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is characterized by chronic abdominal pain and altered bowel habits without obvious organic cause. It is the most commonly diagnosed gastrointestinal pathology. The estimated prevalence of IBS in the United States is between 10% and 15%.¹⁵⁶ IBS tends to affect younger women more than other demographic groups, which means many pregnant women also have IBS. IBS accounts for 25% to 50% of clinic referrals to gastroenterologists and approximately 10% of referrals to primary care physicians.¹⁵⁶

It is unclear whether pregnancy worsens IBS symptoms, because many pregnant women develop constipation or loose stools during pregnancy. Because IBS usually poses no threat to maternal or fetal health, it can be treated symptomatically during pregnancy.

Symptoms

IBS is a heterogeneous collection of symptoms. The most common include chronic abdominal pain and altered bowel habits. Upper abdominal symptoms can also occur. The abdominal pain is often

described as crampy, lower abdominal discomfort (often in left side), which can become worse with stress and better after bowel movements. Patients with IBS often complain of altered bowel movements, with constipation, diarrhea, or alternating constipation and diarrhea. When describing constipation, they often have stools resembling rabbit pellets. They often describe needing to have bowel movements several consecutive times in the morning to completely empty the rectum. They may have mucus in their stools. The diarrhea never wakes them from sleep. Upper gastrointestinal symptoms such as GERD, dyspepsia, and nausea are common, as are symptoms of gas and bloating. Extra-intestinal symptoms include dyspareunia, increased urinary frequency and urgency, and fibromyalgia.¹⁵⁷

Symptoms that do not suggest IBS include blood in the bowel movements, weight loss, and being awakened from sleep for abdominal pain or bowel movements. These symptoms should prompt additional evaluation.

Diagnostic Criteria

The most common diagnostic criteria for standardizing the diagnosis of IBS are the Manning criteria and the Rome III criteria (Table 49-7). The Manning criteria include abdominal pain relieved with bowel movements, looser and more frequent stools with onset of pain, passage of mucus, and sense of incomplete evacuation.¹⁵⁸ The Rome III diagnostic criteria for IBS are recurrent abdominal discomfort with two or more of the following: improvement with defecation, onset associated with a change in stool frequency, and onset associated with a change in stool appearance or form.¹⁵⁹ The Rome III criteria also describes four subtypes of IBS: IBS with constipation, IBS with diarrhea, mixed diarrhea and constipation IBS, and unsubtyped IBS.

Pathophysiology

The pathogenesis of IBS is unknown but likely multifactorial. The most common possibilities include altered motility of the gastrointestinal tract and visceral hypersensitivity. There may also be a central nervous system component because IBS patients have an increased frequency of psychiatric abnormalities such as depression, somatization disorders, and generalized anxiety disorders. There also is a subgroup of patients with postinfectious IBS.

Diagnosis

IBS should be suspected with the appropriate clinical symptoms and lack of alarming symptoms (i.e., blood in stool, weight loss, waking from sleep because of pain or bowel movements). The diagnostic

evaluation is often geared to symptoms and may include blood work and endoscopic evaluations. IBS often is a diagnosis of exclusion in the correct clinical setting.

Management

There is no specific treatment for IBS because it tends to be a chronic condition. Reassurance of the patient by an understanding physician is important. Dietary changes may identify foods that worsen symptoms (e.g., dairy products, fatty foods). Supplemental fiber can help a subset of patients, although the mechanism is uncertain. Medications are needed only by a minority of IBS patients. These drugs can include antispasmodic medicines such as hyoscyamine. Low-dose antidepressants can be used to modify chronic abdominal pain. Probiotics have been reported to help symptoms. Diarrhea can be controlled with antidiarrheal medications, and constipation can be controlled by laxatives or lubiprostone. Antibiotics may help the gas and bloating symptoms of IBS in selected patients.¹⁶⁰

Celiac Disease

Epidemiology and Etiology

Celiac disease is also known as celiac sprue or gluten-sensitive enteropathy.¹⁶¹ Gliadin and related proteins activate the immune system, resulting in the inflammation of the small intestinal mucosa and malabsorption.¹⁶¹ Celiac sprue is caused by an abnormal T-cell response against gluten in genetically predisposed people.¹⁶²

Celiac disease is often underdiagnosed. The prevalence of this disorder ranges between 1 in 80 to 1 in 300 individuals.^{163,164} The highest reported prevalence is in Western Europe and places to which Europeans immigrate.¹⁶⁴⁻¹⁶⁶ Genetic predisposition for celiac disease is confirmed by a high rate of concordance in monozygotic twins.¹⁶⁷ The diagnosis may be associated with other conditions such as diabetes, lymphocytic colitis, irritable bowel syndrome, diarrhea, and unexplained anemia. Survival of these patients has improved with appropriate therapy.¹⁶⁸

Diagnosis

Although celiac disease often begins in childhood, clinical symptoms of the disease may begin at any age.¹⁶⁹ One fourth of individuals are diagnosed after the age of 15 years.¹⁷⁰

Celiac sprue may manifest in pregnancy or after delivery, and the diagnosis should be entertained when encountering severe anemia in a gravid patient.^{161,171} Adults usually present with episodic diarrhea,

TABLE 49-7 DIAGNOSTIC CRITERIA FOR IRRITABLE BOWEL SYNDROME

Manning Criteria	Rome III Criteria
Pain relieved with defecation	Recurrent abdominal discomfort at least 3 days per month in the last 3 months associated with two or more of the following:
More frequent stools at the onset of pain	
Looser stools at the onset of pain	
Visible abdominal distention	1. Improvement with defecation
Mucus in stool	2. Onset associated with change in stool frequency
Sense of incomplete evacuation	3. Onset associated with change in form of stool
	Supporting features: abnormal stool frequency (<3 bowel movements per week or >3 bowel movements per day), abnormal stool form, defecation straining, urgency, sense of incomplete bowel movement, mucus passage, bloating

flatulence, and weight loss. They also may have lactose intolerance and steatorrhea. Patients have abdominal discomfort, bloating, malaise, and recurrent aphthous stomatitis ulcers.¹⁶¹

Laboratory abnormalities include iron deficiency, macrocytic anemia, and vitamin D and K deficiencies. The most widely available screening test for celiac disease is the antiendomysial IgA test. The test has excellent specificity (approaching 100%), but its sensitivity as a stand-alone screen is less because of an increased prevalence of selective IgA deficiency in patients with celiac disease.¹⁶⁸ IgA and IgG anti-gliadin antibodies have moderate sensitivity but are less specific than antiendomysial antibodies; normal individuals and those with gastrointestinal inflammation from other causes test positive.¹⁷² IgA anti-gliadin antibody levels are useful for monitoring dietary compliance, because they become detectable within 6 months of maintaining a gluten-free diet.¹⁶¹ A rapid bedside screening test has been developed that detects IgA and IgG tissue trans-glutaminase. The sensitivity is higher than that for IgA endomysial antibodies.¹⁷³ The gold standard of diagnosis remains biopsy of the small intestine during upper gastrointestinal biopsy from the distal duodenum.¹⁶¹

Management

Management consists of eliminating gluten from the diet. Seventy percent of patients improve symptomatically within 2 weeks.¹⁷⁴ This includes avoidance of wheat, rye, and barley gluten. During the initial phase of treatment, oats and lactose-containing products should also be eliminated.¹⁶¹ Because of problems of malabsorption, multivitamin therapy and specific replacement of vitamin D and calcium may be necessary.

The importance of recognition of celiac disease may be reflected in the studies suggesting that uncontrolled disease may be associated with adverse pregnancy outcome.¹⁷⁵⁻¹⁷⁹ Studies of untreated and treated celiac patients revealed an increased rate of spontaneous miscarriages in the untreated cases.^{175,176} The rate of intrauterine growth restriction is higher among untreated patients.¹⁸⁰⁻¹⁸² Whether these outcomes imply causation or merely association is debatable. An epidemiologic study involving 1521 women with celiac disease suggested that fertility in these patients is similar to that for the general female population.¹⁸³ Although the researchers found somewhat higher miscarriage and cesarean section rates in the affected population, there was also a trend toward delayed childbearing, which may influence the statistics. It appears the negative effects of celiac disease, including miscarriage, is reduced by treatment with a gluten-free diet.¹⁶⁸

Pregnancy may unmask or reactivate celiac disease and should lead the obstetrician to evaluate signs such as anemia refractory to iron, hypokalemia, and hypocalcemia in the absence of clinical symptoms. The reason for worsening symptoms is unknown, but it is speculated to be the loss of borderline tolerance to gluten due to hormonal or endocrine mechanisms.¹⁷¹

Bariatric Surgery

Obesity has become an epidemic in the United States, with 18% of women meeting the criteria of a body mass index (BMI) of 30 kg/m².¹⁸⁴ The prevalence of morbid obesity, defined as a BMI exceeding 40 kg/m² or 35 kg/m² plus comorbidities, also is increasing. Pregnancy outcomes for these women are worse than those with a normal BMI.¹⁸⁵ Complications include gestational diabetes, hypertension, preeclampsia, macrosomia, and an increased cesarean section rate.

The 1991 National Institutes of Health Consensus Developmental Conference concluded that bariatric surgery is the most effective treatment for morbidly obese patients.¹⁸⁶ A consequence of the increased rate of obesity is the increased numbers of gastrointestinal operations performed for weight loss. The number of operations increased from 16,000 in the early 1990s to 103,000 in 2003.¹⁸⁷

Two types of procedures dominate the practice of bariatric surgery. One is diversionary, which constructs a proximal gastric pouch to an outlet of a Y-shaped limb of small bowel (i.e., Roux-en-Y procedure). Variants include biliopancreatic diversion and long limb gastric bypass, which are usually reserved for heavier patients.¹⁸⁸ The second type involves reducing the volume of the stomach and includes gastric banding. The former procedure results in more weight loss, but it is associated with nutritional deficiencies and the dumping syndrome. Because of the lack of functional proximal small bowel, patients can have iron, vitamin B₁₂, vitamin D, and folic acid deficiencies (Table 49-8). Parenteral replacement may be necessary if oral supplementation is not successful. After bariatric surgery, patients can have acute postgastric reduction surgery (APGARS) neuropathy. Prominent features include progressive vomiting, weakness, and hyporeflexia. This disorder overlaps with other syndromes caused by deficiencies of many nutrients.¹⁸⁹ Gastric banding, although less successful, minimizes the risk of deficiencies due to malabsorption.

Pregnancy outcomes in patients with prior bariatric surgery appear to be relatively good. Early case reports described complications, including gastrointestinal bleeding,¹⁹⁰ intrauterine growth restriction,¹⁹¹ and fetal anomalies.¹⁹² However, population-based studies suggest very acceptable outcomes. Sheiner and associates¹⁸¹ identified 298 deliveries complicated by an open or laparoscopic bariatric procedure. They found no differences between procedures, but compared with no prior bariatric surgery, there was a higher rate of labor inductions, fetal macrosomia, cesarean sections, and premature membrane rupture.¹⁸¹ Specifically addressing gastric bypass, Dao and colleagues¹⁹³ evaluated 2423 patients who underwent a Roux-en-Y procedure. Of these, 34 became pregnant, and 21 became pregnant within a year of the surgery. There were no significant differences with respect to outcome compared with those who became pregnant more than a year after surgery.¹⁹³

As the frequency of bariatric operations has increased, so has awareness of the complications of these procedures. Case reports of

↑, mild risk of deficiency; ↑↑, moderate risk of deficiency; ↑↑↑, significant risk of deficiency; ±, negligible risk.

internal hernias causing acute surgical emergencies, including intestinal infarction, have been published in the obstetric literature.^{194,195} Gastric ulcer perforation and gastrointestinal hemorrhage have also been reported.^{190,196} More common problems are the nutritional deficiencies that are associated primarily with gastric bypass. They include iron, vitamin B₁₂, folate, and calcium deficiencies (see Table 49-8).

Constipation

Constipation is defined as difficult defecation and infrequent bowel movements that do not result from an underlying cause.¹⁹⁷ The estimated incidence during pregnancy is between 10% and 40%, as derived from studies done 2 decades ago.^{198,199} The diagnosis is based on the patient's history, and the physician can use the Rome II criteria—12 weeks (not necessarily consecutive) in the prior 12 months when two of the following have occurred: straining, lumpy or hard stools, sensation of incomplete evacuation or anorectal obstruction or manual maneuvers to assist in more than 25% of defecations, and less than three bowel movements per week.²⁰⁰ Problems with adherence to the Rome criteria were highlighted in a study in which 40% to 50% of patients who fulfilled the criteria did not feel constipated.²⁰¹ Constipation can arise *de novo* during gestation or be a chronic condition that is exacerbated by pregnancy.

Factors contributing to constipation during pregnancy include iron supplementation, decreased activity, uterine enlargement, hemorrhoids, and hormonal factors, including increased progesterone and estrogen and decreased motilin levels.¹⁹⁹ In animal studies, progesterone decreases smooth muscle contractility and slows gastrointestinal transit.²⁰² Pregnant and ovariectomized rats given estrogen and progesterone had longer colonic transit compared with nonpregnant or ovariectomy control animals.¹⁶ Human studies of sex hormone effects have relied on orocecal transit times. In nonpregnant women, the transit time was significantly longer during the luteal phase, when progesterone levels are usually higher.¹³ A study involving seven women with intractable constipation and documented slow transit times who required colectomy were compared with six women requiring colectomy for adenocarcinoma. Progesterone receptors were

overexpressed in the patients with constipation. This overexpression was reproduced in normal colonic cells treated with progesterone.²⁰³ Plasma motilin levels are depressed during pregnancy but return to normal within 1 week after delivery.²⁰⁴ Although colonic transit times during pregnancy have not been studied, diaries of patients' symptoms have suggested increased problems with bowel movements in all three trimesters.¹⁹⁸ The causes and treatment of constipation appear to be similar to those for the general population.¹⁹⁹

Education should be the first-line treatment. Patients should be instructed to increase fluid and fiber intake, exercise, and attempt defecation in the morning or after meals, when colonic activity is the highest. Dietary habits should be explored. If needed, 2 to 6 tablespoons of bran should be added to each meal, followed by a glass of water. However, the laxative effect may take 3 to 5 days.¹⁹⁹ Psyllium, polycarbophil, and methylcellulose act by increasing fecal water content and decreasing stool transit time. Hyperosmolar laxatives such as polyethylene glycol, sorbitol, and lactulose are poorly absorbed and increase fecal water content. Because prolonged use may lead to electrolyte imbalances, they should be used with caution. Stimulant laxatives have a fast onset of action and may be considered in patients who fail to respond to bulk or osmotic agents.¹⁹⁹ Their short-term use is generally safe, but long-term use is not recommended. Tolerance, although uncommon in most users, can occur in patients with severe forms of slow colonic transit.²⁰⁵ A list of these agents is provided in Table 49-9.

Hemorrhoids

Hemorrhoids are common in adults.²⁰⁶ One third of pregnant women are symptomatic, and approximately 10% require treatment for hemorrhoids.²⁰⁷ Etiologic factors include constipation and straining at defecation, vascular engorgement from increased intra-abdominal pressure and blood volume, and the absence of valves in hemorrhoidal veins.¹⁹⁹ Internal hemorrhoids originate above the dentate line, and they are supplied by the superior hemorrhoidal plexus and covered with columnar epithelium. External hemorrhoids are below the dentate line, and they are supplied by the inferior hemorrhoidal plexus and covered with squamous epithelium.

TABLE 49-9 PREFERRED LAXATIVES IN PREGNANCY

Laxative	Usual Dose	Advantages	Disadvantages
Bulk forming		Long-term use in patients with uncomplicated constipation	Slow onset of action; risk of mechanical obstruction; unpleasant taste
Psyllium	7 g/day		Potential for anaphylaxis
Methylcellulose	4-6 g/day		
Hyperosmolar		Fast onset of action	Prolonged use may cause electrolyte imbalance; unsuitable for long-term use
Polyethylene glycol	8-25 g/day	Less abdominal bloating and flatulence than lactulose and sorbitol	
Lactulose	15-30 mL/day		Should be avoided in diabetics and those requiring a low-galactose diet; may exacerbate nausea
Sorbitol	15-30 mL/day	Less expensive than lactulose	
Glycerin	3-g suppository		
Stimulant		Fast onset of action.	Long-term use limited to 3 days per week
Bisacodyl	30 mg PO, 10 mg PR		More colic than with senna and cascara
Senna	17-34 mg		
Cascara	2-5 mL	Produces little or no colic	

External hemorrhoids infrequently require treatment unless complicated by thrombosis. For mild discomfort, conservative treatment includes stool softeners, sitz baths, and mild analgesics. If the pain is severe, surgical excision under local anesthesia can be performed during pregnancy.^{199,207} Clot incision with removal is less efficacious, mainly because of recurrent thrombosis.²⁰⁸ Internal hemorrhoids usually manifest as painless bleeding, although they can manifest with discomfort caused by prolapse or incarceration. Diagnosis may require anoscopy. Treatment usually is conservative and includes increased fiber and stool softeners. Local measures, including skin protectants and topical anesthetics, can improve symptoms. Patients with refractory symptoms may require band ligation, injection, sclerotherapy, or coagulation.¹⁹⁹ Rubber band ligation is effective for internal hemorrhoids that are reducibly prolapsed. Sclerotherapy using 5% phenol is safe in pregnancy, and infrared photocoagulation and laser coagulation for first- and second-degree hemorrhoids are theoretically safe.²⁰⁷ Surgical hemorrhoidectomy is reserved for internal hemorrhoids that prolapse and incarcerate or that have failed conservative office measures.¹⁹⁹

Gastrointestinal Endoscopy in Pregnancy

Upper Gastrointestinal Endoscopy and Colonoscopy

Upper gastrointestinal endoscopy (i.e., esophagogastroduodenoscopy [EGD]) and colonoscopy play vital roles in the diagnosis and treatment of a variety of gastrointestinal disorders. Few pregnant patients with gastrointestinal disorders need gastrointestinal endoscopy, but if they do, the main risks are related to the endoscopy itself (e.g., perforation, bleeding, infection) and complications of sedation (e.g., cardiovascular events, pulmonary aspiration, teratogenic risks of medications). Results from several small studies suggest that careful upper endoscopy and colonoscopy are safe during pregnancy.^{93,209-213}

The American Society for Gastrointestinal Endoscopy (ASGE), with input from the American College of Obstetricians and Gynecologists (ACOG) Committee on Obstetric Practice, has published guidelines related to endoscopy in pregnant women.²¹⁴ They have developed general indications for endoscopy in pregnancy (Table 49-10).

Sedation for the procedure poses the greatest risk to the fetus, and consideration should be given in these cases to having anesthesiology supervision. Gastroenterologists usually perform upper endoscopy and colonoscopy on adults using moderate sedation. The drugs commonly

TABLE 49-10 INDICATIONS FOR ENDOSCOPY IN PREGNANCY

<p>Significant or ongoing gastrointestinal bleeding Severe or refractory nausea and vomiting or abdominal pain Dysphagia or odynophagia Strong suspicion of a mass in the upper gastrointestinal tract or colon Severe diarrhea with negative result for noninvasive evaluation Cholelithiasis or cholangitis Biliary or pancreatic duct injury</p>

Adapted from Qureshi WA, Rajan E, Adler DG, et al: ASGE guidelines for endoscopy in pregnant and lactating women. *Gastrointest Endosc* 61:357-362, 2005.

used for gastrointestinal endoscopy sedation, and their FDA category regarding safety during pregnancy, are as follows: meperidine (B), fentanyl (C), naloxone (B), benzodiazepines (D), flumazenil (C), propofol (B), simethicone (C), glucagon (B), and polyethylene glycol (C).

Regarding patient positioning, it is recommended that the patient not lie on her back in the second and third trimesters because the pregnant uterus compresses the aorta and inferior vena cava, causing maternal hypotension and decreasing placental perfusion. Because most procedures are done with the patient in the left lateral position, this is usually not an issue.

Endoscopic Ultrasound

The endoscopic ultrasound (EUS) technique uses an ultrasound probe that is incorporated into the tip of the endoscope. This allows ultrasound imaging from within the luminal gastrointestinal tract. This technique is commonly used to stage gastrointestinal malignancy and to evaluate pancreatic lesions. EUS is used during pregnancy only to look for stones in the common bile duct because it is more sensitive than MRI, CT, or ultrasound and much safer than endoscopic retrograde cholangiopancreatography because of the lack of radiation and no risk of pancreatitis.

Small Bowel Wireless Capsule Endoscopy

The small intestine had been unreachable with the standard endoscopic techniques of EGD and colonoscopy. Wireless capsule endoscopy can visualize the entire small intestine. The procedure involves swallowing a miniaturized camera that has been placed in a large pill. Images are sent back to an external recording device for a total of 8 hours of video as the pill camera moves by peristalsis through the small intestine. It would be unusual to have a pregnant woman swallow a pill camera, unless there was unexplained severe or recurrent gastrointestinal bleeding.²¹⁵ The safety and efficacy of wireless capsule endoscopy of the small bowel has not been tested in humans, and pregnancy therefore is considered a relative contraindication to capsule endoscopy.²¹⁶

Double-Balloon Enteroscopy

A technique using a scope with a balloon on the tip and an overtube with a balloon on the distal end is used to advance a thin endoscope from the mouth into the mid-ileum. Double-balloon enteroscopy allows the endoscopist for the first time to gain access to the middle of the small intestine to obtain biopsies or to perform therapeutic maneuvers. Because this is a time-intensive procedure with a large amount of pushing and stretching in the abdomen, it would rarely be considered for use during pregnancy.

Chapter 50

Diseases of the Liver, Biliary System, and Pancreas

Catherine Williamson, MD, and Lucy Mackillop, BM BCh, MA

Liver disorders may be unique to or commonly associated with pregnancy. Liver disease may precede or develop *de novo* during pregnancy. Some of these disorders are so uncommon that even an experienced maternal-fetal medicine specialist may rarely encounter them. In this chapter, we review preexisting liver conditions and those that are primarily associated with pregnancy.

Liver Function in Normal Pregnancy

There is no evidence that enlargement of the liver occurs during human gestation. Hepatomegaly should be considered a potential pathologic finding, signifying the need to determine whether underlying liver disease exists. The liver is frequently elevated superiorly, especially in the third trimester as a result of the expanding uterus. There is little evidence that the liver undergoes any major histologic changes during pregnancy. Hepatic blood flow remains constant in pregnancy (i.e., 25% to 33% of cardiac output).

Major changes occur in the serum concentration of plasma proteins during gestation, and these alterations may persist for a few months after delivery. Total serum protein concentration decreases largely because of a 20% to 40% decrease in serum albumin concentration. Some of this may be explained by hemodilution secondary to the increase in total plasma volume associated with pregnancy. Maher and colleagues¹ suggested a reciprocal relationship between rising levels of α -fetoprotein and the decline in serum albumin concentration.

Fibrinogen biosynthesis and manufacture of other coagulation factors (i.e., VII, VIII, IX, and X) are increased in pregnancy and with estrogen administration. Estrogens increase hepatic rough endoplasmic reticulum and accelerate synthesis of proteins. Increased amounts of progesterone lead to proliferation of smooth endoplasmic reticulum and an increase in cytochrome P450 isoenzyme levels. The serum levels of other proteins, such as ceruloplasmin and transferrin, also increase with gestation. The concentrations of specific binding proteins, such as thyroxine-binding globulin (TBG) and corticosteroid-binding globulin (CBG), increase in normal pregnancy, which affects the concentration of the bound portion of these hormones.

A prospective, cross-sectional study of 430 women at a single center was carried out to determine the reference ranges for liver function test in uncomplicated pregnancies.² The study confirmed that there is a decrease in the upper limit of aspartate transaminase (AST), alanine transaminase (ALT), and γ -glutamyl transferase (GGT) in normal pregnancy (Table 50-1). The investigators² also demonstrated a decrease in bilirubin concentration, but this finding has not been demonstrated in other studies.³

Total serum alkaline phosphatase (ALP), largely because of placental production, increases dramatically during pregnancy. It may be two to four times baseline by the third trimester, but it returns to normal levels within a few weeks after delivery. Occasionally, the ALP concentration may increase to more than 1000 U/L, and although this is invariably of placental origin, isoenzyme testing may be requested to exclude ALP from liver or bone. Most articles concerning plasma lipids in pregnancy agree that total cholesterol and triglycerides are increased during pregnancy.

Liver function test results change significantly in the puerperium (Table 50-2) and are affected by common obstetric events, such as cesarean section.⁴ This can be a confounding factor in clinical interpretation of women recovering from liver-related illnesses after delivery.

Diagnosis of Liver Disease

Hepatomegaly may signify infiltrative disease (e.g., acute fatty liver of pregnancy [AFLP]), an inflammatory condition (e.g., hepatitis), passive congestion (e.g., right-sided heart failure), Budd-Chiari syndrome, or rarely, a malignancy.

Dermatologic findings of chronic liver disease and acute liver failure, such as palmar erythema and spider nevi, are often found in normal pregnancy. Jaundice and scleral icterus are abnormal findings and warrant further evaluation. Causes of jaundice not related to pregnancy are summarized in Table 50-3, with interpretation of serum and urine bilirubin test results.

Imaging of the liver may be required during pregnancy. Ultrasound remains the primary imaging tool because of its safety record in pregnancy, but it may have limited value in assessing liver architecture. Computed tomography (CT) and endoscopic retrograde cholangiopancreatography (ERCP) can also be used during pregnancy. However, precautions should be taken to shield the fetus from radiation or to provide dosimetry estimates if significant exposure is likely. Magnetic

TABLE 50-1 LIVER FUNCTION TEST RESULTS IN NORMAL PREGNANCY

Test	Not Pregnant	First Trimester	Second Trimester	Third Trimester
AST (IU/L)	7-40	10-28	11-29	11-30
ALT (IU/L)	0-40	6-32	6-32	6-32
Bili ($\mu\text{mol/L}$)	0-17	4-16	3-13	3-14
GGT (IU/L)	11-50	5-37	5-43	5-41
Alk phos (IU/L)	30-130	32-100	43-135	130-418

Alk phos, alkaline phosphatase; ALT, alanine transaminase; AST, aspartate transaminase; Bili, bilirubin; GGT, gamma-glutamyl transferase.

Adapted from Girling JC, Dow E, Smith JH: Liver function tests in pre-eclampsia: Importance of comparison with a reference range derived for normal pregnancy. *BJOG* 104:246-250, 1997.

TABLE 50-2 LIVER FUNCTION TEST RESULTS AFTER DELIVERY IN NORMAL PREGNANCY

Test	Postnatal Peak (day)	Mean Increase (%)	Range of Increase (%)
AST	2-5	88	0-500
ALT	5	147	0-1140
GGT	5-10	62	0-450
Alk phos	Before delivery	—	—

Alk phos, alkaline phosphatase; ALT, alanine transaminase; AST, aspartate transaminase; GGT, gamma-glutamyl transferase.

Adapted from David AL, Kotecha M, Girling JC: Factors influencing postnatal liver function tests. *BJOG* 107:1421-1426, 2000.

TABLE 50-3 SERUM AND URINE FINDINGS USED TO DETERMINE THE CAUSE OF JAUNDICE

Cause of Jaundice	Serum Bilirubin		Urine Bilirubin	
	Unconjugated	Conjugated	Bilirubin	Urobilinogen
Hemolysis	↑	N	A	↑
Gilbert syndrome	↑↑	N	A	N/↓
Crigler-Najjar syndrome	↑↑↑	N	A	N/↓
Hepatocellular carcinoma	↑	↑	P	↑/↓/N
Hepatocanalicular injury	↑	↑	P	↑/↓/N
Extrahepatic disorders	N	↑	P	↓/N

A, absent; N, normal; P, present; ↑, increased; ↓, decreased.

resonance imaging (MRI) has the advantage of no radiation exposure, and it has an established safety profile in pregnancy.

Rarely, histologic diagnosis may be essential to management of a pregnant woman, such as when AFLP is being considered in the differential diagnosis and the biopsy is likely to influence the decision to proceed with delivery. The procedure remains safe in expert hands if coagulation parameters are within normal limits.

Liver Disorders Unique to Pregnancy

Intrahepatic Cholestasis of Pregnancy

Epidemiology

Intrahepatic cholestasis of pregnancy (ICP) affects 0.7% of white pregnant women,⁵ approximately twice as many South Asian women,⁵ and up to 5% of Chilean women.⁶ The geographic variation in prevalence of the condition is likely to be explained by genetic and environmental influences, particularly because ICP is seen less frequently in Chile and Scandinavia than it was in the past.^{6,7} ICP occurs more frequently in winter months.^{7,8} The reasons for these epidemiologic fluctuations is not clear, but they indicate that environmental factors must

play a role in the cause of ICP. There have been reports of ICP occurring more commonly in women with multiple gestation⁹ and in women older than 35 years.¹⁰ The recurrence rate of ICP varies from 60% to 90% in different populations.⁶

Pathogenesis

The cause of ICP is complex, with genetic, endocrine, and environmental factors playing roles. Evidence for a genetic origin includes the demonstration that parous sisters of affected women have a 20-fold increased risk of developing ICP.¹¹ This idea is further supported by pedigree studies^{12,13} and the demonstration of genetic variation in biliary bile acid receptors and transporters. A few women with ICP have relatively highly penetrant heterozygous mutations in biliary transporters that result in abnormal biliary transport and accumulation of bile acids, which produces a clinical picture of cholestasis. Mutations have been reported in the *ABCB4* and *ATP8B1* genes that encode phospholipid transporters,¹⁴⁻¹⁶ the *ABCB11* gene that encodes the principal bile salt transporter,¹⁷ and the primary hepatic bile acid receptor.¹⁸ Women who carry these mutations do not usually have symptoms when they are not pregnant, but they develop cholestasis in pregnancy.

Evidence that elevated levels of reproductive hormones cause susceptible women to develop cholestasis includes the increased prevalence of ICP in multiple pregnancy⁹ and the recurrence of cholestatic symptoms when women who previously had ICP are given exogenous

estrogens or the oral contraceptive (OC) pill.^{13,19} Progestogens may also play a role; 34 (68%) of 50 women in a French prospective series of OC cases had been treated with oral micronized natural progesterone for risk of premature delivery.²⁰

Other environmental factors may influence susceptibility to ICP. Women with hepatitis C infection develop cholestasis more commonly than other pregnant women.²¹ Plasma selenium levels were significantly reduced in pregnant women on OCs compared with controls in Finnish²² and Chilean studies,²³ and it has been proposed that selenium deficiency in women on OCs may contribute to estrogen-induced oxidation damage to hepatocytes.²³ The Chilean study demonstrated that plasma selenium levels have increased in nonpregnant individuals since the 1980s, and the investigators suggested that this may partly explain the reduction in the prevalence of ICP among women on OCs in Chile since then.²³

The pathogenesis of the symptom of pruritus in ICP is not fully understood. Treatments that have some efficacy in treating cholestasis-related pruritus in nonpregnant patients include anion exchange resins, rifampicin, opiate antagonists, ondansetron, and phototherapy.²⁴

Fetal complications that occur more commonly in ICP pregnancies include preterm labor, fetal asphyxial events, meconium staining of amniotic fluid, and intrauterine death. Three studies have demonstrated that ICP patients with higher maternal serum bile acid levels (>40 $\mu\text{mol/L}$ in two studies) more commonly have pregnancies complicated by meconium-stained liquor and fetal asphyxial events,²⁵⁻²⁷ and the largest study also demonstrated that patients with higher levels of bile acids had higher rates of spontaneous preterm labor.²⁷

The likely pathogenesis of the fetal complications of ICP is related to increased levels of fetal serum bile acids, but the precise mechanisms are not understood. Most stillborn infants are of appropriate weight and have no evidence of uteroplacental insufficiency.^{28,29} The evidence suggests that the intrauterine death is a sudden event. Studies have shown an abnormal fetal heart rate^{26,30} or arrhythmia³¹ in pregnancies complicated by ICP, and in vitro studies of neonatal heart cells indicate that they are susceptible to bile acid-induced arrhythmia.³² The increased frequency of preterm labor may be a consequence of bile acid-induced release of prostaglandins, which may initiate labor.³³ The increased rates of meconium-stained liquor^{27,28,30,34} may be related to fetal distress caused by the toxic effects of bile acids or may be a consequence of bile acids stimulating gut motility.³⁵

Diagnosis

ICP should be suspected in pregnant women with pruritus but without a rash. The pruritus is commonly generalized or affects the palms and soles, but it can occur on any part of the body. There is no consensus about the most reliable biochemical test for diagnosing ICP. We recommend measuring levels of liver transaminases and serum bile acids. Because some patients have elevated transaminase levels several weeks before the levels of bile acids are increased, this is a useful screening test. However, there are also cases of ICP with elevated concentrations of serum bile acids and normal levels of liver transaminases. It is therefore advisable to test both.

Cholestasis may also occur in conjunction with other liver diseases. It is advisable to perform a liver ultrasound scan to exclude biliary obstruction. Affected women commonly have gallstones, and this is partly explained by a genetic cause, because some of the genes implicated in ICP are also mutated in pedigrees with familial gallstones.³⁶ However, the gallstones are unlikely to be the cause of the cholestasis unless the woman has symptoms of biliary obstruction. Other conditions that can be associated with ICP are hepatitis C, autoimmune hepatitis, and primary biliary cirrhosis. These conditions have impor-

tant implications for the subsequent health of the mother, and it is therefore advisable to screen for them.

Management

MATERNAL DISEASE

Ursodeoxycholic acid (UDCA) is the only drug that has consistently been shown to improve the maternal symptoms and biochemical features of ICP. There have been several reports about the efficacy of UDCA in ICP,^{37,38} but there have been few randomized, controlled trials. The largest trial showed that UDCA reduced levels of pruritus, liver transaminases, and bilirubin compared with dexamethasone or placebo and that it was particularly effective in women with serum levels of bile acids higher than 40 $\mu\text{mol/L}$.³⁹ UDCA is usually started at a dose of 500 mg twice daily, and the dose may be increased further.

A variety of other drugs have been proposed as treatments for ICP, including dexamethasone, *S*-adenosyl methionine, cholestyramine, and guar gum, but there is less evidence for their efficacy than there is for UDCA.³⁷ Aqueous cream with menthol may improve the symptoms of ICP, although it does not affect the disease process. It is advisable to give affected women vitamin K because of the theoretical risk of hemorrhage in association with ICP.

FETAL CONCERNS

No treatments have been shown to reduce fetal risks associated with ICP. However, it is likely that treatments that reduce levels of maternal bile acids also reduce fetal risk because of the data that implicate bile acids in pregnancies complicated by spontaneous preterm delivery, fetal asphyxial events, and meconium-stained amniotic fluid.²⁵⁻²⁷ None of the UDCA trials has been powered to investigate whether the drug protects the fetus. However, it is known that UDCA treatment improves the serum bile acid levels measured in cord blood and amniotic fluid at the time of delivery.⁴⁰ In vitro studies have shown that maternal cholestasis causes impairment of placental bile acid transfer and that this is restored to normal in the placentas of women treated with UDCA.⁴¹ Studies of neonatal rat cardiomyocytes have also shown that pre-incubation of cells in culture medium containing UDCA or dexamethasone protects networks of contracting cells from the arrhythmogenic effect of bile acids.⁴²

The only forms of fetal surveillance that have been shown to predict which fetuses may be at risk are amniocentesis²⁸ and amnioscopy⁴³ for meconium. However, such an approach is likely to be considered too intrusive to be used routinely by most obstetricians. Many obstetric units review women with ICP several times per week for fetal assessment by electronic fetal monitoring and/or biophysical profile, or both. Although there is no guarantee that this approach can prevent subsequent fetal complications, there are a few reports of abnormal electronic fetal monitoring traces having been identified and emergency cesarean section performed as a consequence. Many women with ICP find this strategy reassuring.

Prevention

The recurrence rate of ICP varies from 40% to 90%.⁶ It is not possible to prevent the condition in predisposed women, although it is possible to screen for biochemical abnormalities before symptoms occur. If a woman with a history of ICP requires antibiotics, it is advisable to avoid drugs that more commonly cause cholestasis in susceptible individuals, such as erythromycin, flucloxacillin, and amoxicillin with clavulanic acid. Women with a history of ICP should be advised to use hormonal contraception with care, because there is a 10% chance of developing pruritus or hepatic impairment, or both.¹⁹

Overlap Syndromes with Liver Dysfunction

Preeclampsia, HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*), AFLP, and liver rupture are separate but similar conditions that usually occur during the third trimester and after delivery. They are often characterized by hypertension, elevated levels of liver enzymes, and thrombocytopenia, and resolution usually follows delivery (see Chapter 35). In some cases, however, there may be progressive disease with multisystem organ failure and possibly maternal death. HELLP syndrome is most often a variant of severe preeclampsia because hypertension and proteinuria are generally accompanying features. There is also overlap between AFLP and preeclampsia, which is present in approximately 50% of patients of AFLP.^{44,45} It is essential for the clinician to differentiate the overlap syndromes from unrelated conditions, which do not improve after delivery. A multidisciplinary team approach consisting of maternal-fetal medicine and liver specialists is recommended to guide therapy.

Fatty Acid Oxidation Pathways

Disorders of fatty acid β -oxidation play a role in the cause of AFLP, the HELLP syndrome, and preeclampsia. Fatty acids are a major metabolic fuel for humans. In the presence of oxygen, fatty acids are catabolized to carbon dioxide and water, and approximately 40% of the free energy produced in this process is conserved as adenosine triphosphate (ATP). The remainder of the energy is released as heat, a process that occurs in the mitochondria by β -oxidation. This enzymatic process is particularly important for the provision of energy when glycogen stores are depleted. It consists of many transport processes and four enzymic reactions that cause two-carbon fragments to be successively removed from the carboxyl end of the fatty acid, which has been described in detail by Ibdah.⁴⁶

An enzyme that plays a central role in this pathway is long-chain 3-hydroxyacyl-coenzyme A dehydrogenase (LCHAD). It is part of an enzyme complex, the mitochondrial trifunctional protein (MTP), which is located on the inner mitochondrial membrane. In LCHAD deficiency, there is accumulation of long-chain hydroxyl-acylcarnitines, free plasma hydroxyl-long-chain fatty acids, and dicarboxylic acids, which results in cell toxicity. MTP defects are autosomal recessive conditions that cause nonketotic hypoglycemia and hepatic encephalopathy in early infancy and that may progress to coma and death if untreated. They also can cause cardiomyopathy, peripheral neuropathy, myopathy, and sudden death, although the latter clinical features are not characteristically seen in isolated LCHAD deficiency. It is important to diagnose MTP disorders because the clinical complications can be avoided with dietary manipulation.

Several case series have demonstrated an increased prevalence of AFLP and, to a lesser extent, HELLP syndrome and severe preeclampsia among heterozygous mothers of children that are homozygous for LCHAD deficiency.⁴⁶⁻⁴⁸ A subsequent study of 27 pregnancies complicated by AFLP demonstrated that 5 had fetuses with MTP mutations and that at least one copy of the common E474Q mutation was present in each case.⁴⁹ The study authors recommended that the neonates of women whose pregnancies are complicated by AFLP should be screened for MTP disorders or for the E474Q mutation. Several studies of pregnancies complicated by HELLP syndrome have not demonstrated that MTP disorders are common in the fetuses,⁴⁹⁻⁵¹ and therefore screening of these offspring is not recommended.

Maternal liver disease also occurs in pregnancies in which the fetus is affected by a spectrum of fatty acid oxidation disorders, including short-chain and medium-chain defects.⁵² In a case-control series of 50 infants from pregnancies complicated by severe maternal liver disease, including AFLP and HELLP syndrome, long-chain defects were 50 times more common in cases than controls, and short-chain and medium-chain defects were 12 times more likely to occur.⁵²

Acute Fatty Liver of Pregnancy

Epidemiology

AFLP is a rare, potentially life-threatening, pregnancy-related disease that affects 1 in 7000 to 16,000 pregnancies.^{53,54} The condition occurs more commonly in primigravidas, multiple pregnancy, and pregnancies carrying a male fetus.^{45,53} In two case series of 32 and 16 affected women admitted to tertiary centers, the maternal mortality rate was 12.5%.^{44,45} However, there were no maternal deaths in two other series of 11 and 28 consecutive patients seen in a district hospital in Chile and the United States, respectively.^{53,54} Perinatal mortality rates are reported as approximately 10% in the latest series,^{44,45,54} although they were higher in another series,⁵² and the investigators proposed that this was principally as a consequence of premature delivery.

Pathogenesis

The pathogenesis of AFLP is not well understood. It is clear from the studies described previously above that fatty acid oxidation disorders contribute to approximately 20% of cases.⁴⁹ In these cases, it is likely that the heterozygous mother has a reduced hepatic capacity to metabolize long-chain fatty acids. Although there is sufficient capacity in the nonpregnant state, when a heterozygous woman becomes pregnant, her liver is required to metabolize fatty acids from the fetoplacental unit in addition to her own. This increased metabolite load likely results in hepatotoxicity. This may be further compounded by the alternations in lipid metabolism that occur in normal pregnancy.

Diagnosis

AFLP typically manifests in the third trimester with symptoms of nausea, malaise, and anorexia. Later symptoms include vomiting and abdominal pain. Polydipsia and polyuria may also occur.^{7,55} Liver function tests should be requested for any pregnant woman reporting these symptoms because quick diagnosis of an acute fatty liver allows stabilization of the patient and rapid delivery.

It is often difficult to differentiate AFLP from HELLP syndrome. Patients with AFLP more commonly have high levels of bilirubin, creatinine, uric acid, and neutrophils; a prolonged prothrombin time; acidosis; and hypoglycemia. Patients frequently have disseminated intravascular coagulation. Although levels of liver transaminases can be markedly increased, they can also be barely higher than normal. The level of ALT or AST should not be taken as a marker of severity of disease, because hepatocytes cannot release transaminases if they have been destroyed by severe injury. Typical biochemical features of AFLP are summarized in Table 50-4.

Imaging modalities that have been used to diagnose AFLP include liver ultrasound, MRI, and CT. A study that compared the three techniques found that CT was the best modality for demonstrating fat in the liver.⁵⁶ However, CT was successful in only 50% of cases. Liver biopsy may be used to obtain a definitive diagnosis using an oil red O stain or electron microscopy. However, this is not always practical, particularly if there is a coagulopathy and rapid delivery is required.

TABLE 50-4 BIOCHEMICAL FEATURES OF ACUTE FATTY LIVER OF PREGNANCY

Biochemical Feature*	Average at Diagnosis	Range at Diagnosis	Peak or Nadir
AST (<32 IU/L)	523	120-2317	692
ALT (<32 IU/L)	423	43-1504	493
BR (3-22 µmol/L)	99.18	15-203	180
LDH (<250 IU/L)	1483	244-3992	1709
Glucose (3.9-5.8 mmol/L)	4.5	0.6-8.7	3.1
Creatinine (µmol/L)	212.2	44-389	4950
Platelets (×10 ³)	88	33-303	88

*Parenthetical values are average normal values in pregnancy.

ALT, alanine transaminase; AST, aspartate transaminase; BR, bilirubin; LDH, lactate dehydrogenase.

Modified from Fesenmeier MF, Coppage KH, Lambers DS, et al: Acute fatty liver of pregnancy in 3 tertiary care centers. *Am J Obstet Gynecol* 192:1416-1419, 2005.

There may be a different underlying diagnosis in some women who present with AFLP. In a series of 32 patients seen in a tertiary referral unit in London, 6 had an additional diagnosis. Two patients had malignancy, one had alcohol-induced fatty liver, another had veno-occlusive disease with antiphospholipid syndrome, and another had acute viral hepatitis A infection.⁴⁴ Poisoning with acetaminophen can cause a clinical presentation that is hard to distinguish from AFLP.

Management

Women with AFLP should be managed by a multidisciplinary team that includes obstetricians, hepatologists, anesthesiologists, obstetric physicians, neonatologists, and intensivists. The mother should be cared for in an intensive care setting. Blood should be taken every 6 hours to ensure that biochemical and hematologic abnormalities are diagnosed and corrected. It is essential to monitor the prothrombin time and other markers of coagulopathy, plasma glucose, platelets, creatinine, liver function test results, and arterial blood gases. Fresh-frozen plasma should be given as required. Women often require large amounts of glucose intravenously to correct hypoglycemia. If multisystem failure develops, it may be necessary to use dialysis and ventilation. *N*-Acetylcysteine is often used by liver units to treat AFLP, and we advocate its use.

Women with AFLP should be assessed regularly for encephalopathy. Mild encephalopathy manifests with confusion, fetor hepaticus (i.e., unpleasant breath), and asterixis (i.e., liver flap). A more objective assessment can be performed by asking women to draw a five-pointed star or a clock face. It is advisable to discuss patients who have AFLP with a liver unit specialist at the time of presentation for advice on the detailed management of fulminant liver failure and because assessment of suitability for orthotopic liver transplantation may be necessary.

The most important management strategy is delivery of the infant. The decision about the mode of delivery is often complex because the mother is likely to have a coagulopathy. Although vaginal delivery reduces the risk of hemorrhage, induction of labor often takes longer, and prompt delivery can improve the maternal outcome. Regional anesthesia should be avoided or used with caution and in conjunction with close monitoring. Blood tests should be performed frequently to ensure that coagulopathy is rapidly corrected in the days after delivery. In a series of 28 cases from a U.S. referral center, many of the patients

who had operative delivery subsequently had wound separation, which was thought to be related to coagulopathy.⁵⁴

Prevention

AFLP does not commonly recur in subsequent pregnancies, although there are recurrent cases reported in the literature. In women who are heterozygous for disorders of fatty acid oxidation, it may be possible to establish whether the fetus is affected, and this can indicate the magnitude of the mother's risk. If she is carrying a fetus that is homozygous for the disease, she will have a greater chance of recurrence. For heterozygous mothers who do not have affected fetuses and for others who do not have a fatty acid oxidation disorder, the recurrence risk is lower. However, the disease has potentially disastrous consequences, and women who have had one affected pregnancy should be managed in an obstetric clinic specializing in high-risk pregnancies. One case series found elevated antithrombin and creatinine levels in women with AFLP several weeks before the onset of clinical symptoms.⁵⁴ It can be helpful to monitor the levels of these markers in a subsequent pregnancy of a woman who previously had AFLP.

Preeclampsia and HELLP Syndrome

Liver involvement often signifies the development of severe preeclampsia. Elevation of liver enzyme levels may also occur as an isolated laboratory abnormality or as a component of the HELLP syndrome. Although severe hypertension may be absent in women with HELLP syndrome, in most instances, there is some degree of accompanying hypertension that helps to differentiate this disorder from other diseases. Although there may be overlap between HELLP syndrome and AFLP, isolated serum transaminase elevations in severe preeclampsia rarely exceed 500 U/L. Elevated serum bilirubin levels occur in women with the HELLP syndrome, partly as a consequence of liver damage and partly in response to hemolysis, but bilirubin levels usually are higher in AFLP. Hepatic failure with encephalopathy and coagulopathy are uncommon in preeclampsia and should prompt consideration of a different diagnosis, including fatty liver and other causes of hepatic dysfunction.

Hepatic involvement occurs in approximately 10% of women with severe preeclampsia.⁵⁷ Most of these women have only liver enzyme elevations and no epigastric pain. The development of right upper quadrant pain usually signifies liver involvement, and liver function tests should be promptly obtained in this setting. Because the pain likely results from hepatic ischemia, the increased transaminase levels may occur several hours after the onset of pain in a manner similar to cardiac enzymes after a myocardial infarction. Histologic descriptions of hepatic involvement in preeclampsia include periportal hemorrhage, sinusoidal fibrin deposition, and cellular necrosis.⁵⁸ The pathophysiologic basis of these findings is likely to include ischemia, although hepatic blood flow primarily depends on the portal venous system.

Women with preeclampsia and liver involvement usually should undergo delivery, although administration of steroids first to promote fetal lung maturity can be undertaken in preterm cases when the maternal condition is otherwise stable. Laboratory abnormalities generally improve within 5 days after delivery, although they may become worse before they resolve. Because HELLP syndrome may develop during the postpartum period in 20% of cases, liver function testing and imaging should be undertaken if abdominal pain, thrombocytopenia, or other clinical features suggesting preeclampsia occur after delivery.

Liver Rupture and Infarction

Epidemiology

Rupture of the liver during pregnancy is a rare but often catastrophic event, with substantial risk for fetal and maternal death.⁵⁹ More than 95% of cases during pregnancy involve severe preeclampsia and HELLP syndrome.^{44,60} However, liver rupture occurs only in a small proportion of women with preeclampsia. For example, in one series, subcapsular liver hematoma was reported in approximately 1% (4 of 442) of women with HELLP syndrome.⁶¹ Hepatic hematoma and rupture may also occur after uncomplicated pregnancy^{62,63} or in association with biliary disease, infection, aneurysm, and hepatic neoplasm.⁶⁴

Pathogenesis

Although the pathogenesis of hepatic rupture remains unclear, subcapsular hemorrhage is a common finding at autopsy in cases of maternal preeclampsia. The right lobe of the liver is affected more commonly than the left. As major hemorrhage might have occurred by the time the patient is seen, there may be minimal or no hypertension. Subcapsular hemorrhage produces stretching of the liver capsule, and significant right upper quadrant pain can result from the distention. If stretching is expanded, rupture will occur. The resultant hemoperitoneum produces peritoneal signs and probable hypovolemic shock.

Diagnosis

Hepatic rupture most often occurs in the setting of HELLP syndrome, and the most common presenting symptoms are right upper quadrant pain, hypertension, and shock. Hypertension may not be present at the time of diagnosis because of hypovolemia, and it may become obvious only after fluid resuscitation. Symptoms that may occur include nausea, vomiting, shoulder pain, and headache.⁶⁰ Diagnostic imaging is required to establish a diagnosis.⁶⁵ Bedside ultrasonography often demonstrates hemoperitoneum. However, CT or MRI is the preferred technique for visualizing liver hematomas. Imaging is critical before consideration of liver biopsy if the diagnosis is unclear, because liver biopsy is contraindicated for patients with suspected subcapsular hemorrhage. To confirm the presence of intraperitoneal bleeding, paracentesis may occasionally be helpful.

Laboratory evaluation of women with subcapsular hematoma or rupture reveals thrombocytopenia, hypofibrinogenemia, or prolonged prothrombin and partial thromboplastin times. Anemia and hemolysis are present, and levels of bilirubin, lactate dehydrogenase, and liver transaminases are elevated. The differential diagnosis for unruptured liver hematoma includes AFLP, placental abruption with coagulopathy, thrombotic thrombocytopenic purpura, and cholangitis with sepsis.

Management

Conservative management is recommended for an intact hematoma without rupture, particularly if the patient is hemodynamically stable.⁶⁵ It is necessary to closely follow these patients in an intensive care setting, with serial imaging studies to define the extent of the subcapsular hemorrhage, its progression, and whether leaking has occurred. Sudden increases in intra-abdominal pressure from coughing or emesis should be avoided, and palpation of the liver should be kept to a minimum.

Management options for hepatic rupture include hepatic resection, hepatic artery ligation, embolization of the hepatic artery and exploration with digital compression of the hepatic artery and portal vein to temporarily arrest the hemorrhage (i.e., Pringle maneuver), and evacu-

ation of hematoma and temporary packing with gauze swabs. When faced with a woman with hepatic rupture, it is likely that surgical exploration by a team skilled in the management of liver trauma will be used to make the diagnosis and for treatment. Fluid replacement, multiple transfusions, and correction of coagulopathy are necessary components in conjunction with an attempt to control the hepatic bleeding. In a patient who is relatively stable, angiography may be attempted while making preparations for potential laparotomy.

Maternal and fetal mortality rates may approach 50% in cases of liver rupture. In a series of seven cases, the four survivors were managed with packing and drainage.⁵⁹ The three women undergoing hepatic lobectomy did not survive. In another series of 10 patients, 9 were treated surgically with a combination of stitching of the lesion, omental patching, hepatic artery embolization, and ligation. The 10th patient was dead on arrival at the hospital. Five patients were treated with hepatic artery ligation, and all survived.⁶⁶ An analysis of all cases in the English language literature from 1960 to 1997 showed an improvement in maternal mortality over time.⁶⁰ This study compared management strategies for 141 cases.⁶⁰ However, because of the retrospective nature of the study, it was not possible to conclude which treatment modality was most effective. In many cases, the diagnosis was made at laparotomy, and this group of patients had a high survival rate that might have been related to the aggressive surgical approach. However, the group that received arterial embolization, whether it was performed with or without a laparotomy, also had a better prognosis than other groups.

Death is often caused by massive blood loss and coagulopathy. Patients who survive commonly experience respiratory insufficiency from adult respiratory distress syndrome or pulmonary edema and acute liver failure. Critical care of fluid and respiratory status monitoring (see Chapter 57) are essential, as is ongoing hepatic imaging to be certain that stabilization has occurred.

Liver Infarction

Infarction involving many areas of liver parenchyma may be a feature of severe preeclampsia or HELLP syndrome.⁶⁷ Presenting signs usually include abdominal pain and frequently fever. Thrombocytopenia is common, and transaminase levels are frequently very high. CT demonstrates clearly demarcated areas of poor vascularization involving many liver segments. Biopsy of these areas demonstrates hemorrhage and leukocyte infiltration in areas adjacent to hemorrhage. In the setting of HELLP syndrome, many adjacent areas of periportal hemorrhage most likely form these infarcted segments. Improvement after delivery can be expected, even in face of laboratory evidence of severe liver inflammation.

Maternal Disorders Coincidental to Pregnancy

Viral Hepatitis

Viral hepatitis is the most common cause of jaundice during pregnancy.⁶⁸ There are six primary subtypes of hepatitis virus: A, B, C, D, E, and G (Table 50-5). The incubation periods vary, and clinical features of acute infection may overlap. The diagnosis ultimately requires specific serologic markers for acute and chronic infection (Tables 50-6 and 50-7; see Table 50-5). The clinical implications of each virus for maternal and fetal or neonatal health vary considerably.

TABLE 50-5 COMPARISON OF VARIOUS FORMS OF VIRAL HEPATITIS

Feature	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Viral type	RNA	DNA	RNA	RNA	RNA
Incubation period	14-50 days	30-180 days	30-160 days	30-180 days	14-63 days
Transmission	Fecal-oral	Parenteral	Parenteral	Parenteral	Fecal-oral
Diagnosis	IgM anti-HAV Ab	HBsAg, anti-HBs, anti-HBc, HBeAg, HBV DNA	Hepatitis C antibody	Delta Ag, IgM-specific Ab	IgM anti-HEV Ab
Carrier risk of chronic infection	0	10-15%	50-85%	Up to 80% when superinfection with Hep D occurs	0
Vertical transmission risk	No	Yes	Yes	Yes	Yes
Vaccination available	Yes	Yes	No	No	No

Ab, antibody; anti-HAV Ab, IgM-specific antibody to hepatitis A; anti-HBc, antibody to hepatitis B core antigen; anti-HBs, antibody to hepatitis B surface antigen; anti-HEV Ab, IgM-specific antibody to hepatitis E; anti-HEV, antibody to hepatitis E virus; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen.

TABLE 50-6 INTERPRETATIONS OF SEROLOGIC TESTING IN PATIENTS WITH HEPATITIS B VIRUS INFECTION

HBsAg	HBsAb	HBcAb	HBeAg	HBeAb	Possible Interpretation
-	-	-	-	-	Never infected
+	-	-	-	-	1. Early acute infection 2. Transient (up to 18 days) after vaccination
+	-	IgM	+	-	Acute HBV infection, highly infectious
+	-	IgG	+	-	Chronic HBV infection, highly infectious
+	-	IgG	-	+	Late acute or chronic HBV infection, low infectivity
-	-	IgM	±	±	Acute HBV infection
-	-	IgG	-	±	1. Low-level HBsAg carrier or remote past infection 2. Passive transfer to infant of HBsAg-positive mother
-	+	IgG	-	±	Recovery from HBV infection and immune
-	+	-	-	-	1. Immune if concentration ≥ 10 mIU/mL 2. Passive transfer after hepatitis B immune globulin

HBcAb, hepatitis B core antibody; HBeAb, hepatitis B e antibody; HBeAg, hepatitis B e antigen; HBsAb, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; IgG, immunoglobulin G; IgM, immunoglobulin M; -, negative; +, positive; ±, equivocal.

The maternal management of viral hepatitis is not altered greatly by pregnancy. Supportive therapy is usually sufficient, although some cases of certain viral subtypes may lead to progressive liver failure. Hepatitis A and B remain the most common viruses responsible for acute hepatitis in pregnancy in North America and Europe. Infection during the third trimester is most common. There is evidence that infection with hepatitis E during pregnancy, which is rare in the United States, can lead to acute liver failure, and this is associated with high mortality rates.⁶⁹ The severity of infection with viruses A through D is not influenced by gestation. Prematurity and perinatal death are uncommon, but their rates are slightly increased over background rates for the general population. In contrast, miscarriage, fetal intrauterine growth restriction, and congenital malformation rates are not increased.

Hepatitis A

Hepatitis A virus (HAV) is a major cause of acute hepatitis in the United States. The virus is a ubiquitous RNA picornavirus, which is primarily transmitted from person to person through fecal-oral contamination, facilitated by poor hygiene and poor sanitation, resulting in contaminated food and water. The disease is more common among immigrants, drug users, and homosexual men.⁷⁰

The incubation period of HAV ranges from 14 to 50 days and is followed by the nonspecific symptoms of malaise, headache, fatigue,

anorexia, nausea, vomiting, and diarrhea. Cholestasis shortly follows with jaundice, acholic stools, and dark urine. Some patients, especially children, may be asymptomatic and therefore represent a key group who has a role in transmission of infection.

The diagnostic test most commonly used is an IgM-specific antibody to HAV. The presence of IgG antibody to HAV indicates post-infection status and immunity. In developing countries with poor sanitation, childhood infection is common and therefore acute HAV infection is uncommon in adult populations. In the United States, seasonal variation and an increasing frequency in adults have been observed. IgM antibody is detectable 1 month after exposure and may persist for as long as 6 months. IgG antibody to HAV appears within 35 to 40 days of exposure and signifies lifelong immunity.

Acute HAV infection rarely requires more than general supportive care. Hepatitis A is a self-limited disease without the chronic process that complicates other viral hepatitis infections, and recovery follows typically within 4 to 6 weeks. HAV infection has been associated with an increased risk for complications such as threatened preterm labor and preterm rupture of membranes.⁷¹ Only 1 in 10,000 patients has a severe or aggressive course.⁷² These individuals may require intensive care for treatment of coagulopathy and encephalopathy.

HAV is excreted in large amounts in stool before the onset of symptoms of jaundice. Affected patients should be advised of their potential

TABLE 50-7 HEPATITIS B VACCINATION RECOMMENDATIONS**Maternal HBsAg Testing**

All pregnant women should be tested routinely for HBsAg.

Vaccination of Infants**At Birth**

Infants born to HBsAg-positive mothers should receive hepatitis B vaccine and HBIG within ≤12 hours of birth.

Infants who are born to mothers whose HBsAg status is unknown should receive hepatitis B vaccine within ≤12 hours of birth.

Term infants ≥2000 g at birth and medically stable who are born to HBsAg-negative mothers should receive hepatitis B vaccine before hospital discharge.

Preterm infants ≤2000 g at birth who are born to HBsAg-negative mothers should receive their first dose of hepatitis B vaccine 1 month after birth.

After the Birth Vaccination

All infants should complete the hepatitis B vaccine series.

Infants born to HBsAg-positive mothers should be tested for HBsAg and HBsAb after completion of the hepatitis B vaccine series at age 9 to 18 months.

HBIG, hepatitis B immune globulin; HBsAb, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen.

Adapted from Centers for Disease Control and Prevention (CDC): A comprehensive immunization strategy to eliminate transmission of hepatitis B virus infection in the United States. MMWR Morb Mortal Wkly Rep 54(RR16):1-23, 2005.

risk for transmission. For short-term protection, immune globulin (IG) is used prophylactically and after exposure. Pregnant women embarking on travel to endemic areas should be screened for immunity to HAV, and if IgG negative, they should receive vaccination because it appears safe for use in pregnancy.⁷²

Perinatal transmission of HAV is rare. In such cases, fecal contamination occurs when maternal incubation coincides with delivery. Infants of mothers manifesting acute hepatitis A should receive IG to prevent horizontal transmission. Although not licensed for children younger than 2 years, vaccination appears to be efficacious in small studies of this age group.⁷² Breastfeeding is not contraindicated, and the HAV vaccine is safe for lactating mothers.

Hepatitis B

Hepatitis B virus (HBV) infection is a worldwide health problem, and it is most prevalent in Asia, Southern Europe, and Latin America. Prevalence of hepatitis B surface antigen (HBsAg) carriers in the general population is 2% to 20%. HBV accounts for 40% to 45% of all cases of hepatitis in the United States.^{73,74} Acute HBV infection occurs in 1 or 2 per 1000 pregnancies.⁷⁵ In the United States each year, approximately 20,000 infants are delivered of HBsAg-positive women.⁷⁶ Infection with HBV in infancy or early childhood may lead to a high rate of chronic infection. In most endemic areas, infection occurs mainly during infancy, and early childhood and mother-to-infant transmission accounts for approximately 50% of the chronic infection cases. The high risk of vertical transmission from carrier pregnant women to their offspring and its potential prevention by screening and immunization are areas of special interest to the practicing obstetrician and maternal-fetal specialist.

ACUTE HEPATITIS B

HBV is a DNA virus with three major structural antigens: HBsAg, core antigen (HBcAg), and e antigen (HBeAg) (see Table 50-6). The core antigen is present only in the hepatocytes and does not circulate in the serum. The intact virus is known as the Dane particle. Transmission occurs principally through parenteral drug use, during sexual intercourse, and vertically after perinatal exposure. The peak prevalence of disease occurs in the reproductive age group, and for females, heterosexual contact represents the most common method of infection. Population groups at increased risk include drug addicts, transfusion recipients, dialysis patients, and non-Hispanic blacks.⁷⁴

Onset of the acute disease is usually insidious, with infants and young children typically asymptomatic. When present, clinical symptoms and signs include anorexia, malaise, nausea, vomiting, abdominal pain, and jaundice. Patients also may have rashes, arthralgias, and arthritis.

HBsAg is found in blood 2 to 8 weeks before the development of symptoms or laboratory abnormalities. Serum HBsAg usually remains detectable until the convalescent phase. HBeAg becomes detectable after HBsAg and indicates a high viral inoculum and viral replication. The diagnosis of acute hepatitis B requires the detection of surface antigen and IgM antibody to the core antigen (IgM HBcAb). Identification of IgM HBcAb is important because certain individuals with fulminant acute hepatitis B may experience a period when HBsAg is not easily detectable. Clinical recovery is accompanied by clearance of HBV DNA followed by HBeAg and HBsAg antigenemia within 1 to 3 months, along with the presence of IgG HBcAb and antibody to HBeAg (HBeAb). The presence of HBeAb indicates recovery, clearance of the virus, and immunity.

CHRONIC CARRIER STATE

Chronic infection occurs in approximately 90% of infected infants, 30% of infected children younger than 5 years, and less than 5% of infected persons older than 5 years.⁷⁷ Of these chronically infected people, 15% to 30% develop chronic acute hepatitis or cirrhosis, and a small but significant group eventually develops hepatocellular carcinoma. Chronic infection is more likely in those who remain HBeAg positive or become superinfected with hepatitis D.⁷³ Other factors associated with the chronic carrier state include infection early in life, symptomless infection, immunosuppression, Asian background, and Down syndrome.

Liver damage is related primarily to immunologic events. Cytotoxic T-cell destruction of infected hepatocytes manifesting core antigen results in massive liver injury over time. Exacerbations of inflammatory activity follow viral replication and mirror the load of HBV DNA detectable in serum.

PERINATAL ASPECTS OF HEPATITIS B

Pregnancy does not increase maternal morbidity or mortality from HBV or the risk of fetal complications such as fetal death or congenital abnormalities. However, spontaneous abortions in the first trimester and preterm labor in the third trimester have been increased among mothers with acute HBV infection, although the rates may be no higher than those for other febrile illnesses.⁷⁸

Women with chronic HBV infection who become pregnant while on therapy can continue treatment, but the stage of the mother's liver disease and the potential benefit of treatment must be weighed against the small risk to the fetus. Lamivudine has been classified as a category C drug by the U.S. Food and Drug Administration (FDA), and it is not recommended in the first trimester. Lamivudine crosses the placenta freely and can be found in breast milk in equivalent concentrations to

those of the mother's serum. Interferon α (IFN- α) does not cross the placenta, but it is a FDA category C drug, and its use must be carefully considered in pregnancy.

In most cases, the principal concern is potential transmission of the virus to contacts and the fetus during pregnancy and delivery. The age at which HBV infection occurs is an important factor affecting outcome. Without neonatal immunoprophylaxis, perinatal transmission occurs from 70% to 90% of individuals positive for HBsAg and HBeAg, but this high rate is reduced to less than 10% of infants born to HBsAg-positive, HBeAg-negative women.⁷⁹ This compares with 5% to 10% of individuals infected in adulthood. High viral loads and coinfection with human immunodeficiency virus (HIV) are additional risk factors for vertical transmission. The presence of HBeAg beyond the second month of life denotes likely chronic carriage. The risk of becoming a chronic carrier is independent of gestational age, birth weight, and viral subtype.

In patients with acute HBV infection, the frequency of transmission depends on gestation, with 10% of neonates becoming infected if infection occurs in the first trimester, increasing to 80% to 90% if infected in the third trimester.⁷⁷ Transmission during labor and birth likely results from the mixing of maternal and fetal blood and contact with infected cervicovaginal secretions and amniotic fluid. Transplacental transmission may occur and explains some failures of immunoprophylaxis.⁸⁰ Delivery by cesarean and avoidance of breastfeeding do not prevent infection of the newborn.

Women who present in labor with unknown HBsAg status should be considered potentially infectious until serologic testing confirms otherwise. In the absence of known natural serologic status, some institutions have used neonatal combined immunoprophylaxis as a cautionary approach.

PREVENTION AND TREATMENT

The American College of Obstetricians and Gynecologists (ACOG) and the Centers for Disease Control and Prevention (CDC)⁷⁶ continue to endorse universal prenatal screening for hepatitis B. This strategy has been deemed cost-saving in identifying 20,000 HBsAg-positive women and preventing 3000 chronically infected neonates per year in the United States. High-risk status, including admitted intravenous drug use and prostitution, may identify no more than 50% of infected women. Screening is performed at the first prenatal visit; however, testing should be repeated later in pregnancy and after delivery in seronegative mothers at high risk.⁸¹

A combination of passive and active immunization can effectively prevent most cases of horizontal and vertical transmission of hepatitis B. Individuals who have had household or sexual contact with infected individuals should undergo serologic testing to determine their immune status. If they are found to be seronegative, hepatitis B immune globulin (HBIG) in addition to hepatitis B vaccination may be given. HBIG is also recommended for the neonate immediately after birth; the hepatitis B vaccination series is then instituted within 12 hours of birth (see Table 50-7). This vaccine is composed of inactivated portions of the surface antigen manufactured by recombinant DNA technology. The strategy of neonatal immunoprophylaxis is between 85% and 95% effective in preventing neonatal hepatitis B infection.⁸²

Despite recommendations for maternal screening and newborn immunoprophylaxis, approximately 10% of neonates of infected mothers fail to receive HBIG and vaccination after birth.⁷⁶ Each institution should provide a systematic review of maternal hepatitis B status. Postimmunization testing is important for high-risk groups likely to have carriers within a household. The CDC has recommended universal hepatitis B vaccination for all infants.⁸¹ Testing is recom-

mended at 12 months to ensure presence of antibodies to HBsAg. The detection of IgM anti-HBc suggests recent infection, whereas maternal IgG anti-HBc may persist beyond 12 months. Immunization failures are thought to result from a genetically predetermined response, in utero infection, immunosuppression (e.g., from intercurrent HIV infection), other diseases, or the emergence of antibody escape variants of HBV.⁸³

MEDICAL PERSONNEL CONCERNS

Health care workers may acquire hepatitis B infection from patients. Approximately 380,000 American hospital-based workers sustain percutaneous injury each year.⁸⁴ Transmission of HBV, HCV, and HIV is well described, and it is estimated that percutaneous injuries account for up to 37% of HBV infections among health care workers.⁸⁵ Prevention of these infections is promoted by vaccination of health care workers, vaccination of individuals at high risk for contracting hepatitis B, and following universal precautions about sharp objects and handling of body fluids. Testing for antibodies to HBsAg (HBsAb) approximately 1 month after the third vaccine dose is advisable, because poor responders account for 20% of vaccinated individuals. Levels of HBsAb decline greatly over time; however, immunocompetence is demonstrated in most individuals by an appropriate increase in antibody to an antigen challenge (i.e., immune memory). The minimum level of protective anti-HBs is unknown. Individuals who are poor responders to vaccination should receive HBIG after an exposure.

Infected health care workers may pose a risk to patients by transmitting HBV during invasive procedures. If a patient does not have immunity to hepatitis B, an infected health care worker is obligated to inform the patient about the possibility of transmission of the virus if blood-to-blood exposure occurs. After consent is obtained, great care and caution should be used to prevent any sharp injury.

Hepatitis C

Hepatitis C virus (HCV) infection affects more than 1% of the world population and approximately 4 million individuals in the United States, where it is the leading cause of chronic liver disease. The prevalence of HCV infection among pregnant women varies from 1% to 5%, with the highest rates of infection found in urban populations.⁸⁶

Because HCV is blood-borne, it is more common among intravenous drug users and individuals who have received many transfusions. Sexual and vertical transmission may be alternative modes of transmission. Blood transfusion donors have been routinely tested for HCV since 1990, and the risk of HCV infection is less than 1 case per million screened units of blood. The disease has a peak incidence in people between the ages of 30 and 49 years; however, a large percentage of those affected report no risk factors. Only 24% of infected pregnant women gave a history of receiving blood products, and a similar percentage (27%) denied transfusion or intravenous drug use.^{87,88}

Acute HCV infection has an incubation period of 14 to 180 days. Seventy-five percent of acute cases are asymptomatic, and this means that only 25% to 30% of infected individuals are diagnosed.⁸⁹ However, the data suggest that 80% of infected patients will develop chronic liver disease with biochemical evidence of liver dysfunction, 35% will develop cirrhosis, and 5% will progress to hepatocellular carcinoma.^{90,91} HCV infection follows an indolent course in most patients, and the average time is 10 years to significant hepatitis, 20 years to cirrhosis, and 30 years to hepatocellular carcinoma. This course may be altered and accelerated by coinfection with HIV.

The diagnosis of HCV infection relies on the identification of anti-hepatitis C antibody. Initial screening consists of an enzyme

TABLE 50-8 DEFINITIONS OF HEPATITIS C VIRUS INFECTIONS

Type of Infection	Status of Patient
HCV	HCV Ab positive
Chronic HCV	HCV Ab positive and HCV RNA positive for 6 months
Chronic active HCV	HCV Ab positive and HCV RNA positive for 6 months and abnormal liver function test results

Ab, antibody; HCV, hepatitis C virus.

immunoassay. Confirmation is then obtained through a recombinant immunoblot assay against four specific viral antigens. Antibody may not be present until 4 to 5 months after acute infection. The presence of antibody does not differentiate acute from chronic disease or determine the extent of viremia. Branched-chain DNA and reverse-transcriptase polymerase chain reaction assays may be used to quantify HCV RNA and viral loads (Table 50-8).

PREGNANCY CONCERNS

There is no evidence that HCV infection affects fertility. The indolent nature of the disease, with the peak incidence occurring in the childbearing-age group, makes potential HCV infection a primary concern for the obstetrician. Pregnancy does not appear to affect the clinical course of acute or chronic hepatitis C, and there appears to be no increased risk for adverse pregnancy outcomes among HCV-infected women; specifically, there is no increased risk of miscarriage, preterm delivery, or increased obstetric intervention.⁹² Vertical transmission of HCV may occur, although less frequently than HBV infection. However, the diagnosis of vertical transmission is not a straightforward one. Many infants born to HCV-infected mothers are found to have passively acquired transplacental IgG antibodies for up to 18 months of life, making antibody testing of the newborn of little value. Diagnosis can be reliably established by a positive HCV RNA identification on two occasions 3 to 4 months apart after the infant is at least 2 months old and by detection of anti-HCV antibodies after the infant is 18 months old.⁹³

Overall, the risk of perinatal transmission is approximately 5%.^{94,95} HIV coinfection, drug abuse, and high HCV viral loads are associated with an increased risk of perinatal transmission.^{96,97} In a review of 383 cases of vertical transmission,⁹⁸ weighted transmission rates were calculated to adjust for sample size and variance. For a mother who was HCV antibody positive but RNA negative, the vertical transmission rate was 1.7%, compared with 4.3% for an RNA-positive mother, and this increased to 36% in another study if titers were more than 10⁶ copies/mL.⁹⁹ Vertical transmission rates were higher (19.4%) for RNA-positive mothers coinfecting with HIV. There is some evidence that treatment of HIV infection with highly active antiretroviral therapy (HAART) during pregnancy reduces the risk of HCV vertical transmission.

PREGNANCY MANAGEMENT

There is no contraindication to pregnancy in HCV-infected women. The risk of perinatal infection must be discussed and the extent of maternal disease considered before making recommendations. IFN- α and pegylated interferon in combination with oral ribavirin may ameliorate disease and are being used as first-line therapy for chronically infected individuals. IFN- α does not cross the placenta, but it is a cat-

egory C drug, and its use must be carefully considered in pregnancy. Ribavirin is a category X drug and should not be used in pregnant women, women attempting to become pregnant, or their male partners because of its risk of teratogenicity.

There is no association between mother-to-infant transmission and gestational age,¹⁰⁰ but prolonged rupture of membranes (>6 hours) may increase the risk of transmission.⁹³ There is conflicting evidence about whether the practice of using fetal scalp electrodes increases the risk of transmission, and this practice is discouraged.⁷⁸

There appears to be no benefit in cesarean delivery to prevent vertical transmission in HIV-negative, HCV-positive women. Gibb and colleagues¹⁰¹ reported an overall transmission rate of 6.7%, with no cases of perinatal transmission in 31 elective cesarean sections. A large study of 275 HCV-positive women⁹⁴ found no difference in vertical transmission rates (4% vaginal versus 6% cesarean). Breastfeeding is not considered a risk factor for vertical transmission.

There is no vaccine available for HCV. Whereas passive immunization with immunoglobulin is recommended after percutaneous exposure, immunoprophylaxis of the newborn has not been beneficial in clinical trials.

Hepatitis D

Hepatitis D is an RNA virus that depends on the hepatitis B virus for replication and expression. HDV infection is found only as a simultaneous (coinfection) acute infection acquired with HBV or as a superinfection in an individual who is a chronic HBV carrier. Epidemiologic features of hepatitis D are similar to those for hepatitis B.

Coinfection with HBV is generally self-limited and carries a similar risk of progression to chronic liver disease as isolated acute hepatitis B infection. However, superinfection with hepatitis D is associated with an 80% progression to chronic hepatitis. Superinfection ultimately occurs in 25% of chronic HBV carriers. Those who develop chronic hepatitis have a 75% to 80% risk of cirrhosis with potential for liver failure. HDV is transmitted by blood and blood products, and the risk factors for infection are similar to those for HBV.

The diagnosis of acute coinfection is confirmed by the presence of delta antigen or IgM-specific antibody in sera of an individual demonstrating HBsAg and core antigen IgM. Superinfection is marked by delta antigen or IgM to HDV and positive hepatitis B core antigen IgG, indicating chronic hepatitis B infection.

Women with acute hepatitis D are managed supportively as with acute hepatitis of other causes. Those with chronic infection require monitoring of liver function, including coagulation parameters. Perinatal transmission of HDV has been reported¹⁰²; however, active measures to prevent transmission of HBV to the neonate can prevent HDV transmission.

Hepatitis E

The hepatitis E virus (HEV) is an RNA virus found most frequently in Asia, Africa, and South America. It is similar to hepatitis A in that it is transmitted by the fecal-oral route and does not progress to chronicity. The incubation period is 2 to 9 weeks, with an average of 45 days.¹⁰³ In the nonpregnant person, HEV infection is usually self-limiting and mild. However, pregnancy seems to be associated with an increased risk of contracting the virus, which leads to a particularly poor outcome. Acute liver failure has been reported for approximately 20% of pregnant women with acute HEV infection, and mortality rates in these cases are 10% to 20%.^{104,105} The incidence of acute liver failure due to HEV infection increases with advancing gestation and is most common during the third trimester. HEV-associated acute liver failure is associated with significant obstetric complications such as antepar-

tum hemorrhage, intrauterine death, poor fetal outcome, and preterm delivery.⁶⁹

Diagnosis of hepatitis E relies on identification of IgM antibody to HEV in the sera of infected individuals. Women with HEV infection may require intensive care if liver failure develops. Although perinatal transmission is uncommon, it has been reported and may be associated with biochemical evidence of liver injury, hypoglycemia, and neonatal death.¹⁰⁶ Precautions should be taken when caring for infected women to minimize contact with infected feces and contaminated clothing.

Hepatitis G

Hepatitis G virus (HGV) is a single-stranded RNA flavivirus that was first described in the 1960s. Although it is found in approximately 1% of blood donors in the United States and persistent viremia is common, clinical disease and chronic hepatitis rarely occur. There are scarce data about this disease in pregnancy; however, a few case reports have documented vertical transmission.

Other Hepatic Viruses

Primary herpes simplex virus (HSV) infection is a rare cause of hepatitis in pregnancy, but it may lead to severe maternal illness and may be associated with transplacental virus transmission with consequences such as abortion, stillbirth, and congenital malformations.¹⁰⁷ Maternal and perinatal mortality rates of 39% have been reported for HSV hepatitis during pregnancy.¹⁰⁸ A high index of suspicion is warranted when disseminated maternal herpes simplex infection is present because typical mucocutaneous lesions and jaundice may be absent in affected patients. Antiviral therapy with acyclovir may be used in affected patients.¹⁰⁶

Primary cytomegalovirus (CMV) infections affect 1% to 4% of seronegative women during pregnancy, and the risk of transmission to the fetus is 30% to 40%.¹⁰⁹ Acute CMV infection in pregnancy is usually asymptomatic. However, it may cause maternal hepatitis, and it is the most common viral cause of congenital infection that is associated with hearing loss and neurodevelopmental disability in the neonate.¹¹⁰ CMV hepatitis is more common in individuals with advanced HIV infection and transplant recipients. Serious CMV infections, including hepatitis, are treated with intravenous ganciclovir. There are few data regarding the use of this medication during pregnancy, and it is unknown whether maternal treatment prevents fetal infection. Similarly, data are sparse regarding the safety of phosphonoformate (foscarnet), another drug used to treat severe CMV infections. No vaccine is available, and prevention includes hygienic measures such as hand washing after contact with saliva or urine.

Hepatitis is a well-described feature of Epstein-Barr virus infection (i.e., mononucleosis). Most cases are self-limited, although liver failure may occasionally follow infection.

Human Immunodeficiency Virus Infection

Liver disease is common in patients with advanced HIV infection and acquired immunodeficiency syndrome (AIDS) (see Chapter 38). Liver abnormalities may follow drug-induced hepatotoxicity with HIV drugs such as nevirapine and with the concomitant use of the antituberculosis drugs isoniazid and trimethoprim-sulfamethoxazole for the treatment of *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) infection. Acute and chronic hepatitis may be caused by common etiologic agents and by herpes viruses. Opportunistic and fungal infections may lead to inflammation and obstruction of the biliary tract, cholestasis, and

right upper quadrant pain. Potential agents include *Cryptosporidium*, CMV, toxoplasmosis, *Cryptococcus*, histoplasmosis, and *Mycobacterium* species. Intrahepatic neoplasms most likely associated with HIV infection include non-Hodgkin lymphoma and Kaposi sarcoma.

The clinical presentation of most liver diseases in women with HIV infection is nonspecific. Fever, hepatomegaly, right upper quadrant pain, and biochemical abnormalities consistent with cholestasis are typical features. Viral loads (RNA levels) usually are high in such cases. Imaging studies are valuable in differentiating HIV-related processes from other causes of cholestatic jaundice. To avoid irradiation of the fetus, ultrasound or MRI is preferable to CT. Liver biopsy may be valuable in securing tissue for culture and diagnosis.

Chronic Liver Disease in Pregnancy

Chronic Nonviral Hepatitis

Chronic nonviral hepatitis may result from a variety of autoimmune conditions, alcoholism, and drug- or toxin-induced injury. Most cases of chronic nonviral hepatitis in reproductive-age women result from autoimmune disease. Autoantibodies to smooth muscle and liver-specific proteins are present, as are antinuclear antibodies in most cases.

Amenorrhea and infertility are common in affected women, but treatment with immunosuppressive regimens commonly stalls progression of disease and results in renewed fertility. The most commonly used immunosuppressive agents are prednisolone and azathioprine, although cyclosporin and tacrolimus may also be used.¹¹¹ If disease activity is well controlled, most women have a good prognosis for pregnancy. However, approximately 30% of cases have a flare of the disease after delivery.¹¹¹ A review of 101 pregnancies in 58 women with autoimmune hepatitis reported a perinatal mortality rate of 4%,¹¹² and a subsequent study of 63 pregnancies in 35 Scandinavian women reported one stillbirth and one infant who died of severe liver disease soon after delivery.¹¹¹ Rates of prematurity and fetal growth restriction are higher than in the general population, although congenital malformation rates are not. Flares in some women are related to stopping treatment. Given the reassuring data available related to the use of azathioprine¹¹³ in pregnancy and breastfeeding,¹¹⁴ women with autoimmune hepatitis should continue treatment because the risk of a flare outweighs the potential risk from treatment.

Primary Biliary Cirrhosis

Primary biliary cirrhosis is an autoimmune liver disease that is characterized by the presence of antimitochondrial antibodies. It occurs more commonly in women and classically manifests at a later age than autoimmune hepatitis. Data about the disease in pregnancy are limited.

Affected women commonly have pruritus with elevated serum levels of bile acids in addition to cholestatic hepatic impairment, and it is reasonable to anticipate that the fetal risks related to increased concentrations of bile acids will be the same as in ICP. Primary biliary cirrhosis is treated with UDCA or cholestyramine. Both drugs should be continued in pregnancy if their use is associated with an improvement in the maternal disease. However, cholestyramine binds fat-soluble vitamins, and vitamin K supplementation should be given. Fetal surveillance strategies should be the same as for ICP.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic disease of unknown origin that is characterized by fibrosis and inflammation of the intrahepatic and extrahepatic bile ducts. The disorder follows a progressive course, leading to biliary cirrhosis, hepatic failure, and ultimately, death. Affected individuals are also at risk for the development of cholangiocarcinoma. PSC usually occurs in patients with ulcerative colitis and to a lesser extent in those with Crohn disease. In most cases, the onset of inflammatory bowel disease precedes the development of PSC. The cause of PSC remains obscure, but the disorder may have an immunologic basis.

The diagnosis of PSC is based on clinical, laboratory, and histology findings and includes a characteristic cholangiographic appearance of diffuse irregularity and narrowing of the hepatic bile ducts. Pruritus, jaundice, and abdominal pain are typical clinical features. Itching usually is severe enough to require UDCA or other therapies. Favorable pregnancy outcomes have been reported for women with PSC.^{115,116} In one series of 13 pregnancies, including three women with onset of PSC during gestation, no significant maternal or neonatal morbidity was observed.¹¹⁶ Individual case reports have detailed variable courses for PSC during pregnancy. In one report, the cholestatic process paradoxically improved with advancing gestation, followed by a decline in hepatic function after delivery.¹¹⁵ Other reports have described deterioration of liver function¹¹⁷ and the need for transplantation during pregnancy.¹¹⁸ Severe elevations in fetal bile acid levels have been documented, indicating placental transfer.¹¹⁵ Meconium passage is common, and fetal surveillance is recommended for maternal PSC in the same way as for patients with ICP.

Wilson Disease

Wilson disease is a rare disorder of copper metabolism characterized by liver failure and neurologic dysfunction. Kayser-Fleischer corneal rings are a hallmark of diagnosis; however, they may be absent in patients with liver disease. Levels of ceruloplasmin are depressed in Wilson disease but may increase to normal with advanced liver disease. The diagnosis must be considered in reproductive-age women presenting with advanced liver disease of unknown origin.

Treatment of Wilson disease consists primarily of penicillamine or trientine, both of which are well tolerated during pregnancy and should be continued. Deterioration in hepatic function may occur if these medications are abruptly discontinued.¹¹⁹ Several series have reported successful pregnancies in women with treated Wilson disease.¹²⁰⁻¹²² The drug crosses the placenta and may result in copper deficiency in the fetus. Most women with Wilson disease are treated with lower doses than those used to treat cystinuria and from which the data on teratogenicity were derived.

Budd-Chiari Syndrome

Budd-Chiari syndrome is a rare disorder primarily of women that results from hepatic vein occlusion, which has been linked to pregnancy and oral contraceptive use.¹²³ In one series, almost 15% of cases were associated with pregnancy.¹²³ The disease may present acutely with obstruction of major hepatic veins or may be chronic and marked by involvement of smaller interlobular veins. The chronic variety is associated with a better prognosis. Both varieties produce congestion and necrosis of centrilobular areas of the liver.¹²⁴ Large-vein obstruction is often associated with pregnancy and preeclampsia.¹²⁵ Some have suggested that Budd-Chiari syndrome complicating pregnancy is asso-

ciated with thrombophilias, including antiphospholipid antibodies and factor V Leiden mutation.^{126,127}

The disorder manifests with abdominal pain, distention, and ascites. Ascitic fluid has a high protein content. Some patients have fever, nausea, vomiting, and jaundice. Laboratory evaluation shows marked elevation of the alkaline phosphatase level beyond that of normal pregnancy levels. Concentrations of liver enzymes are modestly elevated. The results of histologic examination are nonspecific, demonstrating centrilobular zonal congestion with hemorrhage and necrosis. Diagnosis can be achieved by pulsed-wave Doppler imaging demonstrating the direction and amplitude of flow. Percutaneous hepatic venous catheterization can demonstrate elevated hepatic vein pressures, venous occlusion, and collateral circulation. MRI may also aid in the diagnosis.¹²⁵

Women who develop acute major venous obstruction often deteriorate rapidly, with portal hypertension, variceal bleeding, and fulminant hepatic failure. Pregnancy outcome depends on maternal status. Porta caval shunting may improve portal hypertension and ascites, although many pregnant women are not surgically stable enough to undergo this procedure. These procedures have been primarily accomplished in postpartum cases. There are reports of successful pregnancies after mesocaval shunting.¹²⁸ Patients developing Budd-Chiari syndrome should be evaluated for underlying thrombophilias. Even in the absence of such disorders, treatment with anticoagulation is advised, although therapy does not eliminate the risk of recurrent thrombosis.

Cirrhosis

Pregnancy in women with cirrhosis is uncommon because most of these women experience oligomenorrhea and infertility. Nonetheless, there have been considerable reports of end-stage liver disease coexisting with pregnancy. It is doubtful that any single institution or maternal-fetal specialist has managed a large number of such cases. Many of the series in the literature are 25 years or older.

Cirrhosis is associated with an increased risk for premature delivery and perinatal mortality. In a series of 95 pregnancies in 78 women with cirrhosis, 10 stillbirths were observed, and no significant change in liver function occurred in two thirds of the women.¹²⁹ Prematurity (20% risk) and need for early termination (18% risk) have also been reported.¹³⁰ Maternal complications associated with cirrhosis include anemia, preeclampsia, postpartum hemorrhage, and bleeding from esophageal varices.¹³⁰

Bleeding from esophageal varices remains the most feared complication of cirrhosis and pregnancy. Esophageal bleeding is a cause of maternal death. Bleeding occurred in 18 of 23 women with known esophageal varices in an older series.¹³¹ Portal decompression procedures were used successfully in several cases without adverse maternal-fetal effects. The risk for variceal bleeding is thought to increase as pregnancy advances because of increased circulating blood volume, elevation in portal pressure, and vena cava compression resulting in enhanced flow through the azygos venous system. Most bleeds occur during the second and third trimesters, with some occurring in the postpartum period. The likelihood of bleeding may be decreased in individuals who have undergone portal caval decompression procedures before pregnancy. In a study that aimed to address this topic, only one death occurred among 21 women who had undergone previous portosystemic shunting, and it was caused by hepatic coma in the postpartum period.¹³⁰ It follows that the pregnant woman with cirrhosis must be evaluated endoscopically for varices and appropriate treatment undertaken (see the Portal Hypertension section).

Because most women with cirrhosis have uncomplicated pregnancies, careful monitoring should allow progression to term. Nutritional

intervention such as limiting protein intake is advised only in advanced cases and after surgical portal decompression. Maneuvers to reduce straining and thereby portal pressure are advised if varices have been documented. Vaginal delivery is the preferred route of delivery, with an attempt to shorten the second stage by forceps or vacuum extraction to limit excessive pushing and increases in intra-abdominal pressure. The pharmacokinetics and metabolism of anesthetic agents must be carefully considered. Postpartum bleeding may be increased, and vitamin K, fresh-frozen plasma, and platelets should be available.

Portal Hypertension

Although studies indicate that the pregnant woman with cirrhosis will most often have an uncomplicated pregnancy, the substantial risk of hemorrhage from bleeding varices must be emphasized to the patient and her family. The death rate for pregnant women with cirrhosis ranges from 10% to 18%, with most of these cases complicated by massive gastrointestinal bleeding.¹³² Women at highest risk are those with a history of gastrointestinal bleeding antedating pregnancy.

Management of bleeding varices may be accomplished with sclerotherapy as an alternative to portacaval anastomosis. Some authorities suggest it is superior to portosystemic shunting in reducing recurrent bleeding episodes. In a study of 11 women with cirrhosis during pregnancy, 4 of 6 with documented varices experienced gastrointestinal hemorrhage requiring endoscopic sclerotherapy.¹³² Five of these women also had significant coagulation disorders. In the entire series, there were six growth-restricted infants, three preterm deliveries, and one neonatal death. In addition to sclerotherapy, portal pressure may be reduced with β -blocker therapy and vasodilators. Portal decompression surgery has been accomplished during pregnancy, but it is used less often than endoscopic sclerotherapy.

Another feared complication associated with portal hypertension is the development of splenic artery aneurysm. Pulsed-wave Doppler and CT imaging may be helpful in establishing the diagnosis. Elective laparoscopic surgery with ligation should be strongly considered before pregnancy because rupture carries with it an enormous risk of maternal and fetal death.

The emerging literature describes the outcome of pregnancy in women with noncirrhotic portal hypertension, which is most commonly caused by noncirrhotic portal fibrosis, Budd-Chiari syndrome, or extrahepatic portal venous obstruction. Affected women are more likely to be of childbearing age than are women with cirrhosis. This group of women rarely has abnormal liver function, and their fertility rates are the same as controls.^{133,134} There are varied reports on the fetal risks associated with noncirrhotic portal hypertension. An Indian series of 116 pregnancies in 44 patients¹³³ and a U.S. series of 38 cases¹³⁵ reported fetal loss rates between 7% and 8%. Two other series that included only women with extrahepatic portal venous obstruction reported fetal loss rates of 23% to 28%,^{131,132} which may reflect the different causes of portal hypertension in this group.

The frequency of variceal bleeding in pregnant women with noncirrhotic portal hypertension is lower if they have had treatment for esophageal varices before pregnancy by endoscopic injection sclerotherapy or a decompression operation. In an Indian study of 50 pregnancies in 27 women, the rate of bleeding for 35 women for whom the disease was diagnosed and treated before conception was 8.6%, compared with a rate of 93% for 15 women whose disease was diagnosed during pregnancy.¹³⁴ In women with bleeding varices during pregnancy, treatment with sclerotherapy is safe.¹³³ For prevention of rebleeding, it is advisable to use β -blocker therapy in addition to sclerotherapy. In summary, the overall prognosis for women with non-

cirrhotic portal hypertension in pregnancy is better than for those with cirrhosis, particularly if the disease was diagnosed and treated before conception.

Acute Liver Failure during Pregnancy

Acute liver failure is an uncommon medical emergency during pregnancy that is associated with significant maternal and fetal morbidity and mortality. Acute liver failure is defined as the development of hepatic encephalopathy caused by severe liver dysfunction within 12 weeks of onset of symptoms in a patient with previously normal liver function.¹³⁶ It may be further categorized as hyperacute, acute, or subacute liver failure, depending on the interval between jaundice and encephalopathy of 0 to 7 days, 8 to 28 days, or 29 days to 12 weeks, respectively.

Clinical features of acute liver failure are not diagnostic. Cutaneous stigmata such as spider nevi and palmar erythema can be seen in acute liver failure, chronic liver disease, and healthy pregnancy. Other symptoms include nausea, vomiting, fatigue, and abdominal pain. Clinical signs may include hepatomegaly, splenomegaly, and ascites. Altered mental state and icterus are the clinical hallmarks of severe liver disease, and early recognition of this is essential because affected individuals should be promptly transferred to a tertiary facility where transplantation is available.

Laboratory investigations compatible with acute liver failure include abnormal liver function test results for bilirubin, AST, ALT, ALP, and GGT. Levels of transaminases higher than 2000 IU/L suggest liver ischemia, rupture, or infarction. However, low or declining levels may indicate extensive hepatocellular necrosis and lack of regenerating hepatocytes, which carries a poor prognosis. Other laboratory indices that carry a poor prognosis include low serum levels of albumin and an elevated prothrombin time, which are markers of poor hepatic synthetic function. Acidosis (pH < 7.35) and renal impairment are associated with acute liver failure, as is profound and sometimes refractory hypoglycemia. These features also indicate a poor prognosis. Hyponatremia and thrombocytopenia ($<100 \times 10^9/L$) are commonly found in acute and chronic liver disease. The causes of acute liver failure are summarized in Table 50-9.

TABLE 50-9 CAUSES OF ACUTE LIVER FAILURE

Viral hepatitis (e.g., CMV, HIV, HSV, EBV, hepatitis A, B, C, D, or E virus)
Acetaminophen overdose
Idiosyncratic drug reactions
Pregnancy-related causes (e.g., AFLP, HELLP syndrome, preeclampsia, severe hyperemesis gravidarum)
Budd-Chiari syndrome
Ischemic necrosis
Wilson disease
Autoimmune hepatitis
Toxin exposure (e.g., alcohol)
Malignancy (e.g., lymphoma, hepatocellular carcinoma)

AFLP, acute fatty liver of pregnancy; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HELLP, hemolysis, elevated liver enzymes, and low platelets; HIV, human immunodeficiency virus; HSV, herpes simplex virus.

TABLE 50-10 KING'S COLLEGE HOSPITAL CRITERIA FOR PREDICTING POOR OUTCOMES FOR PATIENTS WITH ACUTE LIVER FAILURE**Patients Taking Acetaminophen**

pH < 7.30 (regardless of encephalopathy grade)
 Or
 PT > 100 seconds (INR > 6.5) and serum creatinine level >300 $\mu\text{mol/L}$ (>3.4 mg/dL) in patients with grade III or IV encephalopathy

Patients Not Taking Acetaminophen

PT > 100 seconds (INR > 6.5, regardless of encephalopathy grade)
 Or any three of the following variables (regardless of encephalopathy grade):
 Age <10 or >40 years
 Cause: non-A, non-B hepatitis; halothane hepatitis; idiosyncratic drug reactions
 Duration of jaundice before onset of encephalopathy >7 days
 PT > 50 seconds (INR > 3.5)
 Serum bilirubin >300 $\mu\text{mol/L}$ (>17.5 mg/dL)

INR, international normalized ratio; PT, prothrombin time.

In the nonpregnant woman, acetaminophen overdose and viral hepatitis are the most common causes of acute liver failure in the United States.¹³⁷ There have been no epidemiologic studies of acute liver failure in pregnancy, but viral hepatitis (particularly hepatitis B and E) is probably the most common cause in the developing world, with acetaminophen overdose and pregnancy-related causes being more common in more developed nations.

Management

It is imperative to rule out pregnancy-associated diagnoses such as acute fatty liver, HELLP, or preeclampsia because delivery often leads to improvement or resolution of the maternal condition. There is no evidence that delivery affects the course of liver failure in cases of viral hepatitis. However, delivery of a viable fetus should be considered because the fetal mortality rate is high for these patients.

Patients with acute liver failure should be considered for transfer to a tertiary care center with transplantation facilities. King's College Hospital criteria (Table 50-10) are widely used in Europe and to a lesser extent in the United States, and they have been shown to accurately predict poor outcome and indicate those who should be transferred.¹³⁸

Management comprises strenuous efforts to confirm the cause of acute liver failure coupled with intensive monitoring and supportive treatment until recovery begins or transplantation is undertaken. *N*-Acetylcysteine has been shown to improve the prognosis of women with acetaminophen overdose. Therapy should be commenced as soon as possible, and in practice, it is given to most patients until acetaminophen overdose has been ruled out.

Administration of fresh-frozen plasma without overt bleeding does not alter the outcome and obscures results of the prothrombin time test. Parenteral vitamin K₁ and folic acid should be given routinely. Fresh blood and blood products should be available to support any obstetric or surgical intervention. Gastrointestinal bleeding from gastric erosions is decreased by the prophylactic administration of a proton pump inhibitor. The stomach should be emptied hourly to prevent aspiration of gastric contents. Early enteral feeding reduces

translocation of microbes from the intestinal wall into the circulation and reverses the catabolic state. Elective endotracheal intubation may be required to protect the airway (particularly before transfer and surgical procedures, including delivery) before the development of overt cerebral edema. Intubation must be performed by an experienced anesthetist.

Profound hypoglycemia remains a common cause of fetal and maternal death. Blood glucose levels should be closely monitored and immediate provisions made to administer large quantities of glucose by a central venous catheter. The patient should be maintained at 10 to 20 degrees of elevation with minimal turning and stimulation. Early manifestations of cerebral edema include peaks of systolic hypertension and tachycardia and should be treated by mannitol (0.5 to 1.0 g/kg given as a bolus) to induce a diuresis. Mannitol is potentially nephrotoxic and is ineffective in renal failure. Serum osmolalities should be maintained between 290 and 315 mOsm/L. Ultrafiltration and hemodialysis may be required to remove excess fluid. Levels of blood urea may be misleadingly low, and the renal function is best monitored by serial levels of blood creatinine and creatinine clearance. Hyperventilation to reduce the partial pressure of carbon dioxide further reduces the limited brain flow and is no longer recommended. Intracranial pressure monitoring should be considered early in the patient likely to progress to grade IV coma and in transplantation candidates. Seizures seem to be more common than previously realized and should be suspected in a deteriorating patient without specific elevations in intracranial pressure. They should be considered for assisted ventilation, especially if they require benzodiazepines and other sedative drugs. Detailed microbiologic cultures and analysis should be performed serially on all body fluids, including blood, urine, and sputum. Infections, including fungal infections, are common in patients with liver failure.

Prognosis

The overall survival rate with medical treatment is 10% to 40%. The prognosis depends on the cause. It is best for patients with acetaminophen overdose or hepatitis A and less favorable for other causes. The time to the onset of encephalopathy also affects the prognosis, with hyperacute failure having a better prognosis than subacute failure. The outcome for transplantation for acute liver failure is improving, and success rates are 75% to 90%.¹³⁹

Liver Transplantation and Pregnancy

Several case reports,¹⁴⁰⁻¹⁴³ registry data,^{144,145} and two retrospective reviews^{146,147} have cumulatively described pregnancy outcomes for more than 200 women with liver transplants. In contrast to the reduced fertility and menstrual dysfunction associated with end-stage liver failure, restoration of menses occurs, and fertility rates increase within months after liver transplantation. Successful outcomes for pregnancy can be expected in these women, although they are at increased risk for preeclampsia, preterm birth, and low-birth-weight and small-for-gestational-age infants.

Pregnancy should be delayed for at least 1 year after transplantation because pregnancies occurring within that period appear to have an increased incidence of prematurity, low birth weight, and acute cellular rejection compared with those occurring later than 1 year.¹⁴⁷ Liver transplant recipients with biopsy-proven acute rejection during preg-

nancy are at greater risk for poorer outcomes and recurrent rejection episodes.¹⁴⁸ However, pregnancy itself does not seem to impair graft function or accelerate graft rejection if the patient is adequately immunosuppressed.

Immunosuppressive therapy, such as cyclosporin and tacrolimus, that is commonly used in liver transplant recipients does not appear to be teratogenic, and breastfeeding is advocated. Careful monitoring of plasma levels is advised because of the physiologic changes in pregnancy that can alter the pharmacokinetics of immunosuppressive therapy.¹⁴⁹ Malabsorption due to hyperemesis gravidarum may decrease plasma levels of the drug.

Liver transplantation has been described during pregnancy for a number of pregnancy-related and coexistent conditions, including Budd-Chiari syndrome, viral hepatitis, AFLP, and HELLP syndrome with associated hepatic rupture and necrosis. In women who do survive acute liver failure and transplantation operation during pregnancy, increased risks for impaired homeostasis as a result of coagulopathy remain throughout pregnancy and delivery. Infection, renal failure, hypoglycemia, and adult respiratory distress syndrome are common complications.

Gallbladder Disease

Epidemiology

Cholelithiasis is common in the adult population. Cross-sectional studies of nonpregnant women in the United States found that 6.5% of women between 20 and 29 years old and 10.2% of women between 30 and 39 years old have gallstones or have had a cholecystectomy.¹⁵⁰ Pregnancy and the postpartum period appear to predispose women to gallstone formation. This is attributed to the increase in sex steroid hormone levels in pregnancy, causing biliary stasis, prolonged intestinal transit, and increased cholesterol saturation of bile. Multiparity is a risk factor; one study found that gallstones occurred in 7% of nulliparous women, with the rate rising to 19% of women with two or more pregnancies.¹⁵¹ Pre-pregnancy obesity is associated with an increased risk of gallbladder disease with an odds ratio of 4.45 (95% confidence interval, 2.59 to 7.64) for a body mass index greater than 30 kg/m².¹⁵² The risk of gallstones appears to increase during gestation, with sludge (i.e., precursor to stones) or stones being found in 5.1% of 3254 prospectively studied women in the second trimester, 7.9% in the third trimester, and 10.2% by 4 to 6 weeks after delivery.¹⁵² Gallbladder disease is the most common non-obstetric cause of maternal hospitalization in the first year after delivery.¹⁵³

Despite the high prevalence of gallstones, pregnant women are usually asymptomatic, with biliary colic reported in only 1.2% of pregnant women with known gallbladder disease.¹⁵² However, biliary colic was a common presenting complaint of 43 (55%) of 78 symptomatic pregnant women admitted with biliary tract disease.¹⁵⁴ Acute cholecystitis accounted for 25% (20 of 78) of symptomatic pregnant women in the same study. However, for those who develop symptoms, the frequency of recurrence of symptoms during pregnancy is high.

Clinical Features and Diagnosis

Table 50-11 summarizes the most common gallbladder diseases. The symptoms of gallbladder disease in pregnancy are similar to those in the nonpregnant population. Biliary colic can manifest as intermittent right upper quadrant pain. More serious symptoms include anorexia, nausea, vomiting, and severe right upper quadrant or epigastric pain.

TABLE 50-11 GALLBLADDER DISEASES

Biliary colic*
Acute cholecystitis
Common bile duct obstruction
Ascending cholangitis
Gallstone ileus
Pancreatitis

*Gallbladder disease may be complicated by any combination of the disorders listed.

Symptoms may be associated with signs of infection—classically, a mild leukocytosis and elevated temperature.

Laboratory investigations may reveal elevated serum bilirubin and ALP levels, although the level of ALP is commonly increased in normal pregnancy because of placental production. Levels of AST and ALT may also be increased. Jaundice or hyperamylasemia may be signs of complicated gallbladder disease (see Table 50-11). The differential diagnosis includes appendicitis, pancreatitis, peptic ulcer disease, pyelonephritis, AFLP, and HELLP syndrome.

Abdominal ultrasound should be performed. It has an accuracy of 97% in diagnosing cholelithiasis. If extrahepatic ductal stones are suspected but not demonstrated on ultrasound, MR cholangiography may be performed. ERCP, with its associated radiation exposure, should be limited to cases in which treatment for documented ductal stones is required.

Management

Operative management for complicated gallbladder disease is advocated as in nonpregnant women. However, the appropriate management for biliary colic and acute cholecystitis during pregnancy is controversial. Traditional conservative measures include withdrawal of oral food and fluids, administering intravenous fluids, nasogastric aspiration, and providing analgesia and antibiotics, with avoidance of surgical intervention when possible. A more aggressive approach has been advocated, leading to more surgical interventions in pregnancy. A retrospective review of 78 pregnancies in 76 patients showed that nonoperative management of symptomatic cholelithiasis (i.e., biliary colic or acute cholecystitis) led to suboptimal clinical outcomes in 38% of patients, including a 34% relapse rate and significantly higher rates of labor induction, cesarean section for treatment, and preterm delivery compared with the operative group.¹⁵⁴ Of the 10 patients undergoing operative management, 8 underwent surgery in the second trimester and 2 in the early third trimester. Operative management was associated with an increased risk for premature contractions, which were treated successfully with tocolytics. The laparoscopic approach appears to be feasible even in the third trimester of pregnancy.¹⁵⁵ Perioperative fetal monitoring and low pneumoperitoneum pressures are recommended.

Pancreatitis

Epidemiology

Acute pancreatitis is a rare and serious complication during pregnancy. The true incidence of pancreatitis complicating pregnancy is difficult to ascertain and may range from 1 case in 1000 to more than 3000 pregnancies.¹⁵⁶ In a series of 500 patients with acute pancreatitis, only

7 women developed the disease while pregnant.¹⁵⁷ Although alcohol is the most common cause in nonpregnant patients, studies have repeatedly shown that gallstones are the most common cause in pregnancy.¹⁵⁸ Other causes, particularly hyperlipidemia, have been described in pregnancy, as has an association between AFLP and pancreatitis, which carries a particularly poor prognosis.¹⁵⁹

Clinical Features and Diagnosis

The clinical presentation of pancreatitis is not significantly altered in pregnancy. The disease may occur at any stage in gestation but is more common in the third trimester and the puerperium. Epigastric pain, which may radiate to the flanks or shoulders along with abdominal tenderness, should prompt appropriate laboratory investigations. Occasionally, a patient presents with nausea and vomiting as her only complaints. She may have mild fever and leukocytosis, and radiologic examination of the abdomen may reveal an adynamic ileus. Ultrasound imaging of the pancreas can be difficult. If significant pancreatic necrosis is suspected, CT becomes preferable. In most cases, this radiologic study is unnecessary.

In evaluating the pregnant patient with suspected pancreatitis, the differential diagnosis includes most causes of abdominal pain in young women. These are principally peptic ulcer diseases, including perforation, acute cholecystitis, biliary colic, and intestinal obstruction. Elevated amylase levels should suggest pancreatitis, although they may occur with other conditions, such as cholecystitis. Serum amylase concentrations greater than three times normal suggest pancreatitis.

Management

In most cases, acute pancreatitis resolves spontaneously within several days.¹⁵⁶ However, 10% of patients have a more severe course, and they are best managed in an intensive care environment. The general principles of management are the same as for nonpregnant women: bowel rest with or without nasogastric aspiration, intravenous fluids and electrolyte replacement, and parenteral analgesics. Meperidine is the drug of choice for analgesia because, unlike morphine, it does not constrict the sphincter of Oddi. Important additional measures for the pregnant patient include fetal monitoring, attention to the choice of medications, consideration of radiation to the fetus, and positioning of the mother to avoid inferior vena cava constriction. Because there is a high likelihood of associated gallstone disease, ERCP may be beneficial if common duct obstruction has occurred. Early surgical intervention is advocated for gallstone pancreatitis in all trimesters, because 70% of these patients will otherwise relapse before delivery.¹⁶⁰

For women with mild disease that is responsive to conservative management, the prognosis for mother and fetus is excellent. However, for women with more severe disease, fetal morbidity and mortality rates increase. Of 43 women with acute pancreatitis, perinatal outcomes were available for 39.¹⁵⁶ Thirty-two newborns were delivered at term without complications, and six were delivered before term, including two stillbirths and one early neonatal demise.¹⁵⁶ One patient underwent therapeutic abortion. The mechanisms of demise included placental abruption and profound metabolic disturbance, including acidosis. This highlights the importance of regular fetal monitoring and consideration of delivery if the maternal disease is deteriorating.

Pancreatic Transplantation

The National Transplant Pregnancy Registry reported 56 pregnancies in 36 patients with kidney-pancreas transplants.¹⁶¹ Maternal and fetal

morbidity rates were high, with maternal hypertension complicating 75% of pregnancies, preeclampsia occurring in 34%, and infection occurring in 55%. The mean gestational age at birth was 34 weeks (compared with 36 weeks for kidney-only recipients), and the mean birth weight was significantly lower, with 68% being below 2500 g. Twenty-six infants had neonatal complications, including one death due to sepsis. There were six graft losses within 2 years. Adverse outcomes for the mother and fetus appear to be greater for kidney-pancreas recipients than for kidney-only recipients.

Pregnancy in transplant recipients should be planned, and multidisciplinary care is imperative. Women desiring pregnancy should be encouraged to wait until immunosuppression doses are stable. Couples should consider waiting until a minimum of 1 year after transplantation, when the risks for the mother and fetus are lower. After 1 year, it is presumed that there is a reduced risk of graft rejection and lower medication doses,¹⁶² but there is a paucity of data to confirm this. Attention to the effects of medication on the fetoplacental unit and, if necessary, substitution of immunosuppressants should be undertaken before conception. Drug concentrations in maternal blood should be monitored throughout pregnancy because the physiologic changes associated with pregnancy can affect drug bioavailability. Increased surveillance of the mother and fetus should be undertaken to quickly detect any complications.

Chapter 51

Pregnancy and Rheumatic Diseases

Michael D. Lockshin, MD, Jane E. Salmon, MD, and Doruk Erkan, MD

Epidemiology

The systemic rheumatic illnesses commonly complicating pregnancy are systemic lupus erythematosus (SLE), antiphospholipid syndrome, rheumatoid arthritis, scleroderma, juvenile arthritis, spondyloarthritis, and Takayasu arteritis. SLE and Takayasu arteritis affect 15- to 45-year-old women in a ratio of 9 women to 1 man. Antiphospholipid syndrome has a female-to-male ratio of 7 to 1; rheumatoid arthritis and scleroderma have a ratio of 3 to 1; juvenile arthritis is almost gender neutral; and spondyloarthritis has a ratio of about 1 to 3. Rheumatoid arthritis and scleroderma affect middle-aged more than young women. SLE has a higher prevalence among African Americans than among whites (4 to 1). Up to 1% of all women have rheumatoid arthritis. One of 5000 to 10,000 women have SLE, and antiphospholipid syndrome may be as common as SLE, whereas the other diseases are less common.

Because of these epidemiologic patterns, the autoimmune illnesses most frequently encountered in obstetric practices are SLE and antiphospholipid syndrome. Rheumatoid arthritis is a more common illness, but it occurs most often after the childbearing years and is therefore seen less often in pregnant women.

Diagnosis of the systemic rheumatic diseases rests more on clinical than on serologic criteria (discussed with the individual diseases). Features common to all are arthralgia or arthritis; fever, myalgia, and malaise; and markers of inflammation. Current theories consider the systemic rheumatic diseases to be driven by disordered immune mechanisms, probably resulting from a genetic defect in processing exogenous infectious material, but the mechanisms and possible triggers are different among the illnesses. Systemic rheumatic illnesses are chronic and relapsing, with temporary remissions. It is more likely that a new pregnancy will be diagnosed in a woman with an established diagnosis of rheumatic illness than that a new diagnosis will be made for a previously healthy pregnant woman. Table 51-1 provides the epidemiologic, clinical, and laboratory characteristics of the rheumatic diseases most often encountered in pregnant women.

Pathogenesis

No single theory of pathogenesis explains all autoimmune diseases. Each has a clear genetic association; **most prominent are the spondyloarthropathies, in which human leukocyte antigen (HLA)-B27 is present in more than 80% of patients**, compared with an incidence of

less than 5% in general European white populations, less in Asian and African populations, and more in some Native American populations.¹ Class II HLA and non-HLA genetic associations occur in people with SLE and rheumatoid arthritis.^{2,3} Complement protein deficiencies and other immune deficits appear to predispose to SLE.⁴ **Smoking increases the risk of rheumatoid arthritis.**⁵ Deficits in T-cell regulation or uncontrolled B-cell upregulation or other abnormalities in the relevant cytokine profiles are common in autoimmune disease, although no dominant abnormality explains the pathogenesis of any rheumatic illness. Rheumatoid arthritis is successfully treated with agents that block the effect of tumor necrosis factor α (TNF- α), suggesting a critical role of that cytokine in pathogenesis.⁶ Interferon upregulation characterizes SLE.⁷ Details of how these abnormalities lead to the specific symptoms of arthritis, nephritis, and vasculitis are conjectural.

Serologic abnormalities potentially precede the clinical onset of illness by decades.⁸ **High prevalence and titer of antibodies to Epstein-Barr virus in lupus patients suggest that this virus may have an etiologic role.**⁹

With regard to immunologic phenomena of pregnancy that may be relevant to autoimmune disease, in vitro data show that estrogens upregulate and androgens downregulate T-cell responses, immunoglobulin synthesis, and leukocyte production of interleukin 1 (IL-1), IL-2, IL-6, and TNF- α , though changes in these cytokines are quantitatively small and remain within physiologic ranges.¹⁰ In pregnancy, cell-mediated immunity is depressed, as reflected by abnormal lymphocyte stimulation, decreased ratios of T cells to B cells, increased ratios of suppressor T cells to helper T cells, and decreased ratios of lymphocytes to monocytes, all of which vary with the stage of pregnancy.^{11,12} The pregnancy-specific proteins α -fetoprotein, β_1 -glycoprotein, and β_2 -macroglobulin suppress in vitro lymphocyte function. IL-1, IL-3, TNF- α , interferon γ , and granulocyte-macrophage colony-stimulating factor are critical in sustaining pregnancy.¹³ IL-3 levels are low in women with repeated pregnancy loss. In normal pregnancy, total C3, C4, and hemolytic (CH₅₀) complement levels are usually unchanged or raised relative to nonpregnant levels, but increases in classic pathway complement activation products suggest that low-grade classic pathway activation is a normal phenomenon in pregnant women. Complement activation products can alter the balance of angiogenic factor production by inflammatory cells and result in excess soluble vascular endothelial growth factor receptor type 1 (sFlt-1), which has implications for placental development and the risk for preeclampsia.¹⁴ Inhibition of complement activation in the placenta may be essential for fetal survival,¹⁵ and the trophoblast may be a target of autoimmunity.¹⁶ Theoretically,

TABLE 51-1 EPIDEMIOLOGIC, CLINICAL, AND LABORATORY CHARACTERISTICS AND PREGNANCY ISSUES OF COMMON AUTOIMMUNE RHEUMATIC ILLNESSES

Disease	Epidemiology	Common Symptoms	Laboratory Results	Pregnancy Issues
Systemic lupus erythematosus	Age 15-45 yr 9:1 female to male 4:2:1 black to Asian/ Hispanic to white	Arthritis, rash, fever, anemia, thrombocytopenia, nephritis, neurologic disease, alopecia	High positive ANA value Anti-DNA and/or Smith (diagnostic) Antiphospholipid, anti-SSA/Ro, SSB/ La, RNP antibodies (common) Raised ESR level Anemia, thrombocytopenia Proteinuria Low complement level	Fetal loss, neonatal lupus, organ system flare
Antiphospholipid syndrome	Age 15-60 yr Female > male White > black	Blood clots, fetal loss, livedo reticularis, thrombocytopenia, cardiac valve disease	Anticardiolipin Anti- β_2 -glycoprotein 1 Lupus anticoagulant test Thrombocytopenia Proteinuria	Fetal loss, HELLP syndrome
Rheumatoid arthritis	Age 35-75 yr 3:1 female to male White = black	Destructive arthritis	Anti-cyclic citrullinated peptide antibody Rheumatoid factor Raised ESR, CRP levels Bone erosions at joints	Remission in some cases during pregnancy; positioning for delivery a problem
Spondyloarthropathy	Age 15-60 yr Male > female HLA-B27	Spinal and sacroiliac arthritis	Raised ESR, CRP values HLA-B27 Radiographic sacroiliitis Spinal fusion Enthesitis	Arthritis management
Takayasu arteritis	Age 15-60 yr 9:1 female to male	Large vessel vasculitis, cardiac valve disease	Raised ESR, CRP levels Alternating narrowing and aneurysm formation in aorta and great vessels	Vascular integrity, measurement of blood pressure, cardiac failure
Scleroderma	3:1 female to male	Raynaud phenomenon, skin disease, pulmonary hypertension, hypertensive renal failure, esophageal reflux, pulmonary fibrosis	Fibrosis on skin biopsy Pulmonary fibrosis Esophageal and intestinal hypomotility Reduced pulmonary diffusion capacity Urinary protein, raised creatinine level	Complications related to esophagus, lung, heart, kidneys
Juvenile arthritis	Before age 18 yr Female > male for some types	Polyarthritis; high fever and rash (Still's type)	Raised ESR, CRP levels Raised ferritin level Erosions of joints	Complications related to joint disease

ANAs, antinuclear antibodies; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; HELLP, hemolysis, elevated liver enzymes, and low platelets; RNP, ribonucleoprotein.

these pregnancy-related changes may alter the course of specific autoimmune diseases, but clear documentation that they do is lacking.

Diagnosis

Establishing a diagnosis of a systemic rheumatic illness requires combining symptoms and physical findings with compatible serologic abnormalities, markers of inflammation, and sometimes, imaging abnormalities. Established criteria exist for diagnosis of many of these diseases.¹⁷⁻¹⁹ Critical clinical and laboratory findings that can differentiate the various rheumatic diseases are displayed in Table 51-1.

Inflammatory arthritis may be indistinguishable in patients with SLE, rheumatoid arthritis, or juvenile arthritis, but in the latter two, it is more likely to be sustained than transient, and it is more likely to cause deformity. In patients with these illnesses, arthritis involves peripheral joints; in spondyloarthropathy, axial joint involvement pre-

dominates. The rashes of SLE and scleroderma are diagnostic. Livedo reticularis is common in antiphospholipid syndrome but is not specific for this diagnosis. Asymptomatic or minimally symptomatic pulselessness or vascular bruits suggest Takayasu arteritis; arterial occlusion due to antiphospholipid syndrome is usually abrupt and symptomatic.

A diagnosis of SLE in an untreated patient requires a strongly positive result for antinuclear antibody and anti-DNA or anti-Smith antibody. However, the concept of “lupus-like” is accepted, and these patients are managed as if they had unequivocal lupus. Similarly, the diagnosis of **antiphospholipid syndrome requires the presence of one or more of the following: a moderate to high titer (>40 IU) of anticardiolipin antibody of the IgG or IgM isotypes, lupus anticoagulant defined by the International Society on Thrombosis and Haemostasis standards,²⁰ or IgG or IgM antibody to β_2 -glycoprotein 1 present for at least 12 weeks. Diagnoses of rheumatoid arthritis, scleroderma, and juvenile arthritis can be made on clinical grounds alone. A diagnosis of Takayasu arteritis requires a biopsy, angiogram, or magnetic reso-**

nance or positron emission image that documents involves of the aorta or its great branches.

Management and Prevention

Knowledge of the pharmacology of drugs specific to systemic rheumatic disease is essential to the management of pregnant patients.²¹⁻²³ Because these diseases are chronic and likely to exacerbate, withdrawal of medications before or during pregnancy is usually ill advised. Planning for pregnancy must take into consideration the medications that the patient can take safely when she conceives.

Nonsteroidal anti-inflammatory drugs (NSAIDs) may cause oligohydramnios or, rarely, injure fetal kidneys or induce premature closure of the ductus arteriosus. Prednisone and methylprednisolone are largely inactivated by a placental hydroxylase and do not reach the fetus in significant concentrations. Fluorinated corticosteroids (i.e., dexamethasone and betamethasone) are not inactivated and should be used only when there is intent to treat the fetus. Whether the commonly used pulse administration of corticosteroid (1000 mg of methylprednisolone by rapid intravenous infusion, usually on 3 consecutive days) is safe in pregnancy is unknown.

Azathioprine, which is widely used in renal transplant recipients and patients with Crohn disease, is relatively safe,²⁴ but fetal malformations have occurred in animal models.²⁵ Cyclophosphamide, methotrexate, and leflunomide are contraindicated in early pregnancy because of their teratogenic and abortifacient properties, although a few infants of women given cyclophosphamide late in pregnancy have been normal.²⁶ The TNF- α inhibitors (i.e., etanercept, infliximab, and adalimumab) are rated relatively safe, despite the lack of long-term experience with these drugs.^{21-23,27} Table 51-2 summarizes conclusions of an international review group that systematically reviewed the published data.²¹

Patients with SLE, antiphospholipid syndrome, or spondyloarthropathy have normal fertility, and those with rheumatoid arthritis and scleroderma probably have slightly lower than normal fertility. Oral contraceptives likely do not induce exacerbation of SLE; they have a small or no effect on disease incidence.²⁸ Ovulation induction for purposes of enhancing fertility likely does not induce flares of lupus nor induce thrombosis in patients with antiphospholipid syndrome.²⁹ Except for imparting genetic susceptibility, paternal rheumatic illness does not cause infertility nor affect the child.

Rheumatic Diseases

Systemic Lupus Erythematosus

Although SLE patients may have intrinsic hormonal abnormalities, they are quantitatively minor and have no discernible effect on pregnancy outcome.³⁰⁻³² Pregnancy probably does not induce serious lupus flare.^{33,34} Diagnosing flare during pregnancy is difficult because pregnancy-induced thrombocytopenia, preeclamptic proteinuria, and palmar and facial erythema resemble SLE flare. Flare is most confidently diagnosed when a pregnant patient has new or increasing diagnostic rash (not erythema alone), lymphadenopathy, arthritis, fever, or anti-double-stranded DNA (anti-dsDNA) antibody.

Fetal health is threatened because approximately one third of all SLE patients have anti-Ro or anti-La antibodies, or both, as do a few patients with discoid lupus, most with subacute cutaneous lupus, and most with Sjögren syndrome. These antibodies predispose to neonatal

lupus. One third to one half of SLE patients have antiphospholipid antibodies, predisposing to fetal loss (discussed later).

Maternal Complications

Maternal complications are best considered by affected organ system, because global SLE exacerbation is rare. Approximately one fourth of all SLE patients develop thrombocytopenia during pregnancy, compared with about 7% of normal women.³⁵ Patients with antiphospholipid antibodies often have asymptomatic, low-grade thrombocytopenia ($>50 \times 10^9/L$) that worsens slightly during pregnancy. Abrupt, severe thrombocytopenia of the immune thrombocytopenia (ITP) type and lupus-related, low-grade chronic thrombocytopenia occur independent of pregnancy. No specific test clearly differentiates types of thrombocytopenia in pregnant patients with SLE. In our experience, in pregnant patients with lupus, thrombocytopenia equally often results from antiphospholipid antibodies, active SLE, and preeclampsia.

In patients with proteinuria, clinical signs of active SLE, rising levels of anti-dsDNA antibody, very low concentrations of complement, and urinary erythrocyte casts favor a diagnosis of lupus nephritis rather than preeclampsia. Rapid worsening over days suggests preeclampsia. Hypertension, thrombocytopenia, hyperuricemia, and hypocomplementemia occur in both; normal complement levels suggest preeclampsia. Two thirds of pregnant lupus patients who entered pregnancy with renal disease develop preeclampsia, compared with less than 20% of those without prior kidney disease.³⁶ In women with preexisting renal disease who develop preeclampsia, renal function may not return to its pre-pregnancy baseline.

Because skin blood flow increases in pregnancy, existing rash may become more prominent as pregnancy progresses. Patients who discontinue hydroxychloroquine for pregnancy often have recurrence of rash.

Joints previously damaged by lupus arthritis may develop noninflammatory effusions when ligament loosening occurs in late pregnancy. Neurologic lupus during pregnancy is rare, but case reports document chorea and transverse myelitis induced or exacerbated by pregnancy. In patients with seizures late in pregnancy accompanied by hypertension and renal failure, it may not be possible to distinguish between cerebral SLE and eclampsia. Treatment for both is usually indicated. Pulmonary hypertension may develop or worsen during pregnancy. Concomitant care with the obstetrician and rheumatologist is advisable.

Fetal Complications

If antiphospholipid antibodies, anti-Ro and anti-La antibodies, maternal fever, severe anemia, uremia, hypertension, and preeclampsia are absent, active SLE itself does not compromise the fetus. Infants born of SLE mothers with IgG-induced thrombocytopenia usually have normal platelet counts. Rarely, Coombs antibody causes hemolysis in the fetus; anti-dsDNA antibody has no apparent pathologic effect. Thrombosis due to antiphospholipid antibodies rarely occurs in the fetus.

The neonatal lupus syndrome includes photosensitive rash, thrombocytopenia, hepatitis, and hemolytic anemia, all of which are transient, and congenital complete heart block, which is not.³⁷ The syndrome occurs exclusively in neonates of women with high-titer anti-Ro/SSA or anti-La/SSB antibodies, or both, many of whom are clinically well (a small number later develop SLE or Sjögren syndrome). With the exception of neonatal lupus syndrome, there are no congenital abnormalities associated with SLE.

Congenital heart block is first diagnosable in utero by fetal electrocardiography, ultrasound, or cardiac rate monitoring between 18 and 25 weeks' gestation (average, 23 weeks). Among SLE patients with anti-

TABLE 51-2 PREGNANCY-RELEVANT CHARACTERISTICS OF COMMONLY USED ANTIRHEUMATIC DRUGS

Drug	FDA Pregnancy Class*	FDA Lactation Class [†]	Safety	Comments
Aspirin [‡]	D [§]	S(?)	Variable: depends on dose and time of use	Low dose may be partially protective against fetal death in antiphospholipid syndrome; may cause maternal and fetal bleeding if administered near term; high dose of uncertain safety
Naproxen, ibuprofen, ketoprofen, nabumetone, and similar drugs [‡]	B/D [§]	S(*)	Variable, depends on dose and time of use	Experience largely accumulated through treatment of headache or dysmenorrhea; no major teratogenicity; use after 34 weeks not advised
Ketorolac [‡]	C	S(*)	Causes dystocia and neonatal death in animals	Insufficient human experience
Celecoxib	C	S(?)	Few data	Insufficient human experience; not protective against thromboembolic disease
Indomethacin [‡]	B/D [§]	S(*)	Variable, depends on dose and time of use	Fetal pulmonary hypertension if used at term in third trimester; oligohydramnios
Prednisone	B	S	Generally safe	Trivial passage across placenta; safe in lactation but may suppress milk production
Methylprednisolone	B	NS	Probably safe	Similar to prednisone but fewer data available
Dexamethasone, betamethasone	C	NS	Probably safe in late pregnancy	Important transfer across placenta; used to induce fetal lung maturation
Hydroxychloroquine	C	S	Likely safe	Small published experience indicating safety
Azathioprine	D	NS	Safety uncertain	Large experience with renal transplant patients indicates no immediate danger to offspring if maternal dose is < 2 mg/kg/day; rare reports of congenital anomalies, including immunodeficiency
Cyclosporine	C	NS	Probably safe	Little experience, none suggesting high fetal risk
Cyclophosphamide	D	NS	Dangerous	Abortifacient, teratogenic
Methotrexate	X	NS	Dangerous	Abortifacient, teratogenic
Leflunomide	X	NS	Dangerous	Abortifacient, teratogenic
Etanercept	B	S(?)	Appears to be safe	No long-term studies in children
Infliximab	B	S(?)	Appears to be safe	No long-term studies in children
Adalimumab	B	S(?)	Appears to be safe	No long-term studies in children
Heparin	B	S	Appears to be safe	Anticoagulant of choice; causes osteoporosis
Low-molecular-weight heparin	B	S(?)	Similar to heparin	Similar to heparin, fewer data
Warfarin	X	S	Teratogenic and possibly fetotoxic	Fetal warfarin syndrome when given in first trimester; may cause central nervous system defects in second and third trimesters; risk of severe neonatal hemorrhage when given near term
Intravenous immunoglobulin	B	—	Appears to be safe	Administered antibodies carried to fetus

*U.S. Food and Drug Administration (FDA) pregnancy risk classification: A, controlled trials show no risk in humans; B, animal studies show no risk but no definitive studies in humans; C, animal studies show risk or no studies in humans or no information; D, positive evidence of risk but risk-benefit ratio may be acceptable in some circumstances; X, fetal risk and risk-benefit ratio always unacceptable.

[†]Lactation classification: S, safe; S(*), potential for significant effects on nursing infants, give only with caution; S(?) unknown, theoretically safe, insufficient literature; NS, not safe, contraindicated, known danger.

[‡]All inhibitors of prostaglandin synthesis activity may inhibit labor and prolong gestation. There is also a risk of in utero closure of the ductus arteriosus, particularly when used after 34 weeks' gestation.

[§]Risk category D when used in the third trimester.

^{||}Drug use restricted in patients with arterial occlusive disease.

Ro antibody, the risk that a liveborn child will have neonatal lupus rash is 25%, and congenital complete heart block is less than 3%. However, the risks of recurrent congenital heart block and neonatal lupus rash are 18% and 25%, respectively. Cardiac injury may be related to expression of the cardiac 52B Ro antigen after apoptosis of cardiomyocytes

and to induction of profibrotic cytokines around the conducting system.^{38,39} No specific antibody pattern predicts neonatal lupus rash. Several dizygotic twins and at least one monozygotic twin pair have been discordant for neonatal lupus, suggesting fetal contribution to illness.

Dexamethasone and plasmapheresis for the mother and early delivery have been used, with variable success, to treat fetal incomplete heart block, myocarditis, heart failure, and hydrops fetalis. Complete heart block in a newborn usually requires a permanent pacemaker. Even with a pacemaker, progressive fibrosis of the conducting system, cardiac failure, and sudden death may occur before age 5.

Preliminary data suggest that boys of SLE mothers have increased risk for learning disabilities but have normal intelligence, compared with sex- and gestational age-matched controls.⁴⁰ Children with complete congenital heart block remain at risk for cardiac death. Although case reports have described survivors of neonatal lupus who developed systemic lupus when they became adults, such events are rare. Other than the inherited tendency to develop rheumatic illness, there are no other known risks to children of other rheumatic disease mothers.

Antiphospholipid Syndrome

(See Chapter 40 for in-depth discussion of coagulation effects of antiphospholipid antibodies.)

Untreated patients with antiphospholipid syndrome and history of a fetal loss have a high frequency of mid-pregnancy intrauterine growth restriction or fetal death. Very high levels of antibody worsen the prognosis, and the simultaneous presence of several antiphospholipid antibodies increases risk, as does a prior fetal death.⁴¹ Low-level IgM and IgG anticardiolipin antibodies are not associated with poor fetal outcome, nor is an isolated false-positive test result for syphilis in the absence of other markers. Anti- β_2 -glycoprotein 1 antibodies predict fetal death in the occasional patient who tests negative for anticardiolipin and lupus anticoagulant.⁴² Few antiphospholipid syndrome patients suffer thromboses during pregnancy, possibly because most are prophylactically treated with heparin and low-dose aspirin. Risk of stroke and thrombophlebitis increases after delivery, especially after discontinuation of anticoagulant therapy. Ischemic cardiomyopathy and myocardial infarction may also occur after delivery. Thrombocytopenia, if a new occurrence during pregnancy, usually remits after delivery.

A pregnancy compromised by antiphospholipid antibodies is often initially uneventful, but the fetal growth rate then slows. Antepartum fetal heart rate monitoring studies show nonreactive fetal heart rate pattern, spontaneous bradycardia, diminished fetal motion, decreased amniotic fluid, reduced placental size, and, if delivery is not accomplished, fetal death. The mother may show no evidence of illness or may develop severe preeclampsia or HELLP syndrome (i.e., hemolysis, elevated liver enzymes, and low platelets). With treatment, fetal survival rates of more than 80% are possible, compared with less than 20% in the earliest series of untreated patients. After a patient has had a strongly positive test result for antiphospholipid antibodies during pregnancy, the fetal prognosis does not improve if lupus anticoagulant activity disappears or if anticardiolipin antibody levels decrease.

Placentas of SLE patients without antiphospholipid antibodies exhibit ischemic-hypoxic change and chronic villitis, whereas those of patients with antiphospholipid antibodies can also have decidual vasculopathy, extensive maternal floor infarction (Fig. 51-1) due to uteroplacental or spiral artery thrombosis, endothelial cell proliferation, or other fetoplacental vasculopathy.^{43,44} Antiphospholipid antibody, β_2 -glycoprotein 1, and placenta anticoagulant protein 1 (PAP-1) deposit together in placentas of mothers with antiphospholipid syndrome.⁴⁵ Studies^{46,47} underscore the importance of inflammatory infiltrates and complement deposits in placentas from patients with antiphospholipid antibodies.

Rights were not granted to include this figure in electronic media.
Please refer to the printed publication.

FIGURE 51-1 Patients with antiphospholipid antibodies may have decidual vasculopathy, extensive maternal floor infarction, endothelial cell proliferation, and other fetoplacental vasculopathy. **A**, Placental biopsy specimen demonstrates a lack of physiologic conversion, resulting in decidual vasculopathy. Arrow indicates spiral arterioles with smooth muscular walls and a small lumen. **B**, Placental biopsy specimen demonstrates fibrinoid necrosis in the decidual vessel wall (small arrows) and thrombosis in the decidual vessel (large arrow). (George D, Vasanth L, Erkan D, et al: Primary antiphospholipid syndrome presenting as HELLP syndrome. *Hosp Special Surg J* 3:216-221, 2007).

Monitoring of antiphospholipid syndrome pregnancies consists of ultrasound evaluation of the fetal growth rate and placental volume and appearance. Weekly antepartum fetal heart rate testing may begin as early as 25 weeks. In the 25- to 32-week period, a reactive nonstress test is defined as 2 accelerations of at least 10 bpm during a 20-minute interval. Thereafter, 15 bpm is used. Nonreassuring fetal testing indicates a need to deliver. Choice of the route of delivery is determined by obstetric criteria, as well as maternal and fetal platelet counts. Newborns who test positive rarely have pathologic clotting. Short-term follow-up studies of infant survivors of lupus patients indicate that these children develop normally compared with children of equivalent prematurity, but detailed information regarding children of non-SLE patients with antiphospholipid syndrome is not available.

The relationship of autoantibodies, particularly antiphospholipid antibodies, to failure of in vitro fertilization (IVF) and embryo transfer is unproven. Murine models of antiphospholipid syndrome show

abnormal blastocyst development and impairment of embryo implantation.⁴⁸ In animal models, fetal death depends on complement and adhesion molecules, and prevention of complement activation prevents fetal death. Heparin, the standard of care for pregnant patients with antiphospholipid syndrome, inhibits activation of complement and blocks leukocyte adhesion.^{15,49} Further evidence that these antibodies do not appear to be associated with very early pregnancy loss is found in a meta-analysis of seven studies examining the impact of antiphospholipid antibodies on IVF outcomes. Hornstein and associates⁵⁰ reported no significant association between antiphospholipid antibodies and clinical pregnancy (OR = 0.99; 95% confidence interval [CI], 0.64 to 1.53) or live birth rates (OR = 1.07; 95% CI, 0.66 to 1.75). The investigators concluded that measurement of antiphospholipid antibodies is not warranted in patients undergoing IVF. Moreover, there is no evidence that treating patients who have antiphospholipid antibodies improves IVF success rates.⁵¹ Other than placental insufficiency, with its risk of intrauterine growth restriction or fetal death, there are no special risks to the fetus.

Treatment recommendations for antiphospholipid syndrome pregnancy are presented in Table 51-3. Controlled treatment trials of women with two or more pregnancy losses demonstrate that low-dose aspirin (81 mg/day) plus subcutaneous unfractionated heparin (5000 to 12,000 units twice daily) begun after ultrasonographic confirmation of a viable pregnancy results in a rate of live births (not necessarily term) of more than 80%.^{52,53} The lower heparin dose is as effective as higher doses, but patients who have had prior thromboses require full anticoagulant doses. Low-molecular-weight heparin has been used successfully but has not been tested in controlled trials. In a small, controlled trial, intravenous immunoglobulin did not show benefit in the primary treatment of antiphospholipid syndrome patients,⁵⁴ but it is often used in those in whom heparin has failed. Warfarin is contraindicated because it is teratogenic. Osteoporosis remains a major potential side effect of heparin treatment,⁵⁵ although it is less common with low-molecular-weight heparin.

Based on empiric data of postpartum thromboses, treated women with no prior thromboses should receive oral warfarin for 6-12 postpartum weeks. Aspirin, if used during pregnancy, should also continue for at least 3 months.

Rheumatoid Arthritis

Whether women have a high rate of pregnancy loss before developing rheumatoid arthritis is controversial. Patients with established rheumatoid arthritis frequently improve during pregnancy. Proposed reasons include the immunosuppressive effects of endogenous corticosteroid, pregnancy-associated plasma protein A, and maternal-fetal human leukocyte antigen HLA-DQ and -DR disparity. The latest data favor the latter explanation.⁵⁶ Flare of rheumatoid arthritis often follows delivery, as does new development of rheumatoid arthritis.

Pregnancy is usually uneventful in rheumatoid arthritis patients. Rheumatoid joints may become unstable in late pregnancy as physiologic joint loosening occurs and as the patient's weight distribution changes. Undiagnosed cervical spine subluxation is a particular concern. Bacteremia occurring during labor, although rare, may seed involved joints. Antiphospholipid, anti-Ro, and anti-La antibodies are uncommon, and neonatal lupus therefore occurs infrequently. High-risk pregnancy monitoring usually is not necessary. There is a slight increase in risk of fetal growth restriction and maternal hypertension, and hospitalizations are slightly longer than normal for patients with rheumatoid arthritis.⁵⁷

Most patients need to continue their pre-pregnancy medications, including NSAIDs, corticosteroids, hydroxychloroquine, azathioprine, and TNF- α inhibitors. Low-dose prednisone is the safest option. Concomitant care with the obstetrician and rheumatologist is advisable.

Before delivery, the team managing the patient must take special care to identify the patient's disabilities to prepare for labor. Points for special emphasis are hip, knee, and neck arthritis and the potential risks of forcing joint motion beyond disease-imposed constraints,

TABLE 51-3 TREATMENT RECOMMENDATIONS FOR PREGNANT WOMEN WITH POSITIVE ANTIPHOSPHOLIPID ANTIBODY RESULTS AND NO OTHER EXPLANATION FOR PREGNANCY LOSSES

Patient Characteristic	Recommendation
High-Titer IgG or IgM aCL (>40 IU) or Positive LA Test*	
Primipara, multipara with most recent liveborn pregnancy or multipara with most recent pregnancy failure < 10 weeks (one loss)	Consider aspirin, 81 mg/day or no therapy initially; if modest (>50 \times 10 ⁹ /L) and thrombocytopenia occurs, add aspirin*
Multipara, multipara with most recent pregnancy failure < 10 weeks (more than one loss), or multipara with most recent pregnancy failure \geq 10 weeks (fetal loss)	Aspirin while trying to conceive; add heparin, 5000 units bid or low-dose LMWH at confirmation of fetal heartbeat, continue for duration of pregnancy
Multipara with prior premature birth due to preeclampsia or IUGR	Aspirin beginning after first trimester; consider heparin, depending on blood pressure control and renal function
Low-Titer IgG or IgM aCL	
Primipara, multipara with most recent liveborn pregnancy or multipara with most recent pregnancy failure < 10 weeks (one loss)	No therapy
Multipara, multipara with most recent pregnancy failure < 10 weeks (more than one loss), or multipara with most recent pregnancy failure \geq 10 weeks (fetal loss)	Aspirin while trying to conceive; add heparin, 5000 units bid or low-dose LMWH at confirmation of fetal heartbeat, continue for duration of pregnancy
Multipara with prior premature birth due to preeclampsia or IUGR	Aspirin beginning after first trimester; consider heparin, depending on blood pressure control and renal function

*For thrombocytopenia <50 \times 10⁹/L, consider intravenous immunoglobulin or prednisone, or both.

aCL, anticardiolipin antibody; aPL, antiphospholipid antibody; Ig, immunoglobulin; IUGR, intrauterine growth restriction; LA, lupus anticoagulant; LMWH, low-molecular-weight heparin.

causing fracture or other injury. Elective cesarean delivery may be necessary. If intubation is planned, an anesthesiologist familiar with temporomandibular arthritis and rheumatoid cervical spine disease should be available. There are no special risks to the fetus other than those related to maternal therapy.

Sjögren Syndrome

Sjögren syndrome is characterized by generally less severe arthritis but keratoconjunctivitis sicca. Sjögren syndrome often results from another autoimmune disease, and little is known about the interaction of pregnancy with the primary syndrome. **About 80% of Sjögren patients have anti-Ro/SSA and anti-La/SSB antibodies, and their children are therefore at risk for neonatal lupus.**⁵⁸ Intrauterine growth restriction is uncommon. Management of patients with Sjögren syndrome is the same as that for rheumatoid arthritis, except for the monitoring necessary for neonatal lupus. Treatment of the eye and mouth manifestations of primary Sjögren syndrome is the same as in the nonpregnant patient, but the effect of pilocarpine or cevimeline (U.S. Food and Drug Administration [FDA] category C drugs) on a fetus is unknown.

Scleroderma

Scleroderma often affects women in their late reproductive years, and pregnancy during established disease is uncommon. Patients with scleroderma generally do well but may tolerate pregnancy poorly if they have limited pulmonary, cardiac, or renal function. **Occasionally, scleroderma renal crisis occurs during pregnancy; it may be difficult to distinguish from preeclampsia.**^{59,60} Problems derive from nondistensible vascular beds and from preexisting renal, cardiac, and pulmonary insufficiency. **Gastroesophageal reflux, which is common during pregnancy even in women with normal esophageal motility, can be disabling.** Treatment is standard: small meals, elevating the head of the bed, histamine₂-blockers (FDA category B), and proton pump inhibitors (FDA category C), but not the prostaglandin E₁ analogue misoprostol (FDA category X). **Maternal preeclampsia, congestive heart failure, pulmonary hypertension, pulmonary insufficiency, and renal insufficiency may occur. Renal scleroderma may be indistinguishable from preeclampsia; it may justify termination of pregnancy.**⁶¹ Angiotensin-converting enzyme inhibitors and receptor antagonists are contraindicated in the periconceptional period because of their teratogenicity (risk ratio [RR] = 2.71; 95% CI, 1.72 to 4.27) and during pregnancy because of their potential to induce renal failure and fetal deformation due to prolonged oligohydramnios, except if renal hypertensive crisis refractory to all other antihypertension medications occurs.⁶² Patients with severe atonic small bowel disease can carry a pregnancy to term with the use of parenteral nutritional support. Prematurity and intrauterine growth restriction are the greatest risks to the infant. A high and persistent degree of transplacental transfer of fetal cells occurs in scleroderma patients, but the relationship of this finding to disease pathogenesis is unknown. Years after pregnancy is over, fetal cells can still be found in affected maternal skin sites.^{63,64}

Spondyloarthropathy

Women with ankylosing spondylitis have normal fertility. Most patients experience no change or modest worsening of complaints during pregnancy; those who worsen return to baseline after delivery.⁶⁵ Patients with psoriatic arthritis may improve during pregnancy. Other than the specific anatomic problems of spondyloarthropathy (i.e., restricted

motion of the hips and lower back that may impede vaginal delivery), patients have no unusual problems with pregnancy. Treatment for painful back is problematic because indomethacin and other NSAIDs may cause fetal harm.

Vasculitis

Patients with Takayasu disease may do well, but renovascular occlusive disease, pulmonary hypertension, and aortic insufficiency remain important potential problems. Preeclampsia is common. Management during pregnancy involves careful monitoring and treatment of hypertension (diagnosis and monitoring of which is difficult when arm arteries are occluded) and aggressive hemodynamic and pharmacologic management in the peripartum period. Sixty percent of infants have intrauterine growth restriction related to maternal aortic involvement, hypertension, and preeclampsia.

Miscellaneous Disorders

Hip disease of any kind may interfere with normal vaginal delivery, because abduction may be severely limited. Forcing a patient's joint motion beyond the point at which she feels pain or at which resistance is encountered is painful and risks fracture, dislocation, or other permanent harm. **Antibiotic coverage (i.e., a cephalosporin plus gentamicin or vancomycin plus gentamicin) may be indicated in women with artificial joint replacements undergoing vaginal delivery.** Pelvic and back pain may be caused by laxity of the pubic symphysis and sacroiliac joints, which is associated with increased serum levels of relaxin. Labor and delivery are occasionally complicated after delivery by infectious sacroiliitis or osteitis pubis. For diagnosis of back pain in pregnant patients, magnetic resonance imaging is preferable to computed tomography. Ultrasound, infrared therapy, and warm water therapeutic pool therapy may injure the fetus.

Pregnancy Management

Monitoring recommendations for patients with rheumatic disease are presented in Table 51-4. Unexplained elevations of maternal α -fetoprotein and human chorionic gonadotropin occur in patients with lupus and with antiphospholipid antibodies. These abnormalities correlate with preterm delivery, requirements for a higher prednisone dose, and fetal death.⁶⁶ **Because intervention with dexamethasone at the earliest sign of cardiac dysfunction may reverse myocarditis and possibly congenital heart block, women with high-titer anti-Ro and anti-La antibodies and those who have previously given birth to a child with any form of neonatal lupus should undergo fetal cardiac monitoring weekly during the vulnerable period of 18 to 25 weeks' gestation.** In women known to be strongly positive for lupus anticoagulant and anticardiolipin antibody, repeat testing for these antibodies during pregnancy is unnecessary, because spontaneous correction of the lupus anticoagulant level and a decrease in the anticardiolipin antibody level does not improve prognosis. In women with low antibody levels or negative test results, repetition at least once each trimester is useful because overall prognosis is that of the highest level seen during the pregnancy. The platelet count should be repeated monthly. Women significantly positive for antiphospholipid antibodies and who have had a prior fetal loss should be treated with low-dose aspirin and unfractionated or low-molecular-weight heparin.

Decisions regarding timing and route of delivery are dictated by the status of the fetus but may be influenced by maternal illness and its

TABLE 51-4 RECOMMENDED EVALUATION OF PREGNANT PATIENTS WITH AUTOIMMUNE RHEUMATIC DISEASE

Recommended Frequency	Monitoring Test
First visit	Complete blood count and urinalysis* Creatinine clearance Antiphospholipid antibodies Anti-Ro and anti-La antibodies Anti-dsDNA antibody (SLE patients) Complement (C3 and C4 or CH ₅₀) (SLE patients)
Monthly	Platelet count [†]
Each trimester	Creatinine clearance [†] A 24-hour urine protein assay if screening urinalysis is abnormal [†] Complement [†] and anti-dsDNA antibody [†]
Weekly (last trimester, mothers with antiphospholipid antibodies)	Antenatal fetal heart rate testing (nonstress test), and/or biophysical profile [‡]
Between 18 and 25 weeks (mothers with anti-Ro/La antibodies)	Fetal echocardiogram, fetal electrocardiogram (?)

*The erythrocyte sedimentation rate is often abnormal in uncomplicated pregnancy.

[†]More frequently if abnormal.

[‡]Measure of fetal size, activity, and amniotic fluid volume.

CH₅₀, hemolytic complement level; dsDNA, double-stranded DNA; SLE, systemic lupus erythematosus.

complications. Approximately one third of SLE patients undergo operative delivery. The usual indications for cesarean delivery are fetal distress, prior cesarean delivery, prolonged ruptured membranes, failure to progress at labor and other obstetric reasons, thrombocytopenia, and severe maternal illness.

There is little information about the use of tocolytics or stimulators of labor in pregnant women with rheumatic disease. Ritodrine, magnesium sulfate, and prostaglandin suppositories have been used without incident. At delivery, stress corticosteroid doses (usually 100 mg of hydrocortisone every 8 hours from the onset of labor until 24 hours after delivery) are administered to patients currently or recently taking corticosteroids. Asymptomatic bacteremia occurs in 3.6% of vaginal deliveries. Because of limited hip joint movement or risk of bacterial seeding, osteonecrosis of the hip may justify a decision for operative rather than vaginal delivery. The mode of delivery for patients with total hip replacements need not be surgical; patients have been delivered vaginally with appropriate attention paid to the positioning of the patient.

Chapter 52

Neurologic Disorders

Michael J. Aminoff, MD, DSc

Women are as susceptible to neurologic disorders during gestation as at other times, and certain disorders may be aggravated or influenced by pregnancy. Investigation and management of many neurologic disorders may be complicated by the pregnancy and by concern about the safety of the developing fetus. This chapter describes some of the special problems posed by neurologic disorders during pregnancy and by pregnancy in patients with neurologic disorders.

Epilepsy

Women with epilepsy should be advised about possible interactions between anticonvulsant drugs and oral contraceptive agents. Whether oral contraceptives affect seizure frequency or blood levels of antiepileptic drugs is unclear, but certain anticonvulsants, including phenytoin, phenobarbital, primidone, carbamazepine, oxcarbazepine, and topiramate, may interfere with the effectiveness of oral contraceptives, leading to unwanted pregnancy.^{1,2} The possibility of contraceptive failure must be discussed with women taking these anticonvulsants and documented in the records. Regular counseling of women with epilepsy is necessary during the reproductive years, because unplanned pregnancy may occur. Valproic acid and the newer anticonvulsants (i.e., zonisamide, vigabatrin, gabapentin, lamotrigine, levetiracetam, pregabalin, and tiagabine) have not been reported to cause contraceptive failure.^{2,3} When oral contraception is desired in women taking enzyme-inducing anticonvulsants, a formulation that includes at least 50 µg of ethinyl estradiol or mestranol is preferred.

Between 0.3% and 0.6% of pregnant women have epilepsy. Pregnancy may affect the seizure disorder, and the disorder may affect the course of the pregnancy and the manner in which it is best managed. Moreover, recurrent seizures and drugs given to the mother in an attempt to control them may affect fetal development.

Effect of Pregnancy on Seizure Disorders

Pregnancy has an unpredictable and variable influence on epilepsy. When seizure frequency increases, it most commonly does so in the first trimester and usually reverts to the pregestational pattern at the conclusion of the pregnancy, although a few patients experience a permanent deterioration in seizure control. In general, control in patients with frequent seizures (i.e., more than one a month) before pregnancy is likely to deteriorate during the gestational period, whereas only about 25% of patients with infrequent attacks (i.e., less than one every 9 months) experience an exacerbation during pregnancies.

In a prospective study of 136 pregnancies in 122 epileptic women, seizure frequency increased in 50 pregnancies (37%), often in association with noncompliance with a therapeutic regimen.⁴ Among several other series, seizures increased during pregnancy in 23% to 75% of instances.⁵ Tanganelli and Regesta⁶ found that seizures were more likely to be exacerbated during pregnancy in women with more frequent seizures before the pregnancy and in those with partial (focal) seizure disorders. Seizure control is unchanged in 53% to 67% of patients.⁷

It is usually not possible to predict the outcome in individual cases, regardless of the maternal age, the outcome of previous pregnancies, or any apparent relationship between seizures and the menstrual cycle. None of these provides a guide to the effect that pregnancy will have on the course of epilepsy. Moreover, attacks may occur during pregnancy in patients who have been free of seizures for several years.

Epilepsy may appear for the first time during or immediately after pregnancy. It is uncommon for patients in the latter group to have seizures only in relation to pregnancy and at no other time (i.e., gestational epilepsy). Some patients with true gestational epilepsy experience recurrent seizures during pregnancy, and the remainder have only a single convulsion. The occurrence of seizures in one pregnancy is no guide to the course of subsequent pregnancies.

The seizures that occur during pregnancy do not differ clinically from those occurring in other circumstances. Improved compliance with an anticonvulsant drug regimen may sometimes account for the reduction in seizure frequency that occasionally occurs during pregnancy in an epileptic woman.

The increase in seizure frequency that occurs in some epileptic patients during pregnancy may relate to the metabolic, hormonal, or hematologic changes of the gestational period or to fatigue or sleep deprivation. A rapid and excessive gain in weight sometimes occurs before an increase in seizure frequency, providing some support for the belief that fluid retention may occasionally be a factor, perhaps by a dilutional effect on anticonvulsant drug concentration. It is tempting to relate any change in seizure frequency to hormonal factors because estrogens are epileptogenic in animals and progesterone has both convulsant and anticonvulsant properties. Nausea, vomiting, reduced gastric motility, or use of antacids may also lead to reduced absorption of anticonvulsant drugs.

There is sometimes difficulty in maintaining adequate treatment with anticonvulsant drugs during pregnancy. Serum levels of the older antiepileptic drugs generally decline in pregnancy and rise in the postpartum period. For phenytoin, carbamazepine, and valproate (but not phenobarbital), the decline is less for free levels than total levels. An increase in dosage is frequently required to maintain plasma levels at

pre-pregnancy values, but in this regard, it is important to appreciate that the free level, rather than the total level, of the drug correlates best with therapeutic efficacy. Several new antiepileptic drugs, such as felbamate, gabapentin, and lamotrigine, have become available, but the effect of pregnancy on their pharmacokinetics is unclear.

The reason for the changes in drug requirements is unknown. Among the various possibilities are the dilutional effect of increasing plasma volume and extracellular fluid volume. Poor compliance with the anticonvulsant drug regimen, perhaps because of nausea and vomiting or concerns about the effect of medication on the fetus, may also be an important contributory factor, as may decreased plasma protein binding and changes in the absorption and excretion of drugs. The increased metabolic capacity of the maternal liver in pregnancy and possible fetal or placental metabolism of part of the anticonvulsant dose may influence the changes in anticonvulsant drug requirements that occur in epileptic women during pregnancy.

Folic acid therapy may lower the plasma phenytoin level, sometimes to below the therapeutic range, and other drugs taken concomitantly with an anticonvulsant medication also may lead to reduced plasma levels of the anticonvulsant. Antacids and antihistamines merit particular mention, because it is not uncommon for them to be taken during pregnancy.

Status epilepticus sometimes complicates pregnancy and may occur without any preceding increase in seizure frequency, occasionally because of the injudicious discontinuation of anticonvulsant drugs. Fortunately, this is a rare occurrence, but it may lead to a fatal outcome for the mother or fetus. The absence of hypertension, proteinuria, and edema helps in distinguishing this condition from eclamptic convulsions. As in the nonpregnant patient, it is essential to obtain control of the seizures as rapidly as possible, but the former practice of terminating pregnancy is usually unnecessary.

Status epilepticus is treated with anticonvulsant drug therapy, with the pregnancy being allowed to continue to term. Intravenous diazepam (10 to 30 mg) or lorazepam (4 to 8 mg) usually provides temporary control of the seizures, but other anticonvulsant drugs are needed as well to prevent seizure recurrence. Intravenous phenytoin is usually given but is best administered in the form of fosphenytoin sodium, the dose of which is expressed in terms of phenytoin equivalents. Fosphenytoin sodium is water soluble, may be infused with dextrose or saline, is better tolerated at the infusion site than phenytoin, and may be infused three times more rapidly than intravenous phenytoin, with the same pharmacologic effects. It is converted in the body to phenytoin, which may be cardiotoxic, and cardiac monitoring is required while the fosphenytoin is given in a loading dose of 15 to 20 mg of phenytoin equivalents per kilogram, infused at a rate of up to 150 mg of phenytoin equivalents per kilogram. Other anticonvulsants may also be required, including intravenous phenobarbital or midazolam. It is essential to maintain control of the airway and of glucose and electrolyte balance.

Effect of Epilepsy on Pregnancy and Lactation

Only a few studies have attempted to document the effect of epilepsy on pregnancy. The results are often difficult to evaluate because of the limited number of cases reported; the lack of comparative data on non-epileptic women attending the same institutions; differences in the severity of the epilepsy and how it has been treated; differences in age, medical background, and socioeconomic status of the patients reported; and the lack of information concerning relevant social habits such as cigarette smoking and alcohol ingestion.

The incidence of vaginal hemorrhage and of toxemia during pregnancy among epileptic women was found to be increased in some studies but not others. Whether preterm labor occurs more commonly in epileptic women, as is sometimes reported, is unclear. There is a significantly higher rate of stillbirths among epileptic patients, but there does not seem to be an increased incidence of low-birth-weight infants, at least in some studies. Cesarean section is not indicated simply because of maternal epilepsy, except when seizures occur frequently or during labor, when they are precipitated by physical activity, or when patients cannot cooperate during labor because of their neurologic disorder or mental abnormality.⁸ Fetal death can result from maternal seizures, presumably because of the accompanying hypoxia and acidosis. The effect on placental blood flow of maternal seizures is not established, but changes in fetal heart rate suggestive of hypoxia have been described^{5,9}; they may relate to reduced placental blood flow or to metabolic changes in the mother.

An increased incidence of neonatal death has been reported for the offspring of epileptic mothers. The increased rate may relate to several factors, including congenital malformations, iatrogenic neonatal hemorrhage, seizures, socioeconomic issues, and preterm delivery.

Anticonvulsant drugs taken by the mother may be present in breast milk, but their concentration is usually insufficient to have any major effect on the infant. The transmission rate of antiepileptic drugs into breast milk varies with the agent and is about 2% for valproic acid; 30% to 45% for phenytoin, phenobarbital, and carbamazepine; 60% for primidone; and 90% for ethosuximide.¹ When obvious sedation develops in an infant that is likely related to antiepileptic drugs in breast milk, breastfeeding should be discontinued, and the infant should be observed for signs of drug withdrawal. Breastfeeding does not need to be discouraged for reasons related to its content of anticonvulsant medication.

Effect of Maternal Epilepsy and Anticonvulsant Drugs on the Fetus and Neonate

The epileptic woman who becomes pregnant usually is concerned that her unborn child may inherit a similar susceptibility to seizures. The risk of epilepsy in the child depends on the nature of the mother's seizure disorder; it is higher in idiopathic than acquired maternal epilepsy. Precise quantification of the risk is not possible, but it is probably about 2% to 3%. The cause of this increased risk to the offspring of epileptic mothers is unknown. It may relate to genetic factors, seizures arising during pregnancy, or the metabolic and toxic consequences of seizures or anticonvulsant drugs. In general, pregnancy in epileptic women does not need to be discouraged on these grounds, but reassurance and support are necessary.

A major problem in management of epileptic patients during pregnancy is the possibility that certain anticonvulsant drugs may induce fetal abnormalities. However, epilepsy has a relatively low prevalence rate, can occur for a multitude of reasons, can vary markedly in severity, can be treated by a variety of drugs singly or in combination, and can itself be associated with an increased risk of fetal malformations. Some patients may have a common genetic predisposition to seizures and to fetal malformation. Environmental factors may be important in the genesis of congenital abnormalities, and socioeconomic backgrounds must be matched as much as is possible when comparisons are made of the incidence of malformations in different patient populations.

All the commonly used older antiepileptic drugs are teratogenic to some extent, and malformation rates are higher for the offspring of mothers taking drug combinations. The study by Jones and associates¹⁰

revealed a relatively high incidence of craniofacial defects, fingernail hypoplasia, and developmental delay in children exposed prenatally to carbamazepine. Its use during pregnancy, particularly in combination with other drugs, has been associated with an increased risk for spina bifida.¹¹ Valproic acid has an especially high (1% to 2%) rate of neural tube defects^{12,13}; it may also cause cleft lip or palate, delayed development, and disorders of the cardiovascular, genitourinary, and endocrine systems.^{14,15} Trimethadione seems particularly dangerous and causes fetal malformations and mental retardation in more than 50% of exposed infants. This drug, which is now rarely used, should be avoided during pregnancy when possible. Whether newer anticonvulsant drugs, such as felbamate, gabapentin, lamotrigine, tiagabine, topiramate, oxcarbazepine, and vigabatrin, are teratogenic is unknown, but some evidence suggests that lamotrigine and oxcarbazepine are teratogenic.¹⁶

Animal studies lend support to the belief that some anticonvulsants are teratogenic. The mechanism involved is unclear but may include folate deficiency or antagonism. Dansky and associates,¹⁷ for example, showed that low blood folate levels before or early in pregnancy are significantly associated with spontaneous abortion and the occurrence of developmental anomalies. It has also been suggested that certain oxidative intermediary metabolites of anticonvulsants may affect cell division and migration.

Although most children born to epileptic mothers are cognitively normal, prenatal antiepileptic drug exposure may be associated with developmental delay,¹⁸ particularly when more than one drug has been taken by the mother. The mechanisms involved are unclear, but a genetic predisposition may be important.¹⁹ It is also unclear whether some anticonvulsant drugs pose a greater risk than others.

Maternal use of phenytoin during pregnancy has been associated with the fetal hydantoin syndrome, which is characterized by prenatal and postnatal growth deficiency, microcephaly, dysmorphic facies, and mental deficiency. Among infants exposed to phenytoin in utero, 11% have enough clinical features to be classified as having this syndrome, and almost three times as many may show lesser degrees of impairment of performance or morphogenesis. The syndrome is not unlike that ascribed to phenobarbital and carbamazepine,¹⁰ and it resembles the fetal alcohol syndrome. A consistent facial phenotype has also been reported in children exposed to valproic acid or sodium valproate in utero.^{20,21}

Maternal use of barbiturates (60 to 120 mg daily) in late pregnancy may be associated with neonatal withdrawal symptoms beginning a week after birth. They include restlessness, constant crying, irritability, tremulousness, difficulty in sleeping, and vasomotor instability but not seizures.

Clinical or subclinical coagulopathy may occur in the neonate whose mother received anticonvulsants during pregnancy. In affected infants, levels of factors II, VII, IX, and X are decreased, and levels of factors V and VIII and fibrinogen are normal. The abnormalities are similar to those produced by vitamin K deficiency. Bleeding in affected infants tends to occur within 24 hours of birth, rather than on the second or third day, as in classic hemorrhagic diseases of the newborn, and at relatively unusual sites, such as the pleural and abdominal cavities. Prevalence rates average about 10%, but the mortality rate may exceed 30%.⁵ Bleeding may also occur in utero, resulting in stillbirth. No evidence of coagulopathy is found in the mothers.

Maternal ingestion of vitamin K₁ (10 mg daily) during the last month of pregnancy may prevent these hemorrhagic complications in the offspring of treated epileptic mothers,²² but it is unclear whether routine prophylaxis in this manner is justifiable because some studies suggest that such hemorrhagic complications are rare.^{23,24} Vitamin K₁

administration to the newborn infant usually reverses the bleeding tendency, but the infant may die despite such therapy. It is therefore recommended that prothrombin and partial thromboplastin times of cord blood be measured at delivery if the mother received anticonvulsant drugs. If the value is abnormally low or if there is clinical evidence of a coagulopathy during the neonatal period, treatment with infusion of fresh-frozen plasma or concentrates of factors II, VII, IX, and X may have to be considered in addition to the routine administration of vitamin K₁.

General Therapeutic Approaches

It is difficult to make more than general therapeutic recommendations about pregnancy in the epileptic woman. Epilepsy should be treated with the smallest effective dose of an anticonvulsant drug, and monotherapy is preferable to polytherapy. Drug selection is based on seizure type, clinical status, and the maternal and fetal risks.²⁵ Folate supplementation (4 mg daily) usually is provided.

Prenatal counseling is important. If a nonpregnant epileptic woman asks about pregnancy, it is appropriate to inform her that there is a small risk of having a malformed child because of the seizure disorder or the drugs used in its treatment. This risk is probably about double that for the non-epileptic patient, but there is still a more than 90% chance that she will have a normal child.

Data concerning the relative safety and therapeutic effectiveness of different anticonvulsant drugs in the management of pregnant epileptic patients are insufficient to guide the physician responsible for the care of these patients. It seems clear, however, that trimethadione should not be used and that valproic acid should be avoided. If valproic acid must be used, amniocentesis is advisable to detect any increase in α -fetoprotein levels (which is associated with neural tube defects) so that therapeutic abortion can be considered if necessary. Substitution of one anticonvulsant drug for another in epileptic women who are initially seen after the first trimester should be avoided, because major malformation of the fetus has probably occurred already if it is going to occur.

The principles of drug management of a seizure disorder in the pregnant woman are the same as in the nonpregnant woman. Anticonvulsant drugs are as necessary to epileptic patients during pregnancy as at other times. A detailed account of the drugs used in the treatment of epilepsy is unnecessary here, but several points are worthy of comment.

A solitary seizure, unrelated to toxemia, should not lead to a diagnosis of epilepsy because there may be no further attacks. Only time will tell whether an individual who has a single seizure is going to have further attacks, thereby justifying a diagnosis of epilepsy and necessitating prophylactic anticonvulsant drug treatment.

Although some physicians start a patient on anticonvulsant medication after one convulsion, others prefer to withhold medication until the patient has had at least two seizures, at least in the nonpregnant state. During pregnancy, many physicians initiate anticonvulsant therapy after even a single seizure and arrange for neurologic reevaluation after delivery. This approach merits emphasis because many patients with so-called gestational epilepsy have only a single convulsion, and continued treatment in such circumstances may be unnecessary. Simple medical and neurologic investigations are indicated in an adult who has an isolated seizure and is otherwise well with no neurologic signs: hematologic and biochemical screening tests, electroencephalogram, and particularly in the nonpregnant patient, magnetic resonance imaging (MRI) of the head and a chest radiograph. If the findings of such investigations are unremarkable, I discuss the contro-

versial issue of anticonvulsant drug treatment with the patient but generally recommend that treatment be withheld unless a future attack occurs.

Pregnant women experiencing two or more seizures merit prophylactic anticonvulsant drug treatment. In those with a progressive history, abnormal neurologic signs, or a focal electroencephalographic abnormality, it is necessary to exclude an underlying structural lesion by means of MRI of the head. The management of such a lesion is described later in this chapter.

If prophylactic anticonvulsant drug treatment is necessary, it is generally continued until the patient has been seizure free for at least 2 or 3 years. Treatment is started with a small dose of one of the anticonvulsants, depending on the type of seizure experienced by the patient and the considerations outlined earlier. The dose is increased until seizures are controlled, blood concentrations reach the upper end of the optimal therapeutic range, or side effects limit further increments. If seizures continue despite optimal blood levels of the anticonvulsant drug selected, a second drug should be substituted for the first. Patients often respond preferentially to one or another of the various drugs that are available. Experience during pregnancy with certain newer antiepileptic agents (e.g., felbamate, lamotrigine, gabapentin, topiramate) is limited, however, and their effect on the developing fetus is uncertain.

Patients must take medication as prescribed, and treatment should be controlled by frequent monitoring of the plasma anticonvulsant drug concentration. Monthly follow-up visits during pregnancy usually permit satisfactory supervision of the patient. At the initial visit, trough values of total and free concentrations of each drug should be measured. Total levels should then be measured each month in patients whose seizures are well controlled; free levels should be monitored monthly in those with poor seizure control, seizures during pregnancy, or a marked (>50%) decline in total level. Poor compliance with an anticonvulsant drug regimen can often be improved by encouragement and by explanation of the importance of taking medication regularly. Simplifying the dosage schedule so that medication is taken just once or twice daily may be helpful.

As the pregnancy continues, the dose of the anticonvulsant drug may need to be increased if seizures become more common or the free level of the anticonvulsant drug declines by more than about 30%. In some instances, the required dose may reach a level that would probably cause toxic side effects in a nonpregnant patient. If the anticonvulsant dosage is increased during the pregnancy, reductions will probably be necessary in the puerperium to prevent toxicity, but this change must be based on clinical evaluation and measurement of the plasma concentration of the drug, because the period over which drug requirements decline varies considerably. Because of the poorly defined risks of increased obstetric complications among pregnant epileptic women, close supervision of these patients by the obstetrician is mandatory, and delivery in a hospital is advised.

After delivery, the infant must be inspected for congenital malformations and given an injection of vitamin K₁ (1 mg/kg intramuscularly). Clotting factors should be studied after about 4 hours, and further injections of vitamin K₁ should be given if necessary. If hemorrhage occurs, infusions of fresh-frozen plasma or of factors II, VII, IX, and X may also be necessary. Breastfeeding of a healthy infant by an epileptic mother should not be discouraged.

Headache

Headache is a common complaint and may have many causes. Among patients attending headache clinics, symptoms are most frequently

attributed to migraine, tension, or depression. Tension headaches are commonly chronic, last all day, are worse in the evening, may have a tight quality to them, may be accompanied by local soreness and concern about lumps or bumps on the head, and are often accompanied by poor concentration and nonspecific symptoms such as dizziness. The pain frequently commences or is most intense in the neck and the back of the head. If treatment with mild tranquilizers (e.g., diazepam) is unsuccessful, a trial of antimigraine preparations may be worthwhile. Depression headaches are somewhat similar but are often worse in the mornings, may be accompanied by other symptoms of depression, and often respond to a limited extent to tricyclic antidepressant drugs.

Most patients presenting with headache do not have severe underlying structural disease, but it is important to consider this possibility. About one third of patients with brain tumors present with a primary complaint of headache. The headache in such patients is often an intermittent, dull, nonthrobbing ache that is exacerbated by exercise and may be associated with nausea or vomiting, but these features do not in themselves permit any reliable distinction from migraine. Similarly, the severity of the headache is unhelpful in this regard. Headaches that disturb sleep, however, suggest an underlying structural lesion, as do exertional headaches and late-onset paroxysmal headaches.

The duration and course of a headache provide a guide to the underlying cause. A long history of chronic headache without other accompaniments is unlikely to reflect serious disease unless associated with drowsiness, visual disturbances, limb symptoms, seizures, intellectual changes, or other neurologic symptoms. The sudden development of severe headache in a previously well patient is more ominous and may be caused by acute intracranial abnormality (e.g., subarachnoid hemorrhage), glaucoma, or another condition requiring specific treatment.

The evaluation of patients with headaches demands a full general and neurologic examination together with an assessment of mental status. It may be necessary to include examination of the teeth, eyes, paranasal sinuses, and urine, and various investigative procedures may be indicated, depending on the initial clinical impression. If intracranial disease is suspected on the basis of the history or presence of neurologic signs, the need for computed tomography (CT) or MRI of the head, an electroencephalogram, and examination of the cerebrospinal fluid must be decided on an individual basis. Cranial arteritis and cervical spondylosis are important causes of headache but are not expected among patients in the childbearing age group.

Post-traumatic headaches usually pose no diagnostic problem because of the relationship to previous injury, and they usually respond to simple analgesics, mild tranquilizers, or antimigraine preparations. Acute sinusitis typically produces a localized, throbbing headache accompanied by tenderness; the relationship of symptoms to a respiratory tract infection and the radiologic findings permit the diagnosis to be made with confidence, and treatment is directed at the underlying infection.

Migraine

Among women of childbearing age, migraine is an important cause of headache. In classic migraine, episodic headache is preceded by visual, sensory, or motor symptoms, but in other types, there may be no premonitory focal symptoms. Headaches may be lateralized or generalized, usually have a gradual onset, and usually last for less than a day, although they may persist for longer. They may be dull or throbbing; are commonly accompanied by nausea, vomiting, and photophobia; and are often associated with blurring of vision, lightheadedness, and

scalp tenderness. Photopsia, fortification spectra, and other focal neurologic symptoms may precede or accompany the headache, and consciousness is sometimes impaired or lost (syncopal attacks or seizures).

Many women with migraine link the periodicity of some of their attacks to the menstrual cycle, with headaches occurring usually just before or during menstruation. Migrainous attacks without aura are most likely to be related to the menstrual cycle.²⁶ Some patients may have headaches that occur only in relation to the menstrual cycle, although this pattern is much less common. The manner in which hormonal factors provoke migraine remains unclear.^{26,27}

Migraine headaches are commonly exacerbated in women using oral contraceptives, but improvement can occur in some patients. Such exacerbation usually becomes apparent within the first few months of oral contraceptive use. Preparations with a relatively high estrogen content are most likely to influence the headache pattern and are generally not as well tolerated as low-estrogen preparations. Recurrent headache provoked by the use of oral contraceptives may persist despite withdrawal of the offending medications, but whether this is anything more than fortuitous is unclear.²⁸ Of special concern is evidence suggesting that women with migraine exacerbated by oral contraceptives are at increased risk for cerebral infarction,²⁹ perhaps caused by intimal hyperplasia of arteries supplying the brain.³⁰

Migraine often improves considerably after the first trimester of pregnancy, regardless of whether the attacks are related to the menstrual cycle. It occasionally worsens or occurs for the first time during pregnancy, most commonly during the first 3 months of gestation.³¹ The response of migraine to pregnancy does not correlate with sex of the fetus or with differences in plasma levels of hormones.

Management of migraine consists of the avoidance of precipitating factors coupled with prophylactic or symptomatic drug treatment, if necessary. In general populations, when simple analgesics do not provide relief, treatment with extracranial vasoconstrictors (e.g., ergotamine, dihydroergotamine), β -adrenergic blockers (e.g., propranolol), serotonin agonists (e.g., sumatriptan), tricyclic antidepressants (e.g., amitriptyline), or other drugs may be necessary. Menstrual migraine may improve with standard pharmacologic therapy. Hormonal interventions are usually unsuccessful, but bromocriptine (2.5 mg three times daily) is sometimes worthwhile.³²

During pregnancy, medication is best avoided if possible. Dietary and other precipitants of headache should be avoided. When drugs are required, simple analgesics should be used. Acetaminophen is preferred over aspirin, because aspirin may cause hemorrhagic complications and, in large doses in late pregnancy, may prolong labor and increase the incidence of stillbirth.^{33,34} Tryptamine-based drugs should be avoided during pregnancy and breastfeeding, although there is no definite evidence of teratogenicity.³⁵ Meperidine suppositories (50 mg) may be prescribed for severe pain.³⁶ An effort should be made to avoid ergotamine-containing preparations because of the effect this drug may have on the gravid uterus and its potential teratogenicity. Propranolol is also best avoided during pregnancy because it may mildly impair fetal growth³⁷ and may theoretically lead to β -adrenergic blockade in the fetus or newborn. Inhibition of normal β -adrenergic responsiveness to asphyxia or to other stresses may theoretically increase the harmful effects of the latter.³⁸ Other reported potential neonatal complications include prematurity, respiratory depression, hypoglycemia, and hyperbilirubinemia.^{39,40} In patients with frequent headaches, comorbidities such as depression require special consideration.

A study of the possible association of maternal migraine during pregnancy with outcome revealed that women with severe migraine have a higher prevalence of preeclampsia and severe nausea or vomit-

ing but a lower prevalence of threatened abortion and preterm delivery.⁴¹ This did not appear to influence delivery outcome.⁴¹

Postnatal Headache

About one third of women experience headaches in the week after delivery, and most of them have a personal or family history of migraine. The headaches, which are usually mild and bifrontal, respond well to simple analgesics and are self-limited.

Tumors

Any type of intracranial tumor can appear during the gestational period, and accurate diagnosis may then be delayed because symptoms are erroneously ascribed to toxemia of pregnancy. Although the relationship between the tumor and pregnancy is usually fortuitous, pituitary adenomas, meningiomas, neurofibromas, hemangioblastomas, and vascular malformations occasionally exhibit relapses in relation to pregnancy, with symptoms developing or rapidly worsening during gestation, remitting to some extent after delivery, and recurring in a subsequent pregnancy. Attention here focuses on the aspects of intracranial tumors that relate to pregnancy rather than on a more general account of intracranial neoplasms.

Visual field defects sometimes develop during pregnancy in patients with a pituitary adenoma or a craniopharyngioma, which must be excluded in such circumstances. Meningiomas in the suprasellar or parasellar region or on the medial sphenoidal wing may produce symptoms such as diplopia and unilateral scotoma or ptosis, which relapse and remit in relation to pregnancy over several years. Symptoms tend to develop in the last 4 months of gestation and often lead to a mistaken initial diagnosis of multiple sclerosis. Early surgical intervention may help to preserve vision and prevent other neurologic catastrophes.

Symptoms caused by acoustic neuroma may begin or may be aggravated in the latter stages of pregnancy.^{42,43} The symptoms in different patients include hearing loss, tinnitus, headaches, vertigo, dysequilibrium, facial weakness, and diplopia. Aggravation of symptoms in one pregnancy does not necessarily indicate that exacerbation will occur in subsequent ones. Cerebellar hemangioblastomas,⁴⁴ medulloblastomas,⁴⁵ and other tumors may occur during pregnancy. Atypical psychiatric symptoms in the antenatal or postnatal period may result from an intracranial structural lesion that is unrecognized unless the patient is examined neurologically and investigated by neuroimaging studies.

How pregnancy may precipitate or exacerbate symptoms caused by intracranial tumors is unclear. The most likely explanation is that pregnancy leads to a slight increase in the size of the tumor. Tumors with symptoms consistently related to pregnancy are usually located so that only slight enlargement leads to significant involvement of important neural structures. Symptoms of spinal meningiomas may be exacerbated by pregnancy, but convexity meningiomas, which have room for expansion, are unlikely to show any particular relationship of symptoms to pregnancy.

Several possibilities have been advanced to account for the manner in which pregnancy might influence tumor size. Suggested mechanisms include accelerated growth rate, vascular engorgement, and increased fluid content, but supportive evidence for these proposals is lacking. Nevertheless, there is accumulating evidence for sex steroid-binding sites in a number of human tumors, especially meningiomas.⁴⁶ The presence of such receptors in tumors suggests that the natural

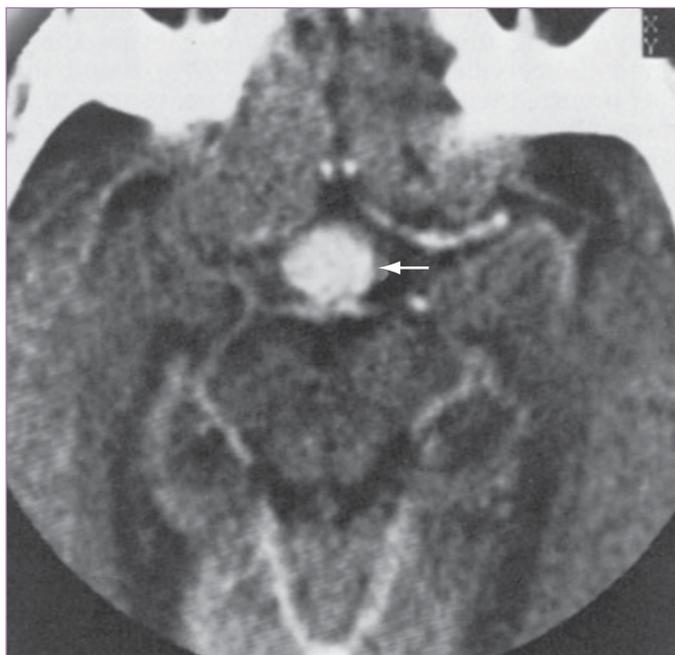

FIGURE 52-1 Computed tomography (CT) of a pituitary adenoma. CT shows an enhancing lesion (*arrow*) in the suprasellar cistern. More inferior axial scans showed this lesion arising from the sella.

history of these tumors may be modified by these hormones or their antagonists.

Patients with intracranial neoplasms may have nonspecific symptoms of cerebral dysfunction, with evidence of raised intracranial pressure or some characteristic combination of symptoms and signs that reflect the location of the lesion. The history and physical findings guide the manner in which these patients are evaluated further. MRI or CT of the head (Figs. 52-1 and 52-2) can provide an enormous amount of additional information noninvasively. MRI is more sensitive for the diagnosis of an intracranial tumor and is safe in pregnant women because it does not involve exposure to radiation. When CT or other radiologic investigations are necessary, shielding may help to protect the fetus from excessive radiation.

Each patient must be treated on an individual basis, and essential neurosurgical treatment should not be delayed because of the pregnancy. For pituitary adenomas or other benign tumors encountered in the latter half of pregnancy, operations can sometimes be delayed until a more propitious time if the patient is carefully observed. However, signs of increased intracranial pressure, visual deterioration, an increasing neurologic deficit, or the clinical features of an infratentorial lesion mandate early or immediate intervention. For patients with pituitary adenomas, pharmacologic intervention (e.g., corticosteroids, bromocriptine) may be adequate. In most instances, visual disturbances improve spontaneously after delivery, regardless of any pharmacologic measures. Cranial irradiation during the first trimester for the treatment of malignant brain tumors is associated with an increased risk of fetal loss or malformation; during later pregnancy, it is associated with an increased risk of childhood leukemia.⁴⁷ A detailed discussion of radiotherapy during pregnancy is provided by Kal and Struiksmans.⁴⁸

In general, pregnancy can be allowed to proceed—at least until the fetus is viable and often to term—in patients with intracranial neoplasms; however, therapeutic abortion may be justifiable for some

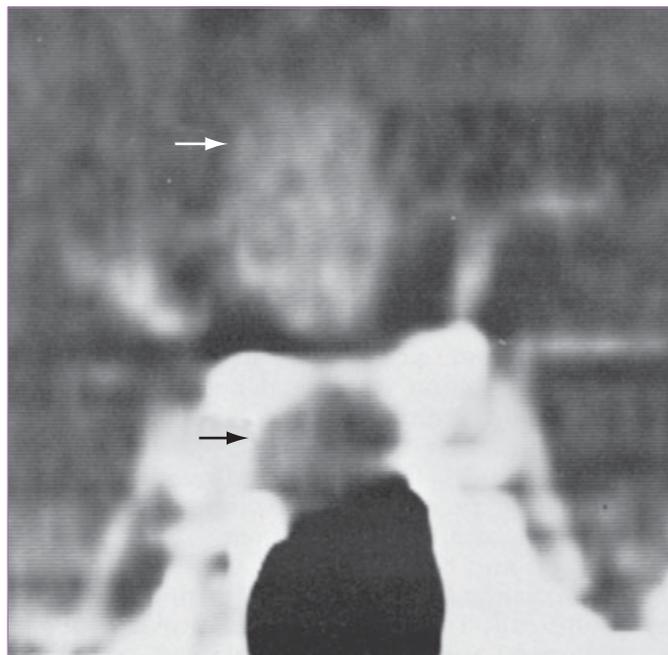

FIGURE 52-2 Coronal reformation of computed tomography (CT) of a pituitary adenoma. In the CT scan of the same patient as in Figure 52-1, the intrasellar extent (*black arrow*) and suprasellar extent (*white arrow*) of the pituitary adenoma can be seen.

patients with malignant brain tumors and if significant symptoms, such as uncontrollable seizures, occur during pregnancy, particularly when the tumor cannot be removed completely. Obstetric management must also be determined on an individual basis. Some investigators have proposed that delivery by cesarean section is safer than spontaneous vaginal delivery in women with cerebral tumors because the vaginal delivery may enhance any increase in intracranial pressure caused by the neoplasm. However, vaginal delivery with adequate regional anesthesia and judicious shortening of the second stage of labor by use of low forceps (to prevent any increase in intracranial pressure associated with the abdominal pushing efforts of this stage) is often satisfactory.

Pregnancy may be followed by the development of choriocarcinoma, which commonly metastasizes to the brain⁴⁹ (see Chapter 43). Neurologic presentation is typically with symptoms of a space-occupying cerebral lesion or with an acute deficit resulting from hemorrhage into the lesion. Treatment of cerebral metastases may involve chemotherapy, radiation therapy, and for isolated metastases, surgery.

Pseudotumor Cerebri

Benign intracranial hypertension is associated with pregnancy and with the use of oral contraceptive preparations. When symptoms do develop during pregnancy, they usually occur in the first trimester or the month after delivery, but they may occur at any time during the gestational period. Symptoms consist of headache and visual disturbances caused by papilledema and possibly diplopia resulting from abducens weakness. The patient looks well despite the grossly abnormal appearance of the optic disks, and neither electroencephalography nor MRI reveals any evidence of a space-occupying lesion. Although lumbar puncture reveals increased pressure of the cerebrospinal fluid, the composition of the fluid is unremarkable. The possibility of intra-

cranial venous sinus thrombosis must be considered when the patient is being evaluated.

Although benign intracranial hypertension is self-limiting, remission may not occur until well after delivery, and the disorder sometimes recurs in a subsequent pregnancy.⁵⁰ If the condition is left untreated, there is a risk of secondary optic atrophy and subsequent permanent impairment of vision. Several therapeutic approaches to lowering intracranial pressure have been reported, including use of high-dose steroids, acetazolamide, furosemide, repeated lumbar punctures, and lumboperitoneal or other shunting procedures. If the response to these measures is unsatisfactory and intracranial pressure remains high enough to endanger vision, optic nerve decompression may be required, as may early delivery of the fetus. There are no specific obstetric complications, and the patient can be expected to give birth to a normal infant.

Occlusive Cerebrovascular Disease

Cerebrovascular disease may develop during an otherwise normal pregnancy as a result of arterial or venous disease. Pregnancy increases the risk of cerebral infarction to about 13 times the rate expected outside of pregnancy.⁵¹ The risk seems to be greatest in the few days around the time of delivery.⁵²

Arterial Occlusive Disease

Arterial disease is not unusual, even in the absence of diabetes or severe hypertension, in women of childbearing age. Major arterial occlusion accounts for most cases of nonhemorrhagic hemiplegia that develop during pregnancy or the puerperium.⁵³ Numerous cases of occlusion of the middle cerebral artery or one of the other major intracranial arteries have been described during pregnancy, with occlusion usually occurring in the third trimester or the postpartum period. Such a stroke usually is caused by the development of a thrombus on a pre-existing atheromatous plaque. Predisposing factors may be anemia, hormonal influences, hypertension, increased platelet aggregation, reduced tissue plasminogen activity, changes in blood coagulation factors (especially factors V, VII, VIII, IX, X, and XII and fibrinogen) during late pregnancy, preeclamptic toxemia with hypertension, and puerperal septicemia. Other causes of stroke in young women include protein C, protein S, and antithrombin III deficiencies; hyperhomocysteinemia; arteritis; meningovascular syphilis; sickle cell disease; antiphospholipid antibodies; polycythemia and other hematologic disorders; prosthetic cardiac valvular disease; and cardiomyopathy.

An embolus resulting from rheumatic or ischemic heart disease, subacute bacterial endocarditis, or a cardiac myxoma may occur. Rare instances of arterial occlusion by paradoxical embolization from a pelvic vein through a patent foramen ovale have also been described. Rarely, fat, air, or amniotic fluid embolism may occur in relation to childbirth and may have a fatal outcome.⁵⁴ Hypotension as a consequence of hemorrhage or related to anesthesia during labor may lead to watershed cerebral infarction.

Transient cerebral ischemic attacks may precede occlusion of one of the major intracranial arteries. The neurologic disorder and the underlying arterial disease must be investigated and treated as in non-pregnant patients. Investigations should include complete blood cell count, blood smear, erythrocyte sedimentation rate, serum cholesterol

FIGURE 52-3 Common carotid angiogram. The angiogram shows atherosclerotic narrowing of the internal carotid artery (*solid arrow*) at its origin. There is some corrugation of the internal carotid artery more rostrally at the level of C1 and C2, reflecting fibromuscular dysplasia (*open arrow*).

and triglyceride levels, prothrombin and partial thromboplastin times, electrocardiogram, echocardiography, and radiologic procedures. CT is an important means of excluding intracranial hemorrhage. Angiography enables the major cerebral vessels to be visualized and may permit recognition of degenerative atherosclerotic disease that can be remedied by transluminal disobliteration (Fig. 52-3). The role of thrombolytic agents such as tissue plasminogen activator for treating acute ischemic stroke in pregnant or nursing women is unclear; they may make hemorrhagic complications more likely in the first few days after delivery.

Surgically inaccessible disease of the intracranial arteries may serve as a source of emboli, and treatment with anticoagulants or aspirin should be considered. Warfarin is best avoided, if possible, because it crosses the placenta and increases hemorrhagic complications and because of the risks of teratogenicity and fetal wastage, especially during the first trimester.⁵¹ Patients requiring anticoagulation during pregnancy are maintained instead on subcutaneously administered heparin, which usually is discontinued when labor begins and resumed about 12 hours after vaginal delivery or 24 hours after cesarean section. With regard to subsequent obstetric management, vaginal delivery, unless specifically contraindicated, is preferable to cesarean section. Other diseases that may be associated with arterial occlusive disease in pregnancy (e.g., eclampsia, thrombotic thrombocytopenic purpura) are discussed in Chapters 35 and 42.

Cerebral angiopathy may complicate an otherwise normal pregnancy or the postpartum period. It is sometimes associated with

hypertension or the use of vasoactive drugs, and it may simulate vasculitis.⁵⁵

The association of stroke with oral contraceptive use is widely accepted. The risk can probably be reduced by lowering other risk factors, such as hypertension. A variety of mechanisms may be involved, including a predisposition to hypercoagulability, but the precise mechanisms have not been defined.

Intracranial Venous Occlusive Disease

Intracranial venous occlusive disease is an uncommon complication of pregnancy and childbirth. When the thrombosis occurs in the first trimester, it usually follows a complication such as spontaneous abortion, therapeutic abortion, or stillbirth, but it may occur in an otherwise normal pregnancy. Intracranial venous thrombosis is more likely in the third trimester or in the puerperium and is sometimes related to preeclampsia.

Intracranial venous thrombosis is characterized clinically by headache, weakness, focal or generalized convulsions, drowsiness, and confusion. Disturbances of speech, sensation, or vision may also occur, and patients may have mild pyrexia. There may be signs of meningeal irritation resulting from subarachnoid bleeding caused by cortical infarction, and fluctuating hypertension is sometimes found. Papilledema may be present, particularly if the superior sagittal sinus is involved. The cerebrospinal fluid pressure may be increased, and the protein or cell content often is elevated; occasionally, the fluid is frankly blood-stained. The diagnosis may be confirmed by CT and magnetic resonance angiography, which are also necessary to exclude arterial pathology and vascular malformation (Figs. 52-4 and 52-5). The symptoms and signs of intracranial venous thrombosis are sometimes ascribed mistakenly to eclampsia, but the absence of previous signs of preeclampsia should help in preventing diagnostic confusion.

The prognosis is not encouraging. In about one third of cases, intracranial venous thrombosis has a fatal outcome. Moreover, if patients do survive, thrombosis may recur later in the same pregnancy, the puerperium, or subsequent pregnancies.

The etiologic basis of aseptic intracranial venous thrombosis is uncertain; coagulation abnormalities, changes in the constituents of the peripheral blood, and intimal damage to the dural sinuses have been suggested as causes. Protein C, protein S, and antithrombin III deficiencies are common inherited prothrombotic states. Protein S deficiency in particular has been associated with cerebral venous thrombosis.⁵⁶ Low levels of protein C and S have been reported during pregnancy.⁵⁷ Activated protein C resistance has been observed in a number of patients with venous thromboembolic events and in those with cerebral venous thrombosis. Deschiens and associates⁵⁸ found that 6 of 40 patients with cerebral venous thrombosis had protein C or S deficiency or activated protein C resistance, and 3 of 12 patients were similarly found by Weih and coworkers⁵⁹ to have the factor V Leiden mutation, a common cause of activated protein C resistance.

The treatment of intracranial venous thrombosis is controversial. It may include anticonvulsant drugs if seizures have occurred; anti-edemic agents, such as dexamethasone and mannitol, to reduce the intracranial pressure; and anticoagulant drugs to prevent extension of thrombosis.⁶⁰ Although anticoagulants may provoke hemorrhagic intracranial complications,⁶¹ the risk has probably been exaggerated; one study suggests that anticoagulation with dose-adjusted intravenous heparin is effective treatment.^{60,62} Labor can usually be allowed to commence spontaneously, with forceps assistance of delivery, if the thrombosis occurred early in pregnancy. If thrombosis occurs shortly before or during labor, however, cesarean section may be necessary.

FIGURE 52-4 Superior sagittal sinus thrombosis. Computed tomography shows curvilinear areas of high density, which represent cortical venous thromboses and adjacent parenchymal venous infarcts.

Several reports have stressed that a strong relationship exists between factor V Leiden mutation and cerebral venous thrombosis,⁶³⁻⁶⁵ particularly in women taking oral contraceptive preparations.⁶⁶ Whether all women should be tested for factor V Leiden before receiving oral contraceptive agents is unsettled. It does seem reasonable, however, to test for activated protein C resistance in patients experiencing a stroke during pregnancy, in the postpartum period, or while receiving oral contraceptives.

Pituitary Infarction

Sheehan syndrome is a well-recognized complication of the peripartum period (see Chapter 48).

Intracranial Hemorrhage

Intracranial (subarachnoid) hemorrhage is more common in women than in men. Mhurchu and colleagues⁶⁷ found that menstrual and reproductive history (other than an older age at birth of the first child) did not influence the risk of hemorrhage; the risk was not affected by use of oral contraceptive agents. Okamoto and associates⁶⁸ found an increased risk of subarachnoid hemorrhage with an earlier age of menarche and with nulligravida; they found no association with regu-

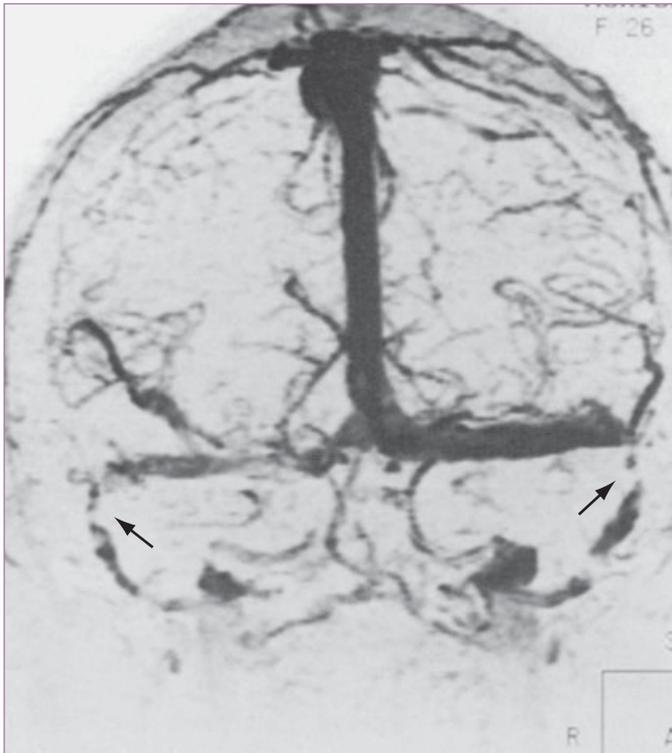

FIGURE 52-5 Intracranial venous thrombosis. A 26-year-old woman presented in the middle trimester of pregnancy with headache, and she had bilateral papilledema. The brain appeared normal in imaging studies. This coronal view of her magnetic resonance venogram (obtained using a two-dimensional time-of-flight technique) shows loss of flow-related enhancement in both transverse sinuses (*arrows*), which is consistent with thrombus formation.

FIGURE 52-6 Evaluation of intracranial hemorrhage. Computed tomography shows hemorrhage into the sylvian fissure and adjacent parenchyma, with surrounding edema or ischemia. The findings are indicative of subarachnoid and intracerebral hemorrhage and localize the source of bleeding to the middle cerebral artery.

larity of menstrual cycle, age at pregnancy or first birth, or number of births.

When intracranial hemorrhage occurs during pregnancy, it is usually, at least in part, into the subarachnoid space. Sudden, severe headache, sometimes accompanied by nausea and vomiting, is the main symptom. Examination reveals signs of meningeal irritation that may be accompanied by depressed consciousness, cranial nerve abnormalities, and a neurologic deficit in the limbs.

In patients in whom subarachnoid hemorrhage complicates otherwise normal pregnancies, the underlying source is most commonly an aneurysm and less often an angioma or of indeterminate cause. Other less common causes of intracranial hemorrhage include mycotic aneurysms, vasculitides, various hematologic disorders, disseminated intravascular coagulation, eclampsia, and metastatic choriocarcinoma. Treatment focuses on the underlying cause. Although bleeding may occur at any time during the pregnancy, aneurysms are somewhat more likely to bleed in the latter half of the gestational period.

Cerebral angiomas, which are located supratentorially in at least 70% of patients, may appear at any age. Intracranial or subarachnoid hemorrhage is the most common manifestation, and the peak age for hemorrhage is between 15 and 20 years. The mortality rate for an initial hemorrhage is approximately 10%, but it has varied in different series; survivors are more likely to experience further hemorrhage than patients who have never had one. Other patients with intracranial angiomas may present with focal or generalized seizures, headache,

focal neurologic deficits, or nonspecific neurologic symptoms. Robinson and colleagues⁶⁹ reported that pregnancy has a deleterious effect on intracranial angiomas, making them more likely to bleed, but their impression has not been substantiated by others⁷⁰ unless there is a history of earlier bleeds.⁷¹

Intracranial saccular aneurysms arise from a developmental arterial defect, and with increasing age, they become more common sources of hemorrhage than angiomas. They usually are located at sites of vessel branching, commonly occurring in relation to the anterior or posterior communicating arteries. Although such aneurysms sometimes cause focal symptoms that relate to compression of neighboring structures, patients usually present with hemorrhage that occurs without warning because of aneurysmal rupture. This type of hemorrhage seems to occur more commonly in the late stages of pregnancy,⁷² and occurrence during labor and delivery has been reported only rarely. In addition to the signs of subarachnoid hemorrhage, focal or lateralizing neurologic signs may be present and help to localize the source of bleeding.

In the evaluation of patients presenting with symptoms of intracranial hemorrhage, the first diagnostic study performed is usually a CT of the head, which is a reliable means of detecting recent subarachnoid or intracerebral hemorrhage and may permit the source of bleeding to be localized (Fig. 52-6). In patients with angiomas, nonhomogeneous areas of mixed density with irregular calcifications are typical, and vermiform areas of enhancement are seen after infu-

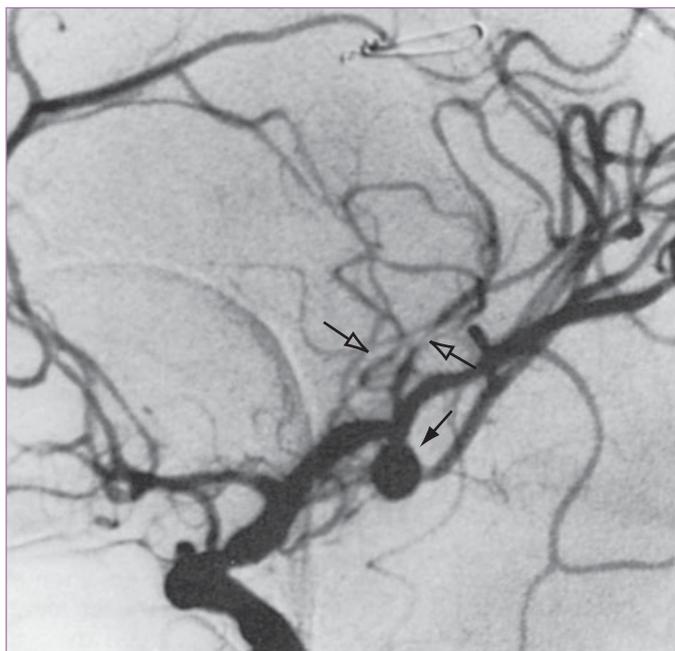

FIGURE 52-7 Evaluation of aneurysm. In the carotid angiogram of the same patient as in Figure 52-6, an aneurysm (*solid arrow*) is shown at the trifurcation of the middle cerebral artery. There is some spasm of vessels in the vicinity of the aneurysm (*open arrows*).

sion of contrast material. Aneurysms are seen as small, round, dense areas after infusion of contrast material and are sometimes evident even without contrast. If CT findings are normal, the cerebrospinal fluid should be examined and angiography undertaken if the fluid is bloodstained or xanthochromic.

Angiography enables the identity of the lesion to be established with certainty and provides important additional information concerning its anatomic features (Fig. 52-7). Special shielding during this and other radiologic procedures should be provided for pregnant patients. All the major intracranial vessels should be opacified; feeding vessels to angiomas sometimes arise from the contralateral side, and many aneurysms may be seen. Angiography does not always reveal the malformation in a patient with a suspected angioma, possibly because the lesion was small and destroyed itself when it bled (i.e., cryptic malformation). Nevertheless, if angiography shows neither an angioma nor an aneurysm in a patient presenting with subarachnoid hemorrhage, the study should be repeated after about 14 days because vascular spasm after a bleed may obscure an aneurysm.

The management of subarachnoid hemorrhage consists of bed rest, with sedation and analgesia as necessary and operative or endovascular treatment of the underlying lesion if feasible. Surgical treatment is aimed at preventing further hemorrhages, but induction of hypotension during the course of the intracranial operation should be avoided unless it is essential because it may be followed by premature labor or fetal death; hypothermia is well tolerated.⁶⁹

If the anomalous vessels constituting an angioma are surgically accessible and do not involve a critical vessel or area of the brain, they can often be excised. Surgery is commonly preceded by embolization of the main vessels feeding the malformation in an attempt to reduce its size. Other oblitative techniques have been developed. The optimal time for treatment of an angioma is uncertain, but therapeutic intervention is often delayed until after childbirth.⁷² In the patient with an aneurysm that has bled, the risk of further bleeding is much greater,

especially in the weeks after the initial hemorrhage. Oblitative treatment, if indicated by the angiographic findings and the condition of the patient, should not be delayed because of the pregnancy.⁷³ An endovascular approach may be successful⁷⁴ and is favored increasingly over surgery.

In patients with aneurysms that have been successfully obliterated or that ruptured before the last trimester, pregnancy and delivery usually can proceed normally. In patients with incompletely obliterated or unoperated aneurysms that ruptured in the last 2 months of pregnancy, cesarean section is probably advisable at 38 weeks' gestation. Some authorities advocate delivery by elective cesarean section at 38 weeks in patients with arteriovenous malformations and further recommend that concomitant sterilization be considered,⁶⁹ presumably if the malformation itself is inoperable. However, the need for either procedure in this context is unclear, and arguments for them are without adequate foundation. In patients showing a steady deterioration in neurologic status and for whom a fatal outcome seems likely, preparations should be made so that the fetus, if viable, can be delivered before it dies of anoxia.

Vascular Anomalies and the Nervous System

The most important vascular anomalies that occur in relation to the nervous system are intracranial aneurysms and cerebral angiomas (discussed earlier). However, several other types of vascular anomalies may manifest during pregnancy, and they merit brief discussion.

Intracranial Dural Vascular Anomalies

Certain intracranial dural vascular anomalies may become evident for the first time during pregnancy. They consist of abnormal arteriovenous shunts involving meningeal branches of the carotid and vertebral arteries and the dural veins and sinuses. Although some represent a developmental anomaly, others are acquired in adult life, occasionally after trauma, presumably because of the close anatomic relationship of certain meningeal arteries and veins.

Shunts involving the anteroinferior group of dural sinuses (i.e., cavernous, intercavernous, sphenoparietal, superior and inferior petrosal, and basilar plexus) are characterized clinically by unilateral orbital or head pain, diplopia, a red or protruding eye, and tinnitus. The onset of symptoms sometimes follows abortion or occurs in the postpartum period, possibly because of rupture of the thin-walled dural arteries during the straining of labor or because of the circulatory changes that occur in pregnancy.

On examination, there is usually a mild proptosis, distended conjunctival veins, increased intraocular pressure, transient sixth nerve palsy, or a bruit over the eye. Angiography reveals a low-volume shunt supplied from meningeal branches of the internal or external carotid arteries, sometimes from the contralateral side. Drainage may be directly into the cavernous sinus or into a more distant dural sinus or venous structure that communicates with the cavernous sinus. The fistula may close spontaneously, but if it remains patent, embolization of the feeding vessels may help to relieve intolerable symptoms or failing vision.

Arteriovenous shunts to the superoposterior group of dural sinuses (i.e., superior and inferior sagittal, straight, transverse, sigmoid, and occipital) may occur, with a female predominance among the reported cases. Symptoms and signs may relate to the shunt itself, to subarach-

noid hemorrhage, to increased intracranial pressure, or to cerebral ischemia.

Tinnitus is the most common complaint, but headache, visual deterioration, subarachnoid hemorrhage, seizures, and various neurologic deficits may also occur. A bruit is often present and may be the sole finding on examination; it is best heard over the mastoid region or behind the ear. Papilledema may be present, and other neurologic signs are sometimes encountered. The arterial supply is commonly derived from branches of the external carotid artery, tentorial branches of the internal carotid artery, and meningeal branches of the vertebral artery. Ligation or embolization of feeding vessels or a direct surgical approach to the lesion may be helpful in patients with disabling symptoms or a history of hemorrhage.

Dural and Intradural Spinal Vascular Anomalies

Spinal arteriovenous fistulas are uncommon but are important to recognize because many are readily treated by surgery. Most are dural; if intradural, they are commonly extramedullary, are posterior to the cord, and are fed by one or more arteries that fail to supply the cord or contribute only to the posterior spinal circulation.⁷⁵

Spinal arteriovenous fistulas may lead to spinal subarachnoid hemorrhage but more commonly give rise to a gradual disturbance in the function of the cord or nerve roots, or both. Spinal subarachnoid hemorrhage is much more common in patients with a cervical malformation than a more caudal lesion, may sometimes occur from an associated (arterial) aneurysm, and is associated with an overall mortality rate of at least 15%. It may be the first symptom produced by the lesion. Approximately one half of the patients who survive the first hemorrhage have a second, and one half of the subsequent survivors have further bleeding episodes unless the underlying malformation is treated. The spinal source of the hemorrhage may not be recognized until the later development of symptoms and signs of cord dysfunction, despite the local occurrence of sudden severe pain at the onset of bleeding, accompanied by signs of meningeal irritation.

Myelopathy or radiculopathy, or both, of gradual or sudden onset is the more common manifestation. By the time of diagnosis, approximately two thirds of patients complain of leg weakness, sensory symptoms, pain, and a sphincter disturbance. In some patients, symptoms, especially pain, are precipitated or aggravated by exercise and relieved by rest, whereas symptoms in other patients may relate to specific postures, such as sitting or bending forward. Symptoms occasionally relate to pregnancy, the menstrual cycle, nonspecific infective illness, a transient increase in body temperature, or trauma. On examination, signs of an upper or lower motor neuron disturbance or a mixed motor deficit are usually found in the legs; sensory deficits are common and are usually extensive, but occasionally, they may be restricted to a radicular distribution. There may be a coexisting cutaneous angioma that occasionally relates segmentally to the spinal lesion, and a bruit may be audible over the spine on auscultation.

Numerous case reports illustrating the influence of pregnancy on these lesions have been published. In one case that I encountered, symptoms occurred during each of three pregnancies, with complete clearing after delivery. Their basis was not recognized until the patient later experienced leg weakness and urinary retention that necessitated immediate hospitalization. Myelography and spinal angiography then demonstrated an arteriovenous malformation that was treated surgically.

The relationship of symptoms to pregnancy in such cases may be based in part on enhancement of preexisting cord ischemia by hemo-

dilution and anemia. Moreover, pressure on pelvic and abdominal veins by an enlarged uterus may aggravate symptoms of caudally situated malformations by obstructing venous return to the heart, with a consequent reduction in the intramedullary arteriovenous pressure gradient and in cord blood flow.⁷⁵

Diagnosis depends on radiologic investigations, which must not be postponed out of concern for the developing fetus, because any delay in establishing the diagnosis may lead to increased, often irreversible, disability in the mother. Spinal MRI may fail to detect the lesion. On myelography, the characteristic abnormality consists of vermiform defects caused by vascular impressions in the column of contrast material, usually without any obstruction in the subarachnoid space. If myelography suggests a vascular malformation, spinal angiography is undertaken to determine the level and extent of the vascular abnormality; the position of the arteriovenous shunt in relation to the cord; the number, origin, and anatomic location of arteries feeding the malformation; and the main supply to the cord in the region of the malformation.

Treatment is indicated in all patients who have progressive symptoms or functional incapacity or who have had a hemorrhage. Delay in these cases may lead to irreversible disability or death. When the fistula is dural or intradural but mainly or completely extramedullary, is posterior to the cord, and is fed by vessels that do not contribute to the anterior spinal circulation, surgical treatment or embolization generally poses no specific problem. Feeding vessels are obliterated, and the fistulous portion of the lesion is removed. Fistulas located anterior to or within the cord are more difficult to treat because of their inaccessibility and because they are often supplied by the anterior spinal artery or one of its feeders. These lesions are often regarded as inoperable, and experience in their treatment remains limited.

Infections

The central nervous system may be infected by bacterial, viral, fungal, or other organisms through the blood supply, by extension from infected adjacent structures, or by direct inoculation such as may follow trauma. The neural parenchyma may be involved diffusely (e.g., encephalitis) or focally (e.g., cerebral abscess), or infection may primarily involve the meninges and parameningeal structures (e.g., meningitis, subdural empyema). Although the resulting neurologic disorder may complicate pregnancy or delivery or may necessitate antimicrobial therapy that can harm the developing fetus, the clinical features, diagnosis, and management of infections during pregnancy are essentially the same as at other times. Further discussion is limited to certain infections that pose some particular problem when they occur during pregnancy or are especially likely to develop in relation to pregnancy.

Poliomyelitis

The development of an effective vaccine has all but eradicated paralytic poliomyelitis in developed countries. Even pregnant women can be included safely in programs of mass vaccination with live oral poliovirus vaccine.⁷⁶ Nevertheless, the disorder still occurs in unprotected persons and remains common in many parts of the world. Moreover, people with residual disability from previous poliomyelitis are seen fairly regularly in most large medical centers, and obstetric management of such patients may be complicated by their neurologic deficits.

Most patients infected with poliovirus are asymptomatic or have only minor, nonspecific respiratory or gastrointestinal symptoms. Nervous system involvement occurs in only a few instances; its clinical manifestations are described in standard neurologic textbooks. Patients with neurologic involvement should be hospitalized, with care taken to provide for any circulatory or respiratory complications that may develop. Simple analgesics can be provided for relief of pain, and physical therapy may be helpful after muscle weakness has stabilized.

During pregnancy, women are more susceptible to clinical poliomyelitis, but it is unclear whether this is because they are more susceptible to the initial viral infection or to invasion of the nervous system. Pregnancy may also alter the course of the infection. The course is unaffected if poliomyelitis develops early in pregnancy, but an increase in severity or distribution of the muscle weakness may occur if childbirth takes place during the acute phase or shortly thereafter.

In early pregnancy, especially during the first trimester, spontaneous abortion may occur in association with a febrile reaction in the acute phase of poliomyelitis or in relation to apparently mild nonparalytic attacks of the disease. Abortion or fetal loss may also occur spontaneously in the second or third trimester but often with maternal illness of such severity that assisted respiration may be necessary.

Even patients with severe poliomyelitis necessitating respirator assistance can usually be managed supportively, and labor can be managed similarly to that in normal women unless there are specific obstetric indications for operative delivery or induction of labor. The uterine muscle is not paralyzed.

Fetal poliomyelitis is rare. Normal offspring can generally be anticipated, but neonatal cases of poliomyelitis are well recognized. If an infant is affected within the first 5 days of life, the disorder is assumed to result from transplacental transmission of the virus. These neonatal cases are associated with a mortality rate of at least 50%, but subclinical infection with poliovirus may also occur in newborn infants.

Tetanus

A worldwide disease, tetanus is rarely encountered in developed countries where immunizations are freely available. *Clostridium tetani* infection by means of tetanus spores may follow injury, surgical procedures, childbirth, abortion, and injections. If the spores are converted into vegetative gram-positive rods and favorable anaerobic conditions exist, tetanospasmin, a toxin that is responsible for the symptoms of tetanus, is produced.

The incubation period varies. In patients with generalized tetanus, the most common presenting symptom is trismus, and the disorder itself is characterized by frequent spasms of various muscles that can be provoked by minor external stimuli and may occur against a background of continuous tonic muscle contractions. Typically, the trunk is hyperextended, the arms are flexed, and the legs are extended; laryngospasm may lead to respiratory obstruction.

Localized tetanus is more benign and is characterized by persistent rigidity of muscles close to the site of inoculation with the organism. A splanchnic form is described after abdominal and pelvic operations or uterine trauma, with prominent involvement of the muscles of deglutition and respiration.

The morbidity and mortality rates vary. Respiratory complications are a leading cause of death, as is the autonomic hyperactivity that sometimes complicates tetanus. Treatment is directed at the following:

- Neutralizing unbound toxin with antitoxin
- Reducing further toxin production by surgical toilet and antibiotic treatment

- Controlling tetanic spasms by drugs such as diazepam, chlorpromazine, and barbiturates
- Assisting respiration mechanically if necessary
- Undertaking general supportive measures

Tetanus may develop as a complication of childbirth or abortion, especially in underdeveloped countries. It leads to abortion in many instances and has a maternal mortality rate that often exceeds 50%. In addition to the measures listed, evacuation of products retained in the uterus may be necessary, and hysterectomy is sometimes required.

Tetanus is a common cause of neonatal death in underdeveloped countries. Infection usually results from a lack of hygiene during delivery, with consequent contamination of the umbilical cord. The clinical manifestations differ from those in older children or adults, in that dysphagia and respiratory problems are often more marked, fever is usually higher, and the disease is generally more severe, often fulminating. Most affected infants are 6 to 9 days old when admitted and have a typical history of continuous crying for up to 48 hours, followed by cessation of sucking and then of crying, accompanied by convulsions and often by fever.

In regions where neonatal tetanus is common, the infant mortality rate is high. Improvement of delivery practices and obstetric services may prevent the disorder, as may the active immunization of pregnant women or of all women of childbearing potential⁷⁷ and the substitution of disinfectants for traditional cord-care practices.⁷⁸ Unfortunately, in most areas with a high incidence of tetanus neonatorum, there are no widely available maternity services, and any prophylactic approach that depends on the early identification of pregnant women is impractical.

Miscellaneous Maternal Infections

Clinical or subclinical maternal infection may involve the fetus and may affect the developing nervous system and therefore the neonate. The resulting neurologic complications merit brief comment here. Fetal infection may be inconsequential or may result in abortion, stillbirth, growth retardation, congenital disease, or developmental anomalies. Gestational age at the time of infection influences the effects (see Chapter 38).

Infection with *Listeria monocytogenes* is an important cause of habitual abortion, and it may lead to a variety of other manifestations in pregnant women. In neonates, infection may take an early-onset, predominantly septicemic form, characterized by prematurity, respiratory distress, heart failure, and increased neonatal mortality, or take a late-onset, predominantly meningitic or meningoencephalitic form. Diagnosis depends on the bacteriologic and serologic findings. Treatment consists of appropriate antibiotic therapy, usually with ampicillin.

Maternal rubella, especially when it occurs in the first 2 months of pregnancy, may cause fetal infection and a congenital syndrome characterized by ocular abnormalities, deafness, mental retardation, seizures, focal neurologic deficits, cardiac anomalies, hepatosplenomegaly, and other abnormalities in a variety of combinations. In rare patients with congenital rubella, pyramidal and extrapyramidal signs, seizures, and dementia occur as part of a progressive panencephalitic illness during the second decade of life; high antibody titers to rubella virus occur in blood and cerebrospinal fluid, and the virus may even be isolated from the brain.⁷⁹

In congenital toxoplasmosis, seizures and pyramidal defects may result from meningoencephalitis together with chorioretinitis, obstruc-

tive hydrocephalus, and cerebral calcification. There may be respiratory and feeding difficulties. Later mental development may be retarded. For prophylactic purposes, pregnant women should be advised to avoid contact with cat feces and ingestion of raw or undercooked meat.

Fetal infections with cytomegalovirus may cause hepatosplenomegaly, jaundice, petechiae, ocular defects, cardiac defects, and other abnormalities. Involvement of the nervous system may lead to cerebral malformation, microcephaly, mental retardation, seizures, obstructive hydrocephalus, cerebral calcification, deafness, or chorioretinitis.

Herpes simplex virus infection in the neonate is characterized primarily by visceral involvement, but the brain may be affected. Seizures, irritability, motor deficits, increased intracranial pressure, and depression of consciousness may occur, sometimes in the apparent absence of more widespread disease.

Children born to women infected with the human immunodeficiency virus (HIV) are at risk of infection with the virus. The risk varies in different series for uncertain reasons. The virus may infect the fetus in utero or the neonate during birth or through breast milk. Infected children may develop acquired immunodeficiency syndrome (AIDS) after an interval ranging from several months to several years. This leads typically to developmental delay and regression as a result of progressive encephalopathy. Calcification of the basal ganglia may occur. Systemic features include failure to thrive, pneumonitis, hepatosplenomegaly, and recurrent bacterial infections. Management of pregnant women with HIV infection therefore includes minimizing the risk of transmitting the infection to offspring, recognizing neonatal infection early, reducing the risk of opportunistic infection, and managing psychosocial aspects. Antiretroviral therapy for infected women during pregnancy and zidovudine therapy for neonates for 6 weeks (or longer and with combination therapy if necessary) may be helpful. The protective effect of maternal therapy depends on the complexity and duration of treatment, and highly active antiretroviral therapy (HAART) is associated with the lowest transmission rates.⁸⁰ Compared with no antiretroviral treatment or monotherapy, combination therapy does not seem to be associated with increased risks of prematurity or other adverse outcomes of pregnancy,⁸¹ although some antiviral agents may be teratogenic (there are limited data concerning safety during pregnancy).^{82,83} The use of infant formula to prevent postnatal transmission through breast milk has helped to reduce the incidence of infection in developed countries.^{84,85} Infants may require monitoring for 1 to 2 years with testing for HIV to exclude infection (see Chapter 38). Fetal infection itself may lead to teratogenicity, with nervous system malformations that are associated with vasculitic microinfarcts of the fetal brain.^{82,83}

The possibility of syphilitic infection must be considered during the evaluation of all pregnant women. Effective treatment of maternal syphilis at an early stage of pregnancy usually prevents fetal involvement, and treatment in later pregnancy affects both mother and fetus. Syphilis may severely affect pregnancy, leading to increased chances of abortion and perinatal mortality and to symptomatic congenital syphilis in many of the surviving infants. Infants may also be infected at birth if they come into contact with an infective lesion. The possibility of congenital infection can be confirmed by various serologic tests. The clinical features of congenital neurosyphilis, which may become apparent after the first few weeks of life or may be delayed for several years, are essentially the same as those of neurosyphilis in adults. Infants with clinical or laboratory evidence of infection require treatment to prevent its occurrence, and penicillin is the drug of choice.

Metabolic Disorders

Several metabolic disorders are considered elsewhere in this chapter, including Wilson disease, hepatic porphyria, and the Wernicke-Korsakoff syndrome. In this section, attention is confined to two other disorders that are important to recognize for therapeutic purposes: vitamin B₁₂ deficiency and phenylketonuria (PKU).

Vitamin B₁₂ Deficiency

Vitamin B₁₂ deficiency is a well-known cause of neurologic disease (i.e., myelopathy characterized predominantly by pyramidal and posterior column deficits, polyneuropathy, mental changes, optic neuropathy) in adults, in whom it may arise from malabsorption, dietary inadequacy, or other causes. Patients may have accompanying megaloblastic anemia, but this may be obscured if folic acid supplements have been taken. Clinical presentation during pregnancy does not differ from that in the nongestational period. Treatment with parenteral vitamin B₁₂ prevents further progression and may lead to partial improvement of the neurologic disorder.

It is not widely recognized that maternal vitamin B₁₂ deficiency during pregnancy and the puerperium may lead to a similar deficiency in the fetus and neonate. A reduced content of vitamin B₁₂ in maternal milk may then lead to frank deficiency in breastfed infants. The resulting clinical syndrome in these infants is characterized by megaloblastic anemia, cutaneous pigmentation, apathy, developmental delay or regression, and involuntary movements. The clinical and biochemical abnormalities are rapidly corrected by vitamin supplementation.

Phenylketonuria

An autosomal recessive disorder, PKU is an important cause of mental retardation, which develops in the absence of adequate dietary treatment. Screening programs for neonates with PKU have enabled identification and treatment of affected infants to prevent intellectual deterioration, but the optimal duration of treatment remains unclear. Women with PKU have a high rate of spontaneous abortion, and their nonphenylketonuric (heterozygote) offspring have a high incidence of certain abnormalities. Among the offspring of pregnancies during which the maternal PKU is untreated, there are marked increases in the incidence of mental retardation, microcephaly, and congenital heart disease compared with the normal population, and these increases correlate with maternal blood levels of phenylalanine.

The fetal effects of maternal PKU occur because of the high maternal blood levels of phenylalanine, not because the infant has PKU. Dietary treatment before or during early pregnancy (i.e., within the first 2 months) may prevent or lessen the fetal effects.⁸⁶⁻⁹⁰ Treatment may need to be in effect at conception for maximal benefit. Even so, a normal child cannot be ensured.

The mother with undiagnosed PKU poses different problems. Antenatal screening for maternal PKU or testing for PKU at the first antenatal visit of a woman with a family history of the disease, low intelligence of uncertain origin, or a history of microcephalic offspring is appropriate.

The newborn offspring of a mother with PKU will be homozygous or heterozygous for the disorder. The homozygotes definitely require a diet low in phenylalanine, but the proper nutritional management of heterozygotes is less clear. The mother should be advised against breastfeeding because her milk will contain a high concentration of

phenylalanine. Elevation of blood phenylalanine levels is only minimal during pregnancy in mothers who are heterozygous for the disorder, and the incidence of congenital anomalies and brain damage does not appear to be increased in their offspring.

Movement Disorders

When dystonia develops during pregnancy, it usually manifests acutely as a consequence of treatment with antiemetic dopamine antagonists (e.g., metoclopramide), neuroleptic drugs, or levodopa. For patients with established dystonia, genetic counseling may be prudent if the disorder has a hereditary basis, and the need to continue on pharmacologic treatment should be evaluated before planned pregnancy. Parkinson disease shows no consistent change during pregnancy, but little information is available concerning the safety of antiparkinsonian agents when taken during the gestational period.

Chorea Gravidarum

The term *chorea* refers to involuntary rapid muscle jerks that occur unpredictably in different parts of the body. When the disorder is florid, choreic limb movements and facial grimacing are unmistakable and distort any concomitant voluntary activity. In mild cases, there may be no more than a persistent restlessness and clumsiness.

Sydenham chorea is regarded as a complication of infection with group A hemolytic streptococci, and the underlying pathology may be an arteritis. When it occurs during pregnancy, it is referred to as *chorea gravidarum*. This disease occurs most commonly in primigravidas, with symptoms tending to occur in the early part of pregnancy and remitting after delivery. A history of chorea and rheumatic fever is obtained in about two thirds of patients, and the other third have clinical signs of rheumatic heart disease. Psychological disturbance may occasionally be conspicuous. Chorea gravidarum may recur in later pregnancies. Death, primarily caused by underlying rheumatic heart disease, is rare.

Symptomatic benefit follows bed rest and sedation, and there is no indication for termination of pregnancy. The prognosis is essentially that of any cardiac complication. No specific obstetric complications are associated with chorea gravidarum, and a normal, healthy infant can generally be anticipated.

Although many cases of chorea gravidarum result from preceding streptococcal infection, in other instances, there is no clinical or laboratory evidence of such an association. Instead, clinical impression suggests that pregnancy has in some way merely exacerbated some preexisting disturbance that then becomes clinically evident. Similarly, chorea is occasionally induced by oral contraceptives in women with preexisting basal ganglia abnormalities resulting from various causes. The dyskinesia in such cases usually begins within about 3 months of the introduction of contraceptive therapy, evolves subacutely, is often asymmetrical or unilateral, and resolves with discontinuation of the offending substance. The pathophysiologic basis of hormonal contraceptive-induced chorea is uncertain, but a vascular or immunologic mechanism or a hormone-dependent alteration in central dopaminergic activity has tentatively been advanced as the underlying cause.

Chorea developing for the first time during pregnancy must not automatically be regarded as a variant of Sydenham chorea, because it may arise for other reasons. The choreic movements of Huntington disease occasionally occur for the first time during pregnancy, but the subsequent course of events and the family history will point to the

correct diagnosis. Systemic lupus erythematosus may also cause chorea that sometimes commences during pregnancy, and a thorough search for evidence of this disorder should be made in all patients without clear evidence of a rheumatic basis for chorea. Finally, as in nonpregnant patients, chorea may result from polycythemia vera rubra, thyrotoxicosis, hypocalcemia, Wilson disease, and treatment with phenytoin or a major tranquilizing drug.

Restless Legs Syndrome

Between 10% and 20% of pregnant patients experience unpleasant creeping sensations deep in the legs and occasionally in the arms.⁹¹ Symptoms generally occur when patients are relaxed, especially at night, and prompt a need to move about. These symptoms usually develop in the latter half of pregnancy, subsiding soon after delivery. Similar symptoms may also occur without any relation to pregnancy.

No abnormalities are found on neurologic examination. The cause of the disorder is unknown, but symptoms sometimes resolve after correction of any coexisting anemia or iron deficiency. Persistent or intolerable symptoms may respond to treatment with drugs such as diazepam or clonazepam. Other drugs that are sometimes helpful include levodopa, dopamine agonists, clonazepam, and opiates, but these drugs are better avoided during pregnancy if possible. Symptoms usually resolve spontaneously within a few weeks of the end of pregnancy.

Wilson Disease

An autosomal recessive disorder caused by a gene defect on the long arm of chromosome 13, Wilson disease is characterized by the accumulation of copper in the brain, liver, and other organs. Neurologic and mental symptoms such as intellectual disturbances, abnormal movements of all sorts, dysarthria, dysphagia, and rigidity are common presenting complaints. After neurologic signs are identified, careful examination of the eyes invariably shows the presence of Kayser-Fleischer rings, which are brown deposits of copper along the edge of the cornea in Descemet membrane. Clinical evidence of hepatic involvement may be present but is variable.

The diagnosis is suggested by the family history, low serum copper and ceruloplasmin concentrations, and increased 24-hour urinary excretion of copper. Treatment with a low-copper diet and with penicillamine, a chelating agent that promotes copper excretion, may lead to marked improvement of neurologic and hepatic status.

Patients with untreated Wilson disease have a high miscarriage rate. Pregnancy generally proceeds normally in patients who have received adequate chelation therapy and carries no particular hazard for the mother or fetus.^{92,93} Although penicillamine therapy has been associated with mesenchymal birth defects, several reports document normal pregnancies and infants in mothers on treatment with it. An alternative approach is treatment with trientine and zinc, but experience with oral zinc salts taken during pregnancy is limited, and trientine is teratogenic in rats.⁹⁴ Labor and delivery may be complicated in patients with portal hypertension. Hemorrhage from esophageal varices may occur, especially during the second or third trimesters. Extradural analgesia helps to avoid straining during vaginal delivery; cesarean section is best reserved for obstetric indications.⁹⁵

Multiple Sclerosis

Multiple sclerosis is a disorder in which plaques of demyelination develop at different times and in different sites throughout the central

nervous system. Its cause remains uncertain; clinical onset usually occurs in early adult life. There is considerable variability in the tempo and character of neurologic symptoms and signs. **The disorder is classically associated with unpredictable exacerbations during which neurologic deficits develop, followed by remissions during which symptoms and signs may partially or completely resolve.** With time, patients become increasingly disabled, although perhaps not for many years after appearance of the initial symptoms. In other patients, the disorder follows a progressive course from its onset.

Several epidemiologic studies have suggested a tendency for remissions during pregnancy and an increased frequency of multiple sclerosis exacerbations in the first 3 to 6 months after childbirth.⁹⁶⁻⁹⁸ **Pregnancy itself or the number of pregnancies has no effect on subsequent neurologic disability.**⁹⁹⁻¹⁰¹ **The remission of multiple sclerosis during pregnancy probably relates to a gestational immunosuppressive state that has a multifactorial basis.**⁹⁸ Similarly, multiple sclerosis does not influence the natural course of pregnancy or childbirth,¹⁰² although some investigators have reported an **increased incidence of small infants for age or of deliveries requiring forceps, vacuum extractor, or cesarean section.**¹⁰³ **When patients on interferon β therapy become pregnant, they have a higher incidence of miscarriages or stillbirths or of small babies.**¹⁰⁴

The possibility of a familial incidence of multiple sclerosis is widely known, but this pattern is uncommon and tends to involve siblings rather than different generations. It may merely reflect common exposure to some unrecognized etiologic agent rather than genetic predisposition to the disorder. With these points in mind, inquiries by a pregnant woman with multiple sclerosis who is worried that her child may later become affected should be met with firm reassurance. **A patient with multiple sclerosis does not need to be discouraged from pregnancy unless she is already so disabled by the disorder that she will clearly be incapable of coping with the responsibilities and physical demands of parenthood.** Patients with minimal incapacity who are anxious to have a child will usually do so anyway and do not need to be discouraged as long as they have some understanding of the nature of their disorder and its unpredictable course. In discussions between such patients and physicians, it seems reasonable to provide optimistic assurance that multiple sclerosis does not shorten life and that significant disability may not occur for many years, if at all.

The management of multiple sclerosis during pregnancy is supportive. The treatment of acute exacerbations consists of bed rest and prescription of a brief course of steroids, which may hasten recovery without necessarily influencing its extent. Patients with sphincter disturbances or who are paraplegic may experience increased difficulties during pregnancy. The method of delivery should depend solely on obstetric factors.

Optic Neuritis

Any type of optic neuropathy may develop fortuitously during gestation. Optic neuritis may develop during pregnancy or lactation¹⁰⁵ in patients with established multiple sclerosis or in patients who will later develop other manifestations of that disorder. Optic nerve involvement by tumors or vascular malformations may also appear for the first time in the gestational period, as may the optic neuropathy that sometimes complicates vitamin deficiency. Optic nerve involvement may complicate hyperemesis gravidarum, with rapid onset of marked, usually bilateral, visual loss; the entity is rare, but if vomiting is unresponsive to treatment, it may be necessary to terminate the pregnancy.

Leber optic atrophy is a hereditary disorder that usually occurs in early adult life. It commonly has a sex-linked recessive mode of inheritance, so that the male offspring of women carriers of the disorder may be affected. Other modes of inheritance have also been described. The clinical deficit commences abruptly with visual loss and leads ultimately to bilateral central scotoma with optic atrophy. No abnormalities are found in the neonate. Other forms of hereditary optic atrophy have been described in which the disorder is congenital or develops in infancy or early childhood and may have a dominant or a recessive mode of transmission. The family pedigree is important for diagnostic and counseling purposes in all such instances.

Traumatic Paraplegia

When spinal cord injury resulting in paraplegia occurs during the course of an established pregnancy, it may be followed by spontaneous abortion or stillbirth. If the pregnancy continues, the detailed radiologic investigations that are needed to determine the nature and extent of the spinal injury may be hazardous to the developing fetus, especially if it is still very immature (see Chapter 20). In such circumstances, the interests of the mother are of paramount importance.

Many patients with established paraplegia are eager to experience motherhood, and because they are capable of sexual intercourse, they inquire about the possibility and potential hazards of childbirth. Urinary tract infection, a common complication of paraplegia, can be exacerbated by pregnancy but is not a contraindication to pregnancy if there is no gross impairment of renal function. In the management of paraplegics, it is important to re-educate the paralyzed bladder so that only a minimal amount of residual urine remains after micturition. If this is achieved, difficulty with micturition can usually be postponed to the last stages of pregnancy, when catheterization is often necessary.

Pregnancy may increase the likelihood of development of pressure sores in paraplegic women. Patients and their families should be informed about the cause of these sores and the manner in which prolonged pressure can be avoided. Because anemia lowers the resistance of paraplegic patients to infection and pressure, particular care must be taken to prevent its development during pregnancy.

The uterus itself contracts normally in labor despite interruption of its nerve supply. However, patients with complete spinal cord lesions above the tenth thoracic segment cannot appreciate the onset of labor or feel any pain during it because afferent fibers from the uterus enter the cord more caudally. Medical attendants need to examine the state of the cervix to identify the onset of labor with certainty. Because labor often commences before term in such circumstances, the cervix is examined at each antenatal visit after 24 to 26 weeks' gestation; the patient should be hospitalized if the cervix is dilated.

The occurrence of symptoms such as leg spasms in association with uterine contractions may be helpful in signaling the onset of labor, as may uterine palpation by the patient's spouse. Routine hospitalization after the 32nd week should be considered. In patients with cord lesions below the 10th or 11th thoracic segment, uterine contractions produce normal pain sensations. A patient with spasticity resulting from the cord lesion may develop painful flexor spasms and ankle clonus during uterine contractions.

Pregnant women with complete cord lesions above the fifth or sixth thoracic segment (i.e., above the splanchnic outflow) may develop the syndrome of autonomic hyperreflexia with excessive activity of a viscus. This is characterized by throbbing headache, hypertension, reflex bradycardia, sweating, nasal congestion, and cutaneous vasodi-

lation and piloerection above the level of the lesion. During labor, these symptoms are most conspicuous with uterine contractions and become especially prominent just before delivery. Electrocardiographic monitoring may facilitate recognition of any changes in cardiac rate or rhythm that occur during uterine contractions. Symptoms are caused by the sudden release of catecholamines.

Treatment in the past has relied on reserpine (which depletes catecholamines from sympathetic nerve terminals but also can cause potentially dangerous nasal congestion in the nasal-breathing neonate), atropine, clonidine, glyceryl trinitrate, or hexamethonium (a ganglion blocker). The syndrome can be prevented or treated by spinal or epidural anesthesia extending to the level of the tenth thoracic segment, and early consultation with an anesthesiologist may therefore be helpful.

Cesarean section is not indicated by paraplegia per se, but it may be required because of bony deformity of the spine or pelvis. If the patient has a permanent suprapubic cystostomy, a vertical incision rather than a lower segment transverse incision must be used. Forceps delivery or vacuum extraction is often required because the muscles responsible for the expulsive efforts of the second stage are paralyzed and because severe hypertension sometimes necessitates shortening the second stage.

Absorbable sutures, such as catgut, are poorly absorbed in paraplegics, and sterile abscesses commonly form around buried catgut. Nonabsorbable sutures, such as nylon, are preferred for repairing an episiotomy. Paraplegic and quadriplegic patients can successfully breastfeed their infants, and they have a normal letdown (i.e., milk ejection) reflex during suckling.

Root Lesions

Prolapsed Intervertebral Disk and Pregnancy

The symptoms and signs of lumbar disk protrusion during pregnancy are similar to those occurring in nonparous women. Radicular pain and low back pain are usually conspicuous features, and there may be a segmental motor and sensory disturbance in the limbs. When the disk prolapses centrally rather than laterally, symptoms and signs in the legs may be bilateral, and sphincter disturbances occur more commonly.

Lumbar disk protrusion must be distinguished from other causes of leg weakness developing during or soon after pregnancy. Lumbosacral palsy may arise during labor from compressive injury of the plexus, but tenderness and rigidity of the lumbar spine, sciatica, and signs of root tension favor the diagnosis of protruded disk. The distribution of muscle weakness may also be helpful; depending on their location, plexus lesions cause weakness and sensory symptoms in a polyradicular or peripheral nerve distribution in the legs. Because only the anterior primary rami contribute to the plexus, a proximal radiculopathy can be distinguished from a plexus lesion by electromyographic examination of muscles supplied by the posterior primary rami (i.e., paraspinous muscles), involvement of which therefore favors a root lesion.

Management is the same as for nonpregnant women. MRI has no known effects on the fetus, but contrast agents are probably best avoided. In patients with lateral protrusion of a lumbar disk, simple analgesics provide symptomatic relief. Surgery can usually be deferred until after childbirth. However, laminectomy and excision of the pro-

truded disk may be necessary during pregnancy, especially if symptoms are bilateral or if there is any disturbance of sphincter function.

Other Lumbosacral Root Lesions

Most disk lesions involve the L5 or S1 roots. Although a disk lesion may occasionally affect the L4 root, involvement of an upper lumbar nerve root suggests other compressive disease. In a patient presenting with an L5 or S1 radiculopathy, there may be a more rostrally situated lesion if no abnormality, such as a protruded disk, is seen in the L4-5 or L5-S1 region, because the spinal cord ends at the lower border of L1 and the roots then descend intradurally before exiting through their respective intervertebral foramina. In such circumstances, the possibility of other compressive lesions must be considered. As with nonpregnant patients, each case is best managed on an individual basis.

Plexus Lesions and Peripheral Mononeuropathies

Certain peripheral entrapment neuropathies are particularly liable to develop in pregnancy and may lead to troublesome symptoms. Recognition of the basis of such symptoms is important because, with reassurance about their benign nature, most patients can tolerate them until they give birth, when the symptoms usually subside spontaneously. Other peripheral nerve or plexus lesions may develop during labor or obstetric surgical procedures as a result of compression or stretch of nerves, especially in anesthetized patients.

Disorders of peripheral nerves may be characterized by slowing or blocking of conduction along intact axons or by axonal degeneration. The former carries a much more favorable prognosis for recovery than the latter, because after axonal degeneration has occurred, recovery can take place only by regeneration, a process that may take many months and may never be complete.

Electrophysiologic Evaluation

In the evaluation of patients with suspected nerve lesions, electrophysiologic techniques have been helpful in several ways.¹⁰⁶ Electromyography can aid in determining whether weakness is neurogenic; if so, the electromyographically demonstrated pattern of affected muscles may indicate the location of the lesion (i.e., whether root, plexus, or an individual peripheral nerve has been affected). The findings may also indicate whether neurogenic weakness is a consequence of impaired conduction along otherwise intact axons or of axonal degeneration, a distinction that has prognostic importance.

The motor responses to nerve stimulation provide complementary information. If axonal degeneration results from a focal lesion in a peripheral nerve, the motor responses to electrical stimulation proximal or distal to the lesion become small or absent about a week after injury, depending on the completeness of the lesion. In contrast, in patients with a conductive disturbance caused by an acute focal lesion, the motor responses to stimulation beyond (distal to) the lesion are generally normal, whereas those elicited by more proximal stimulation may be small.

Motor and sensory conduction velocity can be measured in various accessible segments of peripheral nerves, and focal slowing may provide confirmatory evidence of an underlying entrapment or focal neuropathy. In patients presenting with a mononeuropathy, nerve conduction

studies can be used to exclude the real possibility of an underlying subclinical polyneuropathy.

Lumbosacral Plexus Lesion

The roots of the sciatic nerve may be compressed in the pelvis by the fetal head or obstetric forceps, and the brunt of the resulting motor deficit is then borne by muscles supplied by the common peroneal fibers because of their relationship to the bony pelvis. This type of injury to the maternal lumbosacral plexus is more likely when a short patient with a small pelvis carries a rather large infant, so that labor is complicated by minor disproportion, or when mid-forceps are used during delivery because of malpresentation. The features of the pelvis that predispose to this complication include a straight sacrum, a flat wide posterior pelvis, posterior displacement of the transverse diameter of the inlet, wide sacroiliac notches, and prominent ischial spines.

Symptoms usually are unilateral and develop immediately after delivery, but they may not be noticed until the patient is allowed out of bed. When the common peroneal fibers are involved, the main complaint is of leg weakness, which is sometimes erroneously attributed to a painful episiotomy. In more severe cases, there is footdrop. Numbness and paresthesias may occur over the dorsum of the foot and lateral aspect of the leg, and cutaneous sensation may be impaired in this distribution.

Unless the injury has been severe, the predominant pathologic change is demyelination of the affected fibers, and this is reflected in the electrophysiologic findings. With mild injuries, the prognosis for recovery is excellent; if wallerian degeneration has occurred, recovery may take many months and may never be complete. Physical therapy is all that is needed for the treatment of mild cases, but calipers and night casts may be required in more severe instances to prevent contracture.

Subsequent pregnancies can be allowed to proceed normally if an easy vaginal delivery is anticipated. Low forceps can be used with caution if necessary, but the use of mid-forceps may be hazardous. It seems sensible to advise cesarean section if the infant is very large or if premonitory symptoms suggesting nerve compression occur with attempted engagement of the fetal head in the pelvic brim during the last 4 weeks of pregnancy in a patient with a history of obstetric lumbosacral plexus palsy.

Acute Familial Brachial Neuritis

Several reports document the rare occurrence of brachial plexus neuropathy on a familial basis. Taylor¹⁰⁷ reported that 24 of 119 members of a family covering five generations had experienced single or multiple attacks of acute brachial neuropathy. This disorder was characterized by pain, weakness, atrophy, and sensory loss that was usually unilateral but occasionally bilateral and from which gradual recovery generally occurred. Male and female family members were affected, but among the women, there was a striking association of attacks with pregnancy or the puerperium, in contrast to the more common idiopathic disorder, which is rarely associated with pregnancy. In some instances of the familial disease, the lower cranial nerves were involved, and isolated mononeuropathies of the other extremities were present. Other cases have been described. Treatment with oral steroids may be helpful in relieving pain but does not seem to affect the rate of recovery.

Carpal Tunnel Syndrome

Compression of the median nerve may occur in the carpal tunnel at the wrist, especially when the normal size of the carpal tunnel is

reduced, as by degenerative arthritis, or when the volume of its contents is increased, as in inflammatory disorders involving the tendons and connective tissues at the wrist. Carpal tunnel syndrome is common during pregnancy,¹⁰⁸ perhaps because of excessive fluid retention. Pain and paresthesias are early symptoms and frequently occur at night, awakening the patient from sleep. The symptoms usually involve the first three digits and the lateral border of the ring finger, but some patients report that all digits are affected. Pain may occur in the forearm and occasionally occur in the upper arm. With time, weakness of the thenar muscles may develop. On examination, it is often possible to elicit the Tinel sign (percussion of the nerve at the wrist causing paresthesias in its distal distribution), and the Phalen maneuver (flexion at the wrist for more than a minute) sometimes reproduces or enhances symptoms. There may be mild weakness and wasting of the abductor pollicis brevis and opponens pollicis muscles, impaired cutaneous sensation in a median nerve distribution in the hand, or both motor and sensory signs.

Electrophysiologic testing usually suggests or confirms the diagnosis (Fig. 52-8). In the evaluation of patients, it is important to remember that the carpal tunnel syndrome is commonly bilateral, even though it may be unilaterally symptomatic, and an entrapment neuropathy may be the first manifestation of a subclinical polyneuropathy. These possibilities can be excluded by appropriate electrophysiologic studies.

Symptoms developing or worsening during pregnancy usually respond to the nocturnal use of a wrist splint and clear within about 3 months of delivery, often settling within 1 or 2 weeks.¹⁰⁹ They may recur in subsequent pregnancies. The splint is placed on the dorsal surface so that the wrist can be maintained in a neutral or slightly flexed position. Some patients are helped by injection of steroids into the carpal tunnel and others by treatment with diuretics. The physician must explain to the patient that her symptoms are benign and will generally subside spontaneously after the pregnancy. With such reassurance, most patients accept their symptoms without difficulty.

Surgical division of the anterior carpal ligament may be necessary if symptoms are intolerable or do not clear in the weeks after delivery. Surgical treatment may also be necessary in a patient with clinical or electrophysiologic evidence of increasing nerve dysfunction despite conservative measures, but it can usually be avoided during the pregnancy.

Meralgia Paresthetica

The lateral femoral cutaneous nerve, a purely sensory nerve derived from the L2 and L3 roots, is particularly susceptible to compression or stretch injury during pregnancy, especially during the third trimester. Obesity and diabetes mellitus are other predisposing factors. The nerve usually runs under the outer portion of the inguinal ligament to reach the thigh, but the ligament sometimes splits to enclose the nerve. In the latter circumstance, hyperextension of the hip or an increased lumbar lordosis, such as occurs during pregnancy, leads to compression of the nerve by the posterior fascicle of the ligament. Entrapment of the nerve at any point along its course may lead to similar symptoms, and several anatomic variations may predispose the nerve to damage when it is stretched. Pain, paresthesias, and numbness may occur about the outer aspect of the thigh and are sometimes relieved by sitting. Symptoms are unilateral in approximately 80% of cases.

Little may be found on physical examination, but in severe cases cutaneous sensation is disturbed in the affected area. Symptoms, which are usually mild, subside spontaneously in the puerperium or within

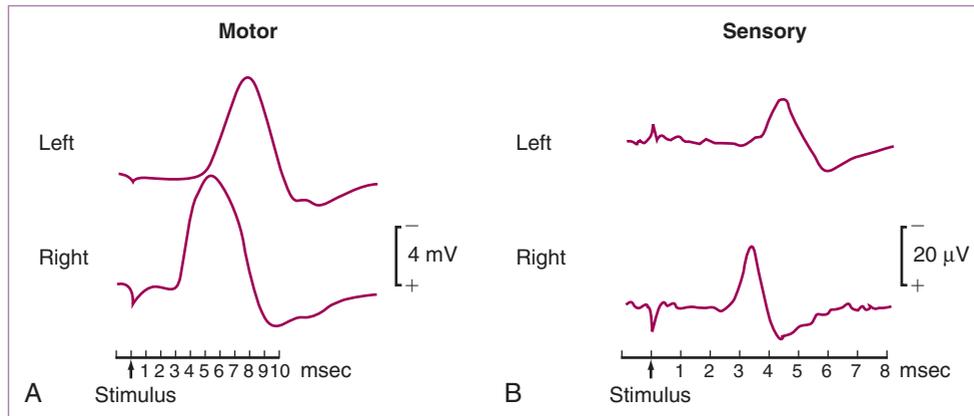

FIGURE 52-8 Nerve conduction studies in a patient with left-sided carpal tunnel syndrome. **A**, Responses are shown for the abductor pollicis brevis muscle to supramaximal electrical stimulation of the median nerves at the wrist. The latency of the response on the left is prolonged. **B**, The sensory action potentials are recorded over the median nerve at the wrist after electrical stimulation of digital sensory fibers in the index fingers. Those on the left have a smaller amplitude and more prolonged latency than those on the right. Maximal motor conduction velocity in the forearm segments of the median nerves was normal.

a few weeks of delivery. Patients should be reassured about the benign nature of the disorder. In a few instances, however, pain has been so severe that labor had to be induced early. Hydrocortisone injections in the region where the nerve lies medial to the anterior superior iliac spine may relieve persistent symptoms for a time, and low-dose tricyclic antidepressant drugs may also be helpful. Anticonvulsant agents, which are sometimes helpful for neuropathic pain, are best avoided during pregnancy. Nerve decompression by transposition may provide more lasting relief but is rarely required.

Traumatic Mononeuropathies

Certain causes and clinical features of traumatic mononeuropathies are likely to develop in relation to obstetric procedures.

The obturator nerve originates within the psoas muscle from the L2, L3, and L4 nerves; it emerges from the medial border of the psoas and enters the pelvis immediately in front of the sacroiliac joint. It sweeps around the lateral pelvic wall and then passes through the obturator foramen, dividing into branches that supply the adductor, gracilis, and external obturator muscles; the skin over part of the medial thigh; and the hip joint. The nerve may be injured during genitourinary operations involving the lithotomy position because of angulation as it leaves the obturator foramen or compression between the fetal head (or a pelvic mass) and the bony pelvic wall.¹¹⁰ An obturator nerve palsy leads to impaired gait, because of weakness of the adductor muscles, and to a sensory disturbance involving particularly the medial part of the middle thigh and lower thigh. Pain may also occur and tends to radiate from the groin down the inner side of the thigh.

The femoral nerve originates within the psoas muscle from the L2, L3, and L4 nerves and passes beneath the inguinal ligament to enter the thigh. It innervates the iliacus, sartorius, pectineus, and quadriceps femoris muscles, and its cutaneous branches supply anterior and medial portions of the thigh and, through the saphenous nerve, the medial portions of the lower leg. Clinical features of a femoral nerve palsy are weakness and, in severe cases, wasting of the quadriceps muscle, sensory impairment over the anteromedial aspect of the thigh and occasionally of the leg to the medial malleolus, and depression or

absence of the knee jerk. This type of palsy can occur as an isolated phenomenon in the patient with diabetes mellitus, a bleeding tendency, or retroperitoneal neoplasm, and it may sometimes arise by angulation and pressure from the inguinal ligament when the thighs are markedly flexed and abducted, as in the lithotomy position in anesthetized patients.

The saphenous nerve, the branch of the femoral nerve that supplies sensation to the medial aspect of the leg below the knee, may be damaged by pressure from leg braces when the patient is improperly suspended in the lithotomy position. The compressive injury leads to numbness and paresthesias that are usually fairly short-lived.

Sciatic or common peroneal nerve palsies are easy to confuse with a plexus palsy because their constituent fibers are susceptible to compressive injury in the sacral plexus during labor. Misplaced deep intramuscular injections are probably still the most common cause of sciatic nerve palsy. The sciatic nerve may also be injured by stretching when a patient is positioned in stirrups on the obstetric table. To avoid this injury, the knee and hip joints should be well flexed, and extreme external rotation of the hip should be avoided.

In patients with sciatic nerve palsy, the resulting weakness and sensory disturbance depend on whether the entire nerve has been affected or certain fibers are selectively involved. In general, the peroneal fibers of the sciatic nerve are much more likely to be damaged than fibers destined for the tibial nerve. The clinical features of a sciatic nerve lesion may simulate those of a peroneal neuropathy, although electromyographic evidence of involvement of the short head of the biceps femoris muscle favors the former. The common peroneal nerve is vulnerable to compression or direct trauma in the region of the head and neck of the fibula and may be injured at this site by pressure from the leg braces of the obstetric table, especially in anesthetized patients.¹¹¹ Weakness of dorsiflexion and eversion of the foot are accompanied by numbness or blunted sensation of the anterolateral aspect of the calf and the dorsum of the foot.

Bell Palsy

Sir Charles Bell first established the motor function of the seventh cranial nerve in the early 19th century. His name soon came to be

associated with all forms of facial paralysis, but the designation of Bell palsy is now used for facial paresis of lower motor neuron type when no specific etiologic agent can be found. Some cases are probably caused by viral infection or an inflammatory reaction involving the facial nerve near the stylomastoid foramen or in the bony facial canal.

The incidence of Bell palsy is increased during pregnancy. The ideas of a relationship with hypertension or preeclampsia is supported by the study of Shmorgun and coworkers.¹¹²

The clinical features of Bell palsy are well known. The facial paresis usually is abrupt in onset, although it may worsen over the following day. Pain around the ear may precede or accompany the weakness in about half the cases but usually lasts for only a few days. The face itself feels stiff and pulled to one side. It may be difficult to close the eye on the affected side, and ipsilateral epiphora may occur. The patient may have difficulty with eating and with fine facial movements (e.g., when applying cosmetics). A disturbance of taste, caused by involvement of chorda tympani fibers, is common, and hyperacusis, caused by involvement of fibers to the stapedius, is occasionally troublesome.

Treatment is controversial. Most patients recover without treatment, and only about 10% of all patients are seriously dissatisfied with the final outcome because of permanent disfigurement or other long-term sequelae. Treatment is best reserved for patients in whom an unsatisfactory outcome can be predicted soon after onset. To be effective, treatment should commence within the first 5 or 6 days.

The best clinical guide to prognosis at an early stage is the severity of the palsy. Patients who have clinically complete palsy when they are first seen are less likely to recover fully than those with an incomplete palsy. Other clinical indicators for a poor prognosis for recovery include advancing age, hyperacusis, and severe initial pain.

The only medical treatment that may influence the outcome of Bell palsy is steroid therapy, although rigorously controlled trials have not always demonstrated benefit. Despite or because of the uncertainty about their effectiveness, many physicians routinely prescribe steroids to patients who are seen within 5 days of onset. Surgical procedures to decompress the facial nerve have not been beneficial.

Polyneuropathies

There were several early reports of the occasional occurrence of a polyneuropathy during pregnancy, but there does not appear to be any specific polyneuritis of pregnancy. Any type of polyneuropathy, such as that caused by diabetes mellitus, may develop during the gestational period. Discussion here is limited to those most likely to manifest clinically or to pose a management problem during pregnancy.

Nutritional Neuropathies

Nutritional deficiency may be the most probable cause of peripheral nerve involvement in patients who come from underdeveloped countries or have hyperemesis. Signs of peripheral nerve involvement may be found in patients with hyperemesis gravidarum who have Wernicke encephalopathy. In the limbs, numbness, paresthesias, and dysesthesias are accompanied by cutaneous sensory loss, depressed tendon reflexes, and distal weakness. Retrobulbar neuropathy may also occur, and tachycardia, postural hypotension, exertional dyspnea, and sphincter disturbances are sometimes conspicuous. The polyneuropathy is accompanied by ophthalmoplegia (e.g., horizontal and vertical nystagmus, impaired lateral gaze, conjugate gaze palsies), ataxia of gait, and a confusional state. The features of Korsakoff psychosis, which consists

of impaired memory and an inability to acquire new information, sometimes accompanied by confabulation, may also be conjoined.

The diagnosis is confirmed by the finding of a marked reduction in blood transketolase activity and a marked thiamine pyrophosphate effect. Treatment consists of thiamine (50 mg), which is given once intravenously and then intramuscularly for several days until a satisfactory dietary intake is assured.

In other instances, a severe polyneuropathy may develop without an accompanying encephalopathy, presumably in relation to a nutritional deficiency, although the specific factors responsible for the peripheral nerve involvement are not known. Patients may complain about pain, paresthesias, and dysesthesias in the extremities; limb weakness; or ataxia. There may be accompanying cardiac involvement, with tachycardia, exertional dyspnea, and heart failure. Treatment consists of a balanced diet and supplements of vitamins, especially B vitamins. Vitamin B₁₂ deficiency may lead to maternal polyneuropathy and other neurologic abnormalities and can affect the fetus and neonate.

Acute Idiopathic Polyneuropathy: Guillain-Barré Syndrome

An acute or subacute polyneuropathy that sometimes follows infective illnesses, inoculations, or surgical procedures but often occurs without any obvious preceding event characterizes acute idiopathic polyneuropathy. In many such instances, the neuropathy follows clinical or subclinical infection with *Campylobacter jejuni*. The disorder may have an immunologic basis, but the precise mechanism is unclear. It can pose an especially difficult management problem when it occurs during pregnancy.

The main complaint is of weakness that varies widely in severity in different patients, is often more marked proximally than distally, and is often symmetrical in distribution. It usually begins in the legs, frequently comes to involve the arms, and often affects one side or both sides of the face. Weakness may progress to total paralysis and may be life-threatening if the muscles of respiration or deglutition are involved. Sensory symptoms are common but are usually less conspicuous than motor symptoms. Autonomic dysfunction may manifest with tachycardia, cardiac irregularities, hypotension or hypertension, facial flushing, disturbances of sweating, disturbed pulmonary function, and other signs and symptoms.

Examination of the cerebrospinal fluid reveals characteristic changes; the protein content is significantly increased, but the cell content is normal. Measurement of motor and sensory conduction velocity in the peripheral nerves may reveal marked slowing, but the chronology of this reduction does not necessarily parallel that of the clinical disorder. In some patients, the conduction velocity remains normal, presumably because disease is restricted to the nerve roots or proximal segments of the nerves. Most patients eventually make a good recovery, but it may take many months, and some patients have persistent disability.

The Guillain-Barré syndrome does not occur more commonly during gestation than at other times, and the course of the disorder does not seem to be influenced by pregnancy. Improvement in neurologic status may occur before delivery and is not necessarily delayed until the infant is born.

Treatment is symptomatic, with attention directed at the prevention of complications, such as respiratory failure and vascular collapse. Plasmapheresis or treatment with intravenous immunoglobulins is helpful in patients with rapidly advancing or severe disease, but experience with such approaches is limited during pregnancy. Severely

affected patients are best managed in intensive care units, where respiratory and circulatory function can be monitored and assisted respiration can be started as soon as is necessary. Ventilatory support may help to avert fetal hypoxia.¹¹³ Ultrasonographic fetal monitoring generally reveals normal fetal movements even when the mother is severely paralyzed.¹¹⁴

Approximately 3% of patients with acute idiopathic polyneuropathy have one or more relapses, sometimes several years after the initial illness. Such relapses, which are clinically similar to the original illness, occasionally occur during pregnancy.

Porphyric Neuropathy

In the hepatic forms of porphyria, the central and peripheral nervous systems may be affected. Acute intermittent porphyria, inherited as an autosomal recessive trait, is characterized by increased production and urinary excretion of porphobilinogen and δ -aminolevulinic acid. Colicky abdominal pain is often the most conspicuous symptom, but the usual neurologic manifestation is a polyneuropathy that is predominantly motor but sometimes occurs with pronounced autonomic involvement, which may take weeks or months to regress, depending on its severity. Cerebral manifestations may also occur, often preceding the development of a severe polyneuropathy and similarly clearing after a variable time. Clinical indicators of disease activity include tachycardia, fever, and a peripheral leukocytosis. In variegate porphyria, cutaneous sensitivity to sunlight is an additional clinical feature.

Attacks may be precipitated by pharmacologic agents such as barbiturates, sulfonamides, and estrogens. Some women have found that relapses are most likely to occur premenstrually; long-term combination oral contraceptives may prevent attacks in these patients.¹¹⁵ In other patients, oral contraceptives may precipitate exacerbations, and this form of contraception is probably best avoided in women with a blood relative who has a hepatic type of porphyria.¹¹⁶

Pregnancy may lead to an acute exacerbation and may even have a fatal outcome, but many patients tolerate attacks without apparent ill effect. When relapses occur, they usually do so in early pregnancy and may lead to spontaneous abortion.¹¹⁶ However, exacerbations may occur at any time during pregnancy or after delivery. The implications and uncertain outcome must be explained to patients who are contemplating pregnancy, and close supervision should be provided during the gestational period. Latent cases may be exacerbated by medication used during or after labor, and particular care must be exercised in this regard. In general, if the pregnancy proceeds satisfactorily, a healthy infant can be anticipated.

Myasthenia Gravis

Variable weakness and fatigability of skeletal muscles, resulting from defective neuromuscular transmission, are the clinical hallmarks of myasthenia gravis. The disorder has an autoimmune basis. It is characterized by a reduced number of available acetylcholine receptors at the neuromuscular junctions. Myasthenia gravis is more common in females. In some patients, the external ocular muscles or levator palpebrae are especially affected; in others, the facial and bulbar muscles are selectively involved; and in other patients, the limb muscles, especially the proximal ones, are predominantly affected. Weakness may remain localized to a few muscle groups or may become generalized, and it can be a life-threatening disorder if the muscles of respiration or deglutition are involved.

Patients are particularly sensitive to even small doses of neuromuscular-blocking agents, such as tubocurarine, but improvement results from treatment with acetylcholinesterase inhibitors. Thymectomy often leads to a remission of symptoms, and myasthenia gravis may be associated with thymoma. Repetitive supramaximal electrical stimulation of motor nerves may lead to an abnormal decline in size of the evoked muscle action potentials. This finding is sometimes of diagnostic help, as is the finding of elevated levels of circulating acetylcholine receptor antibodies or antibodies to muscle-specific kinase and the clinical response to edrophonium or neostigmine. In addition to thymectomy in appropriate cases, treatment may involve the use of anticholinesterases, steroids, intravenous immunoglobulins, and plasmapheresis.

Exacerbations of myasthenia gravis sometimes occur shortly before the onset of the menstrual period and tend to improve after menstruation has begun. This association may disappear after thymectomy.

Myasthenia gravis may first appear during or shortly after pregnancy, but it is difficult to predict the influence of pregnancy on a patient with the disorder. Moreover, the effect of pregnancy may vary on different occasions, so that the outcome in individual cases cannot be predicted on this basis. Relapses can occur in early pregnancy, with partial or complete remission often occurring at a later stage. Batocchi and associates¹¹⁷ found during pregnancy that myasthenia relapsed in 17% of asymptomatic patients who were not on treatment before conception; among patients on therapy, symptoms improved in 39% of pregnancies, were unchanged in 42%, and worsened in 19%. Further, myasthenic symptoms worsened after delivery in 28% of pregnancies. It may be tempting to terminate a pregnancy because of the severity of myasthenic symptoms—death has been reported in pregnancy complicated by myasthenia gravis—and because of the difficulties in their treatment, but termination does not necessarily lead to clinical benefit. Myasthenia gravis should be managed in pregnant patients as it is in nonpregnant patients.

Myasthenia gravis has little effect on the pregnancy itself. Moreover, there may be a marked contrast during labor between the strength of uterine contractions in the second stage and the skeletal muscle weakness exhibited by the patient. If the expulsive phase of labor is prolonged, instrumental assistance may help to avoid maternal exhaustion. Cesarean section should be reserved for patients in whom it is indicated on obstetric grounds. Regional analgesia is preferable to general anesthesia, and the use of muscle relaxant drugs is avoided if possible. Similarly, the use of magnesium sulfate for eclampsia should be avoided because it may precipitate myasthenic crisis. No differences were found in perinatal mortality, gestational age, or birth weight between the offspring of myasthenic and nonmyasthenic women in a population-based cohort study.¹¹⁸

Infants born to myasthenic patients should be carefully watched during the week after delivery for signs of neonatal myasthenia. Such signs include a poor cry, respiratory difficulties, weakness in sucking, a weak Moro reflex, and feeble limb movements, usually becoming apparent within the first 72 hours of birth. Symptoms are usually not evident immediately after birth, and this delay has been attributed to protection of the infant by placental transfer of maternal anticholinesterase drugs.

Neonatal myasthenia is a transient disorder that results from placental transfer of maternal antibody against acetylcholine receptors. It occurs in 10% to 15% of infants born to myasthenic mothers and does not seem to be related to the duration or severity of maternal illness, although disease in mothers of myasthenic newborns is usually generalized rather than localized. It can be treated with anticholinesterase drugs and usually subsides within 6 weeks of delivery, but it may result

in death caused by aspiration or respiratory failure. Facilities should be available for the immediate resuscitation of affected infants or those at risk of being affected. Immunosuppressive therapy is sometimes required. Maternal myasthenia has also been incriminated as a rare cause of congenital arthrogryposis.¹¹⁹

The birth of a child with neonatal myasthenia does not necessarily imply that future children will also have the disorder, although they often do. The transient neonatal disorder that may occur in the offspring of a myasthenic mother must not be confused with congenital myasthenia gravis. The latter is rare, occurs in children born of healthy mothers, and is usually permanent.

Disorders of Muscle

Myotonic Dystrophy

Myotonic dystrophy type 1 is a slowly progressive, dominantly inherited disorder that usually appears in early adult life but may manifest in childhood. It has been related to an expanded trinucleotide repeat in a gene localized to 19cen-q13.2. Increasing numbers of triplet repeat expansions govern clinical expression of disease; prenatal detection of the disorder is possible.^{120,121} Myotonia is accompanied by weakness of the facial, sternomastoid, and distal limb muscles. Associated features may include cataracts, frontal baldness, cardiac and endocrine disturbances, and intellectual changes. During pregnancy, the weakness and myotonia may be aggravated, and the course of the disorder is sometimes accelerated. When deterioration does occur, it often begins at about the sixth or seventh month of pregnancy.

In the antepartum period, the major reported obstetric complications of myotonic dystrophy include threatened, spontaneous, and habitual abortion. Hydramnios is well described. Ectopic pregnancy and placenta praevia may occur, and perinatal loss is increased.¹²² Premature onset of labor in patients with myotonic dystrophy has been attributed in some instances to abnormalities of uterine muscle. Labor may be abnormal because of failure of the uterus to contract normally. The first stage may be prolonged, and retention of the placenta and postpartum hemorrhage may occur. Manual removal of the placenta is sometimes necessary. Skeletal muscle weakness may also lead to poor voluntary assistance in the second stage.

Type 2 myotonic dystrophy (CTG expansion involving the *ZNF9* gene) may first manifest during pregnancy, with worsening occurring in subsequent pregnancies for uncertain reasons; improvement often follows delivery.¹²² Preterm labor is more likely in women who developed initial manifestations or a deterioration of the disorder during pregnancy compared with those in whom pregnancy did not appear to influence the disease course, but obstetric risk is not increased.¹²²

Myotonic dystrophy type 1 may manifest in infancy, occurring congenitally among the offspring of mothers who have the disorder, sometimes only mildly. In such cases, it is often possible to obtain a history of hydramnios or reduced fetal movements during the latter part of pregnancy. Some affected infants die within hours or a few days of birth. The clinical features in affected infants include facial diplegia, hypotonia, neonatal respiratory distress, feeding difficulties, delayed motor development, and mental retardation.¹²³ Myotonia, a cardinal feature of the adult disease, is absent in the congenital form. The neonatal respiratory distress may result from involvement of the respiratory muscles, pulmonary immaturity, aspiration pneumonia, and impaired neural control of respiration. Talipes is present at birth in about one half of all cases and may require surgical correction. Myotonic dystrophy type 2 has not been described in congenital form.

Familial studies have indicated that in almost every case of congenital myotonic dystrophy, transmission occurred from the mother. This type of transmission does not fit with an autosomal dominant pattern of inheritance. Genetic data suggest that the congenital form results from the combination of the gene responsible for the disorder in adults and some maternally transmitted factor, the nature of which is unclear. Others have suggested that the maternal transmission of the congenital form is associated with relative male infertility.

The management of patients requiring anesthesia for obstetric or other reasons merits comment. Depolarizing muscle relaxant drugs should be avoided because they may cause myotonic spasm, and non-depolarizing agents, such as tubocurarine, can be used but should be given in reduced dosage to patients receiving quinine for myotonia. Thiopental sodium (Pentothal) may lead to marked respiratory depression and is best avoided, as are other respiratory-depressant drugs, especially if the patient already has impaired respiratory function. Electrocardiographic monitoring permits the early recognition of any cardiac arrhythmias, to which patients with myotonic dystrophy are prone. For these reasons, regional analgesia is the preferred method of management.

Myotonia Congenita

The dominant form of myotonia congenita, Thomsen disease, is usually present from birth, although symptoms may not appear until early childhood. Patients complain of muscle stiffness (i.e., myotonia) that is enhanced by cold or inactivity and is relieved by exercise; power is full, but the muscles may be diffusely hypertrophied. Pregnancy may aggravate the myotonia, especially in the latter half of the gestational period, and improvement occurs after delivery.

Polymyositis

In polymyositis or dermatomyositis, which can occur at any age, there is weakness and wasting, especially of the proximal musculature, as a result of inflammatory infiltration of muscles and destruction of muscle fibers. The muscles are often painful and tender. There may be an association with malignancy or one of the collagen diseases. The erythrocyte sedimentation rate and serum creatine kinase levels are elevated. Histologic examination of a muscle biopsy specimen usually permits the diagnosis to be made with confidence so that treatment with steroids can be instituted. Pregnancy has a variable effect on the muscle weakness, but a high perinatal mortality rate has been reported.¹²⁴

Psychiatric Disorders

Pregnancy may occur during the course of established psychiatric illness, and psychiatric disorders may first develop during or shortly after pregnancy, although no specific disorders are associated with this period. In the evaluation of patients with psychiatric disorders, physicians must consider that pregnancy can have a number of different psychopathologic implications, depending on the patient's social, cultural, educational, emotional, and medical background. The attitude of a patient to pregnancy, especially with regard to whether it was desired, influences her psychological response, and her capacity to cope with pregnancy depends on her acceptance of it. If the pregnancy was planned, the factors that motivated it are of some relevance because the aim might have been to overcome marital disharmony or to keep up with peers. These aspects clearly govern the response of an

individual patient to pregnancy. Chapter 53 discusses psychiatric disorders.

Chapter 53

Management of Depression and Psychoses in Pregnancy and the Puerperium

Kimberly A. Yonkers, MD

Epidemiology

Approximately one in five women will experience an episode of major depressive disorder over the course of her lifetime. Chronic psychotic disorders are less common but occur in about 1% of women. The risk of developing any type of depressive disorder, bipolar disorder, or a chronic psychotic disorder such as schizoaffective disorder or schizophrenia peaks when women are in their early 20s.¹

The risk of relapse for a woman with bipolar disorder is increased during the postpartum period compared with a nonpregnant woman,^{2,3} but it is less clear whether the postpartum period confers increased risk for a woman with unipolar depression. Pregnancy does not protect against the development of an episode of depression^{4,5} or mania,² making it likely that pregnant patients with these conditions will need behavioral and pharmacologic treatment.

The risk of developing a unipolar mood disorder, such as major or minor depressive disorder, is increased during the third trimester in some reports,^{6,7} but meta-analyses did not find significant differences in risk across pregnancy.^{4,8} The risk may increase in later pregnancy because some women discontinue psychopharmacologic treatment when they become pregnant, which increases the likelihood of relapse at a later point in the pregnancy.⁵ Women with schizophrenia and schizoaffective disorder have chronic conditions with symptoms that are kept under control under optimal conditions because they are taking antipsychotic medication or mood-stabilizing drugs. Unipolar depression and bipolar disorder are characterized by recurrent episodes of illness that may last several weeks to several months.⁹ A lack of symptoms during one trimester does not indicate that a woman with one of these illnesses will remain well throughout her pregnancy.

Whether the postpartum time, compared with pregnancy, constitutes a period of increased risk for a depressive disorder is debated. Although some reports find no increase in depressive symptoms in the puerperium compared with pregnancy,⁶ others find that psychotic depression¹⁰ and severe episodes of depression¹¹ increase after delivery and that women seek treatment more often after delivery than during pregnancy.¹²

Diagnostic Nomenclature for Depressive and Psychotic Disorders

Several features of the various mood and psychotic disorders overlap, but there are specific elements. They are briefly described here because they directly relate to how mood and psychotic disorders are managed clinically (Tables 53-1 and 53-2).

A depressive episode includes symptoms of low mood and diminished capacity to experience pleasure. The condition can occur in pregnant or postpartum women who suffer from a unipolar depressive disorder (e.g., major depressive disorder, minor depressive disorder, dysthymic disorder), bipolar disorder, or schizoaffective disorder. If a woman also experiences episodes of mania or hypomania (see Table 53-2), she has bipolar disorder or schizoaffective disorder, not unipolar depression. Psychotic symptoms such as auditory hallucinations or delusions can also occur in women who have unipolar depression, bipolar disorder, or schizoaffective disorder. However, if a woman is psychotic and is not having an episode of mania or depression, she has schizoaffective disorder. This diagnosis is appropriate because she has psychosis in the absence of mood symptoms. Mood symptoms can occur among women with schizophrenia, but they are not a cardinal feature of that disorder. Psychosis is chronic and central to a diagnosis of schizophrenia and schizoaffective disorder.

Identifying Psychiatric Illness during Pregnancy and the Puerperium

The typical age of onset for schizophrenia and bipolar disorder is in the late teens to early 20s. Many women with these conditions have been diagnosed previously and are usually able to provide this information and describe their lifetime treatment. The first onset of

TABLE 53-1 SYMPTOMS OF DEPRESSION, MANIA, AND PSYCHOSIS

Criteria*	Depressive Episode	Manic Episode	Psychosis
Sad, blue, depressed mood	Yes		
Persistently elevated, expansive, or irritable mood		Yes	
Decreased interest in pleasurable activities	Yes		
Increased interest in pleasurable activities likely to lead to painful consequences (e.g., shopping sprees, sexual indiscretions)		Yes	
Decreased or increased appetite or weight	Yes		
Undersleeping	Yes	Yes	
Oversleeping	Yes		
Physical or mental slowing (includes catatonia)	Yes		Yes
Agitation	Yes (fidgety, cannot relax)	Yes (increase in goal related activities)	Yes (purposeless movements)
More talkative than usual (e.g., excessive, pressured speech)		Yes	
Racing thoughts		Yes	
Decreased energy	Yes		
Increased energy		Yes	
Worthlessness, guilt	Yes		
Grandiose, inflated self-esteem		Yes	
Poor concentration, indecision, distractibility	Yes (unfocused, difficulty concentrating, difficulty making decisions)	Yes (key feature: extremely distractible by irrelevant external stimuli)	Yes (includes incoherence, disorganized speech)
Suicide ideation, intent, or plan	Yes	Yes	
Delusions			Yes
Hallucinations			Yes
Disorganized behavior			Yes
Flat affect, "no emotion"			Yes

*These items comprise criteria for the diagnosis. Patients with any of these diagnoses may have one or more of these symptoms, even if the item is not part of the diagnosis. A depressive episode requires ≥ 5 symptoms, including low mood or diminished pleasure, persisting for 2 weeks. Mania requires ≥ 3 symptoms for at least 1 week. Schizophrenia requires 2 symptoms for 4 weeks.

bipolar disorder may occur during the puerperium, and a woman who develops symptoms listed in Table 53-1 should immediately be evaluated by a psychiatrist. Women with major and minor depressive disorders are somewhat more difficult to identify because they may or may not have had an episode before pregnancy. During pregnancy, they may remit and relapse. Depression screening scales can be helpful in identifying women who are symptomatic. However, the benefits of screening are realized only if practitioners have the skills and resources available to deliver adequate interventions or provide appropriate referrals.

Well-validated screening instruments measure general distress and dysphoria and are often less specific for depression. Appropriate tools for pregnant women include the Edinburgh Postnatal Depression Scale (EPDS),¹³ Inventory of Depressive Symptomatology (IDS),¹³ or Primary Care Evaluation of Mental Disorders (PRIME-MD) depression module.¹⁴ The EPDS is designed specifically for use with perinatal women, although it is less comprehensive than the IDS and does not include all of the criteria for major depressive disorder. The EPDS has 10 items and a mood and anxiety subscale. The IDS measures severity of cognitive features of depression and anxiety and atypical depressive symptoms, such as overeating and oversleeping (rather than undersleeping and undereating); it has a self-report and clinician administered version, as well as a brief version. The PRIME-MD records diagnoses of major depressive disorder and minor depressive disorder and has been used in obstetric-gynecologic settings; it takes 5 to 20 minutes to complete.

Management

Impact of Mood and Psychotic Disorders on Pregnancy Outcomes

Developing a treatment plan for a pregnant or postpartum woman necessitates considering the risks of the underlying illness and risks associated with the various treatment options. Women with an untreated mood or psychotic disorder face a number of risks. These illnesses can lead to poor self-care, partial or total disability that can impair the care of others, and in the worst scenario, suicide or homicide because of psychotic thoughts. Compared with women without a mood or psychotic disorder, those with such conditions are more likely to smoke, use hazardous substances (i.e., alcohol or illicit drugs), and have a concurrent medical condition, and they are less likely to receive adequate prenatal care.¹⁵⁻¹⁸ The review that follows addresses the risk of standard obstetric outcomes, including spontaneous abortion, preterm delivery, growth restriction, and congenital malformations, but it does not address the maternal morbidity occurring because of a psychiatric illness, for which there are few systematic data.

Schizophrenia

Information on the possible impact of schizophrenia on birth outcomes and other post-neonatal complications largely derives from linked administrative databases¹⁹⁻²² that allow investigators to obtain

TABLE 53-2 DEPRESSIVE AND PSYCHOTIC DISORDERS

Psychiatric Disorder	Depressive Episodes?*	Manic Episodes?†	Psychotic Symptoms?‡	Lifetime Prevalence	Typical Treatment Needed
Major depressive disorder	Yes, central feature of the condition	No	Can have a psychotic variant	21%	Antidepressant or psychotherapy; antipsychotic needed for psychotic features
Minor depressive disorder	Yes, central feature of the condition	No	Does not typically have a psychotic variant		Psychotherapy often sufficient in pregnancy, but antidepressant may be useful after delivery
Dysthymic disorder	Yes, chronic	No	Does not typically have a psychotic variant		Psychotherapy often sufficient in pregnancy, but antidepressant may be useful after delivery
Bipolar disorder	Yes, may have depressive episodes or episodes with mixed depressive and manic symptoms	Yes, may have manic or hypomanic episodes; depressive and manic symptoms can coexist	Psychotic symptoms commonly occur but only when the patient is in episode of mania or depression	0.5-1%	Mood stabilizer and/or antipsychotic agent typically needed to maintain stability
Schizoaffective disorder	Yes, may have depressive episodes or episodes with mixed depressive and manic symptoms	Yes, may have manic or hypomanic episodes; depressive and manic symptoms can coexist	Psychotic symptoms commonly occur, even when the patient is not in episode of mania or depression	0.5-1%	Antipsychotic agent typically needed to maintain stability
Schizophrenia	Yes, but mood symptoms are neither necessary nor central feature	No	Yes, central feature of the condition	1%	Antipsychotic agent typically needed to maintain stability

*Depressive symptoms include low mood; decreased interest; alterations in sleep, energy, and appetite; guilt; poor concentration; psychomotor retardation; and suicidal ideation.

†Manic symptoms include diminished need for sleep, decreased appetite, increased energy, racing thoughts, pressured speech, and grandiosity.

‡Psychotic symptoms include auditory hallucinations, visual hallucinations, paranoia, and other delusions.

sufficient sample sizes for relatively uncommon disorders ($\approx 1\%$ for psychotic disorders) and birth outcomes that are seen less frequently. When interpreting findings from these studies, it is important to observe their limitations. For example, most studies were not able to adequately control for smoking and illicit drug use, both of which are more common among schizophrenic women.^{18,23} The possible role of medication treatment in poor birth outcomes has been inadequately addressed because of heterogeneity in medication use and limited cohort sizes.²⁴

Given these limitations, women with schizophrenia appear to have worse birth outcomes than women without the disorder.^{19-21,24,25} In a linked Danish database,²³ women with schizophrenia had a 46% higher relative risk of preterm delivery (95% confidence interval [CI], 1.19 to 1.79), 57% higher likelihood of delivering a low-birth-weight infant (95% CI, 1.36 to 1.82), and 35% higher risk for a small-for-gestational-age (SGA) infant (95% CI, 1.17 to 1.53) compared with the overall population of women. These adverse outcomes had been found earlier by other investigators.^{21,25} Other complications reported for women with schizophrenia include placental abruption²¹ and delivery of offspring with malformations,²⁰ including specific cardiac defects.²¹

Some^{22,24} but not all²⁰ studies show an increased risk of stillbirth and neonatal death for women with psychotic disorders (including women with schizophrenia and bipolar disorder²²) and specifically with schizophrenia.²⁴ There were also differences in the rates of post-neonatal deaths for infants born to women with schizophrenia compared with mortality rates for the general population.²⁰ Postneonatal

death occurred at a rate of 0.73% among children born to women with schizophrenia, compared with 0.26% for those in the general population (relative risk [RR] = 2.76; 95% CI, 1.67 to 4.56). Most of the deaths were attributable to sudden infant death syndrome (SIDS), which occurred at a rate of 0.46% for children born to women with schizophrenia and 0.1% for the general population (RR = 5.23; 95% CI, 2.82 to 9.69).

Bipolar Disorder and Schizoaffective Disorder

There is little information regarding birth outcomes among women with bipolar disorder. The largest study is the Australian study that investigated outcomes for women with bipolar disorder ($n = 1301$), schizophrenia ($n = 618$), unipolar psychotic depression ($n = 1255$), and controls ($n = 3129$).²¹ However, some studies assessed outcomes and found difficulties for all women with a psychotic disorder and did not differentiate among the types of disorders. For example, the increased risk of stillbirth (OR = 4.03; 95% CI, 1.14 to 4.25) described in one report occurred for mothers with psychotic disorders that included pregnant women with schizophrenia or bipolar illness.²² Placenta previa and antepartum hemorrhage occur at a significantly higher rate among women with bipolar disorder than controls (4.2 versus 2.4%; OR = 1.66; 95% CI, 1.15 to 2.39). There were no differences for women with bipolar disorder compared with controls for birth weights, duration of pregnancy, or risk of malformations in one large cohort study.²¹ The latter findings are curious because of the need for treatment with mood stabilizers of individuals with bipolar disorder and the association between these compounds and malformations.²⁶

Unipolar Major Depressive Disorder

Some research suggests that high levels of stress are associated with spontaneous pregnancy loss in chromosomally normal offspring.²⁷ Because depression is a stress-related illness, similar results may be expected for depressed women. Unfortunately, studies looking specifically at depression are small, and the results are mixed, making it difficult to draw definitive conclusions.²⁸⁻³⁰

Most research addressing the relationship between depression and pregnancy outcomes has assessed women with depressive symptoms rather than a diagnosed depressive disorder. This is important because individuals with a number of psychiatric conditions have elevated scores on depressive screening or severity measures. With this caveat in mind, adult women with high levels of depressive symptoms as measured by the Beck Depression Inventory (>21 with a range of 0 to 63) had a 3.4-fold increased risk (95% CI, 3.3 to 3.6) for delivering preterm and a 3.9-fold increased risk (95% CI, 3.8 to 4.2) for delivering a low-birth-weight infant, compared with women with lower depression scores.³¹ Similarly, pregnant, African-American women scoring in the top decile of the Center for Epidemiological Studies Depression Scale (CES-D) were almost twofold more likely (12.7% versus 8%; 95% CI, 1.04 to 3.7) to have spontaneous preterm delivery compared with the remaining women in the cohort.³²

Of 10 prospective studies of depression and preterm birth reviewed by an Institute of Medicine panel, two reported an association. Although depression was not consistently or strongly linked to preterm birth in the general population, behaviors such as smoking, drug abuse, and alcohol use might have explained observed associations between the two.

It is possible that socioeconomic status mediates the effect of psychiatric distress on birth outcomes. In a prospective cohort of 666 pregnant women, elevated CES-D scores at 28 weeks for women with lower socioeconomic status were significantly associated with birth weight, even after controlling for smoking, social support, and other demographic and obstetric factors.

In contrast to earlier studies, a prospective cohort study from Sweden failed to find an association between maternal depressive or anxiety disorders and adverse birth outcomes among 1465 mothers. Power may be limited, however, because only 46 women had major depressive disorders and 86 had anxiety disorders.³³ No studies were found that specifically assessed differences in risk of congenital anomalies among mothers with a depressive disorder compared with those without depression (Table 53-3).

Risks of Psychopharmacologic Treatment during Pregnancy

Antipsychotic Agents

Antipsychotic agents include the older, typical antipsychotic agents and the newer, atypical antipsychotic agents. The older, typical antipsychotic agents are further divided into the low-potency medications, such as the phenothiazines, and high-potency agents, such as the butyrophenones.

There is limited information on the risk of antipsychotic agent use in pregnancy. A comprehensive meta-analysis showed a small increase in the overall malformation rate (increase of 4 cases for every 1000 women) among women who took low-potency agents, but there was no specific pattern to the reported anomalies.³⁴ The lack of a pattern leaves open the possibility that factors other than the drugs contributed to this association.

TABLE 53-3 ANTIPSYCHOTICS AND MOOD STABILIZERS

Drug Name	Dose (mg/day)
Antipsychotics	
Aripiprazole (Abilify)	10-15
Clozapine (Clozaril)	12.5-900
Ziprasidone (Geodon)*	20-160
Risperidone (Risperdal)*	1-8
Quetiapine (Seroquel)*	150-800
Thioridazine (Mellaril)	50-800
Thiothixene (Navane)	6-60
Olanzapine (Zyprexa)*	2.5-20
Mood Stabilizers	
Valproic acid (Depakote)	750
Lamotrigine (Lamictal)	25-200
Carbamazepine (Tegretol and Tegretol-XR)	200-400

*These antipsychotic medications are also approved for the treatment of mania.

There is also limited information regarding the high-potency butyrophenones and birth outcomes. The largest prospective cohort study ($n=206$ first-trimester exposures versus 631 controls) found that elective terminations (8.8% versus 3.8%) and preterm birth (13.9% versus 6.9%) were more common for women who used this class of antipsychotic agent³⁵; mothers also delivered significantly lighter infants if they were taking a butyrophenone. However, there were no differences in the rates of malformations. This small study had limited power to detect malformations unless the rates were greatly elevated.

Information regarding the risks associated with atypical antipsychotics is sparse but is increasing. Postmarketing data regarding pregnancy exposure to risperidone showed rates of malformations and spontaneous abortion that were consistent with population rates (3.8% and 16.9%, respectively).³⁶ However, the findings were based on prospective outcomes for 68 women. The retrospectively reported cases had much higher rates of malformations, but these data were confounded by ascertainment bias.

The atypical antipsychotic olanzapine is approved for use in treating mania. The pharmaceutical company registry of prospectively followed cases found associated rates of 13% for spontaneous abortion, 5% for stillbirth, 5% for preterm delivery, and 0% for malformations.³⁷ Although these are uncontrolled data, the rates are within the range expected for non-exposed populations. Limited data suggest that there may be a risk of gestational diabetes and preeclampsia³⁸ with the use of olanzapine. Diabetes that may be a consequence of insulin resistance and weight gain³⁹ has been associated with the use of this agent in nonpregnant populations.⁴⁰

Mood Stabilizers

LITHIUM

The use of lithium during pregnancy has been comprehensively reviewed by the Institute for Evaluating Health Risks.⁴¹ Early reports from the International Registry of Lithium Babies,⁴² a voluntary physician-reporting database, described a 400-fold increased rate for cardiovascular malformations, most notably Ebstein anomaly, in offspring who were exposed in utero. It is likely that reporting bias led to overestimates because subsequent investigations identified a risk of Ebstein anomaly among lithium users at between 2 per 1000 (0.05%) and 1

per 1000 (0.1%), or 20 to 40 times higher than the rates for the general population.⁴³⁻⁴⁵ A population-based study⁴⁶ found that the odds ratio for any cardiac malformation was 7.7 (95% CI, 1.9 to 7.7), although none of these anomalies was an Ebstein type. The odds ratio for any malformation was 3.3 (95% CI, 1.2 to 9.2) in this study.

Other complications found among women who used lithium in pregnancy include growth reduction,^{41,44} acute lithium toxicity in neonates,^{41,47} and possibly neonatal mortality.^{41,48} There is little support for long-term neurodevelopmental complications from in utero exposure to lithium.^{44,49}

VALPROIC ACID

Valproic acid use during pregnancy is associated with neural tube defects in about 5% to 9% of exposed offspring.^{50,51} Neural tube-related teratogenicity occurs between 17 and 30 days after conception and is dose related.^{52,53} Valproic acid is more commonly associated with lumbosacral than anencephalic lesions.⁵³

Other complications from valproic acid use in pregnancy include growth restriction,⁵³ growth decelerations,⁵³ and withdrawal symptoms of irritability, jitteriness, feeding difficulties, abnormal tone,^{51,54} and hypoglycemia.⁵⁵ Reductions in neonatal fibrinogen levels⁵⁶ have also been reported, as has possible mental retardation.⁵⁷

CARBAMAZEPINE

Like valproic acid, carbamazepine is considered a human teratogen. Neural tube defects are prominent, occurring in 0.5% and 1% of offspring exposed in utero.^{58,59} Other anomalies include craniofacial defects (11%), fingernail hypoplasia (26%), and developmental delay (20%) among liveborn offspring.⁵⁸

The teratogenic potential of carbamazepine is frequently attributed to the toxic epoxide metabolites.⁶⁰ Oxcarbazepine, which does not produce the epoxide metabolite, may be less teratogenic, although this has not been confirmed by empiric data.

Other complications associated with carbamazepine use include reduction in birth weight (about 250 g),⁶¹ mean head circumference (standardized for gestational age and sex),⁶² and hepatic dysfunction.⁶³

LAMOTRIGINE

Data regarding the possible consequences of lamotrigine use among 785 exposures with prospective follow-up data were published by the Lamotrigine Pregnancy Registry maintained by GlaxoSmithKline.⁶⁴ Rates of defects among infants exposed were similar to the base rate estimated for non-exposed populations. However, unpublished results from the North American Antiepileptic Drug Pregnancy Registry suggest a possible association between cleft palate and in utero lamotrigine exposure (personal communication with GlaxoSmithKline representative, July 2007). A follow-up study of 23 infants exposed demonstrated no alterations in development at 12 months of age.⁶⁵

Antidepressants

Increasing numbers of women are undergoing antidepressant treatment during pregnancy.⁶⁶ According to one estimate,⁶⁶ 13% of women took an antidepressant at some point during pregnancy, and information about exposure to antidepressants and birth outcomes is therefore important.

There are several classes of antidepressants, including monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and others (e.g., bupropion) (Table 53-4). SSRIs are the most frequently prescribed antidepressants during pregnancy, whereas MAOIs are rarely used.^{66,67} Information about antidepressant use in pregnancy is greatest for the SSRIs and TCAs.⁶⁶

MISCARRIAGE

A 45% higher risk (95% CI, 1.19 to 1.77) for miscarriage has been associated with the use of antidepressants in early pregnancy according

TABLE 53-4 ANTIDEPRESSANTS

Drug Class	Drug Name	Dose (mg/day)
Selective serotonin reuptake inhibitors (SSRIs)	Citalopram (Celexa)	20-40
	Escitalopram (Lexapro)	10-20
	Paroxetine (Paxil)	20-50
	Paroxetine controlled release (Paxil-CR)	25-62.5
	Fluoxetine (Prozac)	20-80 or 90 on a weekly basis
	Sertraline (Zoloft)	50-200
	Fluvoxamine (Luvox)	50-300
Monoamine oxidase inhibitors (MAOIs)	Selegiline (Emsam)	6-12 mg patch
	Tranylcypromine (Parnate)	
Tricyclic antidepressants (TCAs)	Amitriptyline (Elavil)	50-200
	Clomipramine (Anafranil)	25-250
	Desipramine (Norpramin)	100-300
	Doxepin (Sinequan)	25-150
	Imipramine (Tofranil)	75-200
	Nortriptyline (Pamelor)	25-150
	Protriptyline (Vivactil)	15-60
	Trimipramine (Surmontil)	75-200
		75-200
Serotonin-norepinephrine reuptake inhibitors (SNRIs)	Duloxetine (Cymbalta)	20-60
	Venlafaxine (Effexor)	25-375
	Venlafaxine (Effexor XR)	37.5-225
Other	Bupropion (Wellbutrin)	200-450
	Bupropion sustained release (Wellbutrin S)	150-400
	Bupropion extended release (Wellbutrin XL)	150-450

to one meta-analysis.⁶⁸ The absolute risk in this analysis ($n = 3567$) was 12.4% and 8.7%, respectively, for exposed and non-exposed mothers, raising the question of ascertainment bias in some of the studies included. Information about other maternal illnesses or confounding health habits was not available in most of the studies constituting the meta-analysis.

FETAL GROWTH AND PREMATUREITY

Several studies have reported that antidepressant use during pregnancy is associated with shorter gestations,⁶⁹⁻⁷⁴ particularly for exposures occurring during the third trimester.^{69,70,73} Overall, the effect on length of gestation is modest, with differences of 1 week or less between exposed and non-exposed offspring, but very large sample sizes would be necessary to see the less common, earlier preterm deliveries.^{71,74-79} Of the two studies that attempted to control for a depressive illness, the effect remained in one⁸⁰ but not the other investigation.⁷⁴

Reductions in birth weight, including low-birth-weight and SGA infants, have been associated with SSRI use during pregnancy.^{74,80,81} Study findings regarding the risk of delivering an SGA infant after maternal TCA use in pregnancy are mixed.^{73,81} The differences between exposed and non-exposed infants are small (e.g., increases from 7.4% to 8.5% for rates of SGA infants in one study after exposure to an SSRI⁸⁰). Statistical attempts to control for maternal illness did not account for the possible effects of SSRIs on birth weight.^{74,80}

STRUCTURAL MALFORMATIONS

Available information does not suggest that TCAs increase the risk of structural malformations.^{34,74,82} Older studies did not find an association between SSRIs and structural malformations,^{83,84} but later reports suggest a modestly increased risk of malformations for infants born to mothers exposed to SSRIs in early pregnancy.⁸⁵ Findings of the National Birth Defects Prevention Study⁸⁶ show an association between SSRI use during the month before and the first 3 months of pregnancy with anencephaly (OR = 2.4; 95% CI, 1.1 to 5.1), craniosynostosis (OR = 2.5; 95% CI, 1.5 to 4.0), and omphalocele (OR = 2.8; 95% CI, 1.3 to 5.7). Somewhat different findings were reported by a similar case-control study,⁸⁷ in which the overall malformation rate among SSRI users was not increased, but the rate of omphalocele and septal defects was higher among offspring specifically exposed to sertraline (OR = 5.7; 95% CI, 1.6 to 20.7 for omphalocele, and OR = 2.0; 95% CI, 1.2 to 4.0 for septal defects). Right ventricular outflow tract obstruction defects occurred at a significantly higher rate among paroxetine-exposed infants (OR = 3.3, 95% CI, 1.3 to 8.8). Other studies find an increased risk of cardiac malformations among offspring specifically exposed to paroxetine, compared with those exposed to drugs deemed nonteratogenic⁸⁸ or population-based controls.^{79,89,90} Most defects were atrial or ventricular septum defects, and one report suggests an elevated risk occurred only for infants whose mothers took 25 mg per day or more of paroxetine.⁹¹

If these defects are associated with the class of SSRIs or individual SSRI agents as suggested, the absolute risk remains small. A twofold to fivefold increased risk is small in absolute numbers for the rates of omphalocele (background rate = 1 in 5000), craniosynostosis (background rate = 1 in 1800), and anencephaly (background rate = 1 in 1000). The most common anomalies are cardiac, for which the incidence is 1.8% to 2% for the exposed population compared with about 1% for an unexposed population. It is precisely because these events remain so rare that there are inconsistencies among studies. An editorial acknowledged a possible increased risk of malformations for infants born to mothers who used SSRIs in the first trimester but argued that these data also show that SSRIs are not major teratogens.⁹² Given the

sources for most reports (e.g., linked databases, surveillance database) and the lack of information about maternal illness or concurrent hazardous substance use, confounding effects remain possible.

The newer, non-SSRI antidepressants include bupropion, venlafaxine, duloxetine, reboxetine, nefazodone, and mirtazapine (see Table 53-4). These agents have far less information regarding possible teratogenic effects, and they vary in chemical structure. The largest analysis of risks associated with these agents found no statistically significant difference in the rate of congenital anomalies for offspring exposed to any one of them compared with the offspring exposed to antidepressants in aggregate⁹⁰ or to nonteratogens.^{71,77-79}

OTHER PERINATAL COMPLICATIONS

Compared with unexposed infants, newborns exposed to TCAs and SSRIs in utero are more likely to experience jitteriness, irritability, and, rarely, convulsions.^{70,73,93,94} The underlying mechanisms related to prenatal antidepressant exposure and short-term sequelae are not known but may be a sort of pharmacologic toxicity.⁹⁵ These symptoms are transient and usually resolve by 2 weeks of age.⁹⁶

Persistent pulmonary hypertension has been reported in infants exposed to SSRIs after 20 weeks' gestation,⁹⁷ for whom the likelihood was sixfold higher compared with controls. This translated into an absolute risk of 6 to 12 cases per 1000 exposed, compared with 1 or 2 cases per 1000 non-exposed infants. Neither exposure to SSRI medications before 20 weeks' gestation nor exposure to non-SSRI antidepressants affects the risk of persistent pulmonary hypertension.

Clinical Approach to Treatment during Pregnancy

Clinical guidelines for managing pregnant women with unipolar depression are available from the American Psychiatric Association⁹⁸ and experts in the field.⁹⁹ There are also guidelines available from the American College of Obstetricians and Gynecologists, the American Psychiatric Association, and the American Medical Association. Guidelines for managing women with bipolar illness are available from the American Psychiatric Association.²⁶ There are no American Psychiatric Association guidelines for managing women with schizophrenia who are pregnant, but Trixler and colleagues¹⁰⁰ contributed a thorough review in 2005.

A treatment plan for a pregnant or postpartum woman with depression should begin by determining whether the patient has had recent or past symptoms of mania or psychosis, because this can help to determine the optimal treatment approach. In general, individuals with unipolar depression may need antidepressant treatment (see Table 53-2). If they have psychotic symptoms, treatment with an antipsychotic agent is also required. Because antidepressants can trigger or promote mania, antidepressant treatment must be used judiciously in women with a history of mania. Instead, mood stabilizers or antipsychotic agents with mood-stabilizing properties (e.g., atypical antipsychotics) are necessary (see Table 53-3). Women with schizophrenia or schizoaffective disorder require treatment with an antipsychotic agent and, in the latter case, a mood stabilizer.

Unipolar Depression

Factors that need to be considered to determine optimal therapy for a woman with mood disorders include her treatment preferences, her clinical history and current illness status, and her resources. An evaluation before conception allows a discussion of all treatment options and may allow a change in therapy, if so desired. Some women prefer not to take any medication, but others want to continue medication,

especially if they have a history of severe, recurrent illness and relapse after medication discontinuation. A discussion about therapeutic options and the patient's preferences should be documented in the chart. If appropriate, women may be encouraged to engage in psychotherapy, which may allow them to be medication free during pregnancy or may improve the response to pharmacologic treatment. A healthy mother is the goal. Her well-being promotes the health of her fetus.

Women who do not have a history of severe recurrences after medication has been discontinued may be candidates for a behavioral therapy. Empirically validated psychotherapies include interpersonal psychotherapy¹⁰¹ and cognitive-behavioral therapy.¹⁰² Engaging in psychotherapy may allow the patient to carry her pregnancy to term without medication, with resumption of pharmacotherapy after delivery as needed. Women often have a sense of whether they can or cannot safely discontinue medication during pregnancy. They might have tried to stop pharmacotherapy in the past to prepare for pregnancy. A woman who discontinues pharmacotherapy should be monitored closely for relapse because her risk for a depressive recurrence may be as much as sixfold higher than that for a pregnant woman who continues pharmacotherapy.⁵ For women whose history precludes medication discontinuation, treatment with the lowest effective dose of an agent that has been helpful to them is indicated. Because of the data regarding paroxetine use in pregnancy (discussed earlier), some clinicians and experts prefer using another medication as a first-line agent. However, because the newer data have not confirmed septal defects and other antidepressants have also been associated with low risks of malformations, this recommendation may not be necessary. If this or another agent has been the only agent to which a woman has responded, it should be the medication of choice for that patient.

Women who are already pregnant and develop a depressive disorder may be referred for psychotherapy as a first-line intervention or to augment pharmacotherapy. If the woman relapsed in the setting of discontinuing an antidepressant to which she had responded, she might need to have that medication restarted.

Bipolar Disorder

Because of the seriousness of bipolar disorder and the need for pharmacotherapy, pregnant women with bipolar disorder should be co-managed by a psychiatrist. Women who have a history of mania, whether they are in an episode of depression or not, should be treated with pharmacotherapy. Psychotherapy may be a helpful adjunct for these women, but is not likely to supplant the efficacy of pharmacotherapy. Unfortunately, many of the medications used to treatment bipolar disorder, including selected anticonvulsants such as valproate and carbamazepine, have teratogenic effects as described previously and in Chapter 20. Teratogenic effects have also been found after first-trimester exposure to lithium. As an alternative to these agents, some experts rely on the use of older antipsychotic agents, at least during the first trimester or longer.⁹⁹ Lithium may be reinstated again after the first trimester. Lamotrigine is a possible treatment during pregnancy. It needs to be titrated slowly from about 25 mg daily to about 200 mg daily, and it is therefore not an option for women who need to discontinue another mood stabilizer (e.g., valproic acid, lithium) and rapidly start another one.

Women with bipolar disorder need to be monitored carefully throughout pregnancy. Changes in renal and hepatic function and volume of distribution in pregnancy mean that dosage requirements may increase. This is particularly notable with lithium⁴¹ and lamotrigine.¹⁰³ Not all pregnant women with bipolar disorder can remain euthymic without a mood stabilizer. The beginning signs of relapse should prompt clinicians to restart these treatments. Difficulties sleep-

ing during pregnancy and after delivery may trigger mania or signify incipient relapse. Women who report this symptom should be prescribed adjunctive antipsychotics with soporific effects to aid in sleep and mood stabilization.

Schizophrenia and Schizoaffective Disorder

As for women with bipolar disorder, women who suffer from schizophrenia and schizoaffective disorder typically require pharmacologic treatment to control symptoms. A mood stabilizer may also be indicated, although first-trimester use of valproate, carbamazepine, and lithium should be avoided if possible. There are substantial data about the use of older, typical antipsychotic agents in pregnancy, and clinicians may elect to rely on these agents in pregnancy. Women with these conditions are at high risk for developing a mood disorder after delivery and are liable to experience worsening of their psychosis.²²

Perinatal Complications

Women treated with lithium or lamotrigine during pregnancy require adjustment in dosage after delivery. Some experts recommend withholding lithium for about 24 hours before parturition because of the risk of maternal toxicity when the patient's volume contracts.¹⁰⁴

Neonates exposed to lithium in utero are at risk for neuromuscular complications, respiratory difficulties, cardiac arrhythmias, and renal and hepatic dysfunction.^{41,104} Because neonatal complication rates increase with maternal dosage, maintaining the lowest effective dose is optimal for the infant.¹⁰⁴ In utero exposure to antipsychotic agents may lead to complications among neonates, including hypertonicity, motor restlessness, tremor, and difficulty with feeding.¹⁰⁰ Similarly, in utero exposure to TCAs and SSRIs are associated with increased perinatal complications, including jitteriness, irritability, and convulsions in as many as 20% to 30% of infants.^{34,70,73,105} Acute signs of anticholinergic effects of TCA, such as functional bowel obstruction and urinary retention, have also been described. These problems resolve within a few days to a week.

Studies examining the long-term developmental outcomes of children exposed to TCAs, SSRIs, and lithium in utero have failed to demonstrate that exposure to these agents affects global IQ, language development, or behavioral development, but these investigations were relatively small.^{49,82,106-108}

Pharmacotherapy during Lactation

Psychotropic medications usually are alkaline and lipid soluble. They diffuse into breast milk. Infants have immature renal and hepatic systems, their blood-brain barrier is more permeable, and they may be more vulnerable to side effects. The use of psychotropic medications in lactating women has been extensively reviewed¹⁰⁹ (see Chapter 9).

Several factors should be considered before prescribing psychotropic medications to nursing mothers, including the benefits of breastfeeding for the infant, the severity of the mother's symptoms if left untreated, mothers' preferences, and the potential risk to the infant if psychotropic drugs are ingested through breast milk. With the exception of lithium, which equilibrates well in breast milk,¹¹⁰ the amount of psychotropic drugs excreted in the mother's breast milk is modest.¹⁰⁹ Infants who are younger than 2 months old¹⁰⁹ and those exposed to medication in utero will achieve higher psychotropic drug levels and be at greater risk for side effects.¹¹¹ Fortunately, the data suggest that an infant's exposure to these drugs through breast milk does not seem to have any deleterious effects on growth or development.¹⁰⁹ Because of the narrow therapeutic index of lithium and the immature renal

status of neonates, some experts recommend avoiding this agent during lactation,¹⁰⁹ although the American Academy of Pediatrics does not absolutely contraindicate breastfeeding for women receiving lithium therapy.¹¹²

Another drug to be avoided is the atypical antipsychotic clozapine (Clozaril), because of agranulocytosis may occur in the infant or mother. If a mother decides to breastfeed while taking antidepressant, antipsychotic, or mood-stabilizing agents, she should monitor her infant carefully for irritability, poor feeding, difficulty with arousal, muscle rigidity, tremors, fever, and difficulty gaining weight. Such symptoms should prompt reevaluation and consideration of a trial off breast milk.

Summary

Pregnancy does not protect women from developing or continuing to experience a mood or psychotic disorder. Schizophrenia and bipolar disorder have been associated with severe complications, including stillbirth, neonatal and postneonatal deaths, and low-birth-weight and preterm deliveries.¹¹³ Women with these psychiatric illnesses should be considered to have high-risk pregnancies. Some women with recurrent major depressive disorder may be at risk for preterm delivery or delivery of a low-birth-weight infant. The psychotropic agents most frequently associated with malformations are the antiepileptic mood stabilizers, valproic acid and carbamazepine, and the standard bipolar therapy, lithium. First-trimester use of these agents should be avoided if possible. Women of reproductive potential who are taking these agents should consider taking folate prophylactically in case of unintended pregnancy. Antidepressant agents are not major teratogens, although possible perinatal complications and a low risk of malformations have been associated with the use of some of these agents. Collaboration between obstetric and psychiatric providers in managing pregnant women with mood and psychotic disorders can enhance maternal and infant health and well-being.

Chapter 54

The Skin and Pregnancy

Ronald P. Rapini, MD

The physical and hormonal alterations induced by pregnancy, childbirth, and the puerperium are associated with numerous cutaneous changes. Some occur so frequently that they are not considered abnormal and vary only in degree. This chapter discusses these physiologic changes, the pathologic rashes of pregnancy, and the effects of pregnancy on preexisting dermatologic diseases.

Common Skin Changes Induced by Pregnancy

Pigmentary Changes

Hyperpigmentation occurs in at least 91% of pregnant women.¹ Much of this is presumed to result from the effects of increased levels of melanocyte-stimulating hormone (MSH)² or estrogen and progesterone on the melanocytes in the epidermis (see Chapter 8). Other bioactive molecules, such as placental lipids, can stimulate tyrosinase activity, which increases pigmentation. Pigmentation is typically most accentuated in the areolar and genital skin. The neck and axillae can become hyperpigmented, but if those areas become velvety or papillomatous, the physician should consider acanthosis nigricans associated with diabetes mellitus and other endocrinopathies. Hyperpigmentation of the linea alba, the longitudinal demarcation line on the midline of the abdomen, is called *linea nigra*. Pigmentary demarcation lines may also appear in other locations.³ All of these pigmentary changes regress after delivery.

Melasma is diffuse macular hyperpigmentation of the face, usually involving the forehead, cheeks, and bridge of the nose. Although the antiquated term *chloasma* has often been used as a synonym, it was typically restricted to cases occurring during pregnancy (i.e., mask of pregnancy). Melasma occurs in about 70% of pregnant women but can occur in women who are not pregnant, especially those taking oral contraceptives and other hormones. Increased expression of α -MSH has been found in lesional skin.⁴ The hyperpigmentation is usually blotchy and poorly demarcated, and it is bilaterally symmetrical. It usually resolves after delivery, although it persists for months or years in about 30% of patients.

Avoidance of exposure to sun during pregnancy helps to prevent or minimize the formation of melasma. Topical sunscreen lotions with sun protective factor (SPF) ratings of 15 or greater should be used. For troublesome hyperpigmentation that persists after delivery, topical hydroquinone bleaching creams and solutions (U.S. Food and Drug

Administration [FDA] pregnancy category C), such as Lustra, Alustra, Melanex, or Solaquin, are sometimes useful.⁵ In the United States, 4% hydroquinone cream is available as a generic prescription medication, and lower concentrations are available over the counter, but the FDA has been considering removing them from the market. Treatment is frequently prolonged for months. Cosmetics are useful for covering irregular pigmentation. Additional therapeutic options for melasma persisting after pregnancy include daily topical retinoic acid (tretinoin [Retin-A, Avita]), salicylic acid (SalAc cleanser), or azelaic acid (Azelex, Finacea). A combination of topical fluocinolone, hydroquinone, and tretinoin (Tri-Luma cream) is FDA approved. Chemical peels with trichloroacetic acid, phenol, glycolic acid, Jessner's solution, or kojic acid may be effective. Although the Q-switched lasers (i.e., yttrium-aluminum-garnet, ruby, or alexandrite) have been useful for many other pigmentary problems, they provide little help for melasma. Intense pulsed light (IPL) and the fractionated photolysis laser (Fraxel) have produced good results in some patients.

Pregnancy can produce new melanocytic nevi or enlarge preexisting nevi, but the incidence of changes in nevi and the formation of melanoma seems to be no greater than for nonpregnant women.⁶ Most melanomas exhibit asymmetry, an irregular border, variegated colors (i.e., red or white in addition to black or blue), and a diameter greater than 6 mm. Suspicious lesions should be excised immediately.⁷ Local anesthetic agents, such as lidocaine, are generally regarded as safe. The use of epinephrine in low doses along with lidocaine can expedite surgery. The subject of melanoma during pregnancy is addressed in Chapter 43.

Vascular Changes

Pregnancy induces dilation and proliferation of blood vessels. Although this is thought to result largely from estrogen, the mechanism is not completely understood. Telangiectasias (i.e., persistently dilated blood vessels) that resemble those seen with chronic sunlight or radiation exposure can occur during pregnancy. Spider angioma (i.e., nevus araneus) is characterized by a central arteriole with radiating vascular "legs" resembling those of a spider and is most prevalent in sun-exposed areas. Multiple spider angiomas also can occur in liver disease (resulting from decreased hepatic estrogen catabolism), with estrogen therapy, and in normal, nonpregnant women. These lesions can regress spontaneously. Persistent lesions are best treated with low-energy electrocoagulation or laser ablation.

Palmar erythema occurs in many normal pregnant women and can be associated with liver disease, estrogen therapy, and collagen vascular

diseases. These vascular changes require no therapy and usually resolve after delivery.

Pyogenic granuloma is a misnomer for a red, nodular, often pedunculated, exuberant proliferation of blood vessels and inflammatory cells. This is granulation tissue that is not really a granuloma, which is a nodular aggregate in which macrophages predominate. The surface is often ulcerated, with yellowish purulence (i.e., pyogenic appearance). These lesions can occur anywhere on the skin, most commonly on the scalp, upper trunk, fingers, and toes. They are especially common on the gums, often resulting from gingivitis or trauma, where they have been called *epulis gravidarum*. The terms lobular capillary hemangioma, pregnancy tumor, and granuloma gravidarum are other synonyms for pyogenic granuloma.⁸ Therapy consists of surgical excision or electrosurgical destruction,⁹ but this can often be delayed until after delivery because some lesions regress spontaneously. Regression is associated with apoptosis of endothelial cells and a dramatic decrease in expression of vascular endothelial growth factor (VEGF),¹⁰ mediated by a decline in estrogen and progesterone levels.¹¹ Immediate biopsy should be performed if there is problematic bleeding or if the clinical diagnosis is in doubt because some neoplasms, such as amelanotic melanomas, can resemble pyogenic granulomas.

Venous congestion and increased vascular permeability during pregnancy commonly cause gingivitis and edema of the skin and subcutaneous tissue, particularly of the vulva and lower legs.¹² Severe labial edema has occasionally been reported during pregnancy,¹³ and a search for other causes is sometimes warranted. Varicosities are common on the legs and around the anus (i.e., hemorrhoids). They may regress after delivery but usually not completely.

Connective Tissue Changes

The mechanisms by which collagen and other connective tissue elements are influenced during pregnancy are poorly understood. Striae (i.e., stretch marks) represent linear tears in dermal connective tissue and appear as red or purple atrophic bands over the abdomen, breasts, thighs, buttocks, groin, and axillae. Sometimes, these lesions are pruritic. At least a few striae occur in 50% to 80% of pregnancies, and they are severe in about 10%, especially in teenagers.¹⁴ Risk factors for more severe striae include maternal family history of striae, young maternal age, nonwhite race, larger baseline and delivery body mass index (weight gain >15 kg), increased abdominal and hip girths, increased newborn weight, and larger fetal height and head circumference.^{15,16} Women with striae have an increased incidence of subsequent pelvic relaxation (i.e., prolapse).¹⁷

Despite numerous anecdotal claims of therapeutic efficacy, no topical therapy prevents or affects the course of striae, which ordinarily become less apparent as the red or purple color fades after delivery. There are numerous testimonials regarding the value of olive oil, cocoa butter, vitamin E, tretinoin, and nutritional therapy, but none of these has proved valuable in controlled studies.¹⁸ The pulsed dye laser has been helpful, particularly in obliterating the red color of early lesions, but it is difficult to determine whether the short-term improvement is better than that after long-term observation.

Skin tags (i.e., acrochordons, soft fibromas, fibroepithelial polyps, or molluscum fibrosum gravidarum) are soft, papular or pedunculated growths of fibrous and epithelial tissue that are common in obesity and in pregnancy. They are usually skin colored to dark brown and usually appear on the neck, axillae, or groin. Skin tags often persist after delivery and can easily be electrocoagulated or snipped off with scissors.

Hair Cycle and Growth Changes

The hair growth cycle is divided into three phases: anagen, catagen, and telogen. The duration of the growing phase (i.e., anagen) of each scalp hair follicle persists 3 to 4 years, with an average daily growth rate of approximately 0.34 mm. Growth activity is followed by a relatively short transitional (i.e., catagen) phase that lasts about 2 weeks, followed by a resting phase (i.e., telogen) that lasts several weeks. When the next hair cycle starts, newly forming hair causes shedding of the older telogen hairs.

The activity of each of about 100,000 follicles on the human scalp cycles randomly and independently from the activity of neighboring follicles. At any given time, approximately 10% to 15% of hair follicles are in the telogen phase. If the average duration of growth of each follicle is approximately 1000 days (3 years), it can be calculated that about 100 hairs are shed normally each day.

In late pregnancy, hormones appear to increase the number of anagen hairs and decrease those in telogen. Estrogen receptors found in hair follicles may play a role in this. After hormone withdrawal in the postpartum period, telogen hairs can increase to 35% or more of scalp hairs, resulting in a transient hair loss peaking about 3 to 4 months after parturition. This diffuse hair loss has been called *telogen effluvium*, whether it occurs after delivery, surgery, illness, crash dieting, or some other stressful event.¹⁹ The severity varies greatly, and it takes a total hair loss of 40% to 50% to become noticeable. Telogen effluvium usually is easy to distinguish from other causes of hair loss, and patients should be reassured that regrowth is likely to occur by 9 months after delivery without any treatment.

Hirsutism of the lower facial or sexual skin areas is uncommon, but it occasionally occurs in the second half of pregnancy and can be accompanied by acne. It is presumed to result from the effects of ovarian and placental androgens on the pilosebaceous unit. The possibility of an underlying androgen-secreting tumor of the ovary, of a luteoma, or of a lutein cyst should be considered, although polycystic ovary disease appears to be the most frequent cause. Options for hair removal include waxing, electrolysis, and laser ablation. Shaving does not increase the coarseness or growth of hair, but many women are not inclined to want to treat increased hair by this method.

Several types of nail changes have been reported during pregnancy but do not occur regularly. These changes include transverse grooving, increased brittleness, softening, or distal onycholysis.

Skin Conditions Specific to Pregnancy

Table 54-1 lists the rashes specific to pregnancy. Because of a lack of understanding of the pathogenesis of most of these conditions and the lack of specific diagnostic criteria, the terminology has been confusing.²⁰ Many of these diseases have been described by different investigators using different names for the same conditions.²¹ In general, all tend to be pruritic and usually resolve within a few weeks after delivery. They all can recur in subsequent pregnancies, except the polymorphic eruption of pregnancy and prurigo gestationis. Three of the diseases may be associated with increased fetal mortality. Pregnant women also can experience dermatoses other than those specific to pregnancy. For example, contact dermatitis, eczema, superficial fungal infections, folliculitis,²² erythema multiforme, urticaria, vasculitis, viral exanthems, scabies, secondary syphilis, and drug eruptions can occur, and it can

TABLE 54-1 RASHES OF PREGNANCY

Disease	Estimated Percentage of Pregnancies	Lesion Morphology	Most Common Location	Important Laboratory Features	Usual Trimester of Onset	Increased Fetal Mortality
Pruritus gravidarum	1.5-2.0%	Pruritus, no rash	Anywhere, abdomen	Sometimes increased bile salts, results of LFTs	3	Yes (?)
Pruritic urticarial papules and plaques of pregnancy (PUPPP)	0.6%	Papules, plaques, urticaria	Abdomen, thighs, especially in striae	None	3	No
Atopic eruption of pregnancy (prurigo gestationis)	0.3%	Excoriated papules	Extremities	None	2	No
Pemphigoid gestationis (herpes gestationis)	0.002%	Papules, vesicles	Anywhere, periumbilical	Direct IF biopsy	2 or 3	Yes (?)
Impetigo herpetiformis	Rare	Pustules	Intertriginous, trunk	Biopsy subcorneal pustule	1, 2, or 3	Yes
Autoimmune progesterone dermatitis	Rare	Acneiform, urticarial	Buttocks, extremities	Progesterone intradermal skin test	1	(?)

IF, immunofluorescence; LFTs, liver function tests.

be difficult to distinguish these from some of the pregnancy-specific rashes.

General Treatment

The same treatment principles apply to all of the specific dermatoses of pregnancy. Few drugs have been proved safe during pregnancy, and the risk-benefit ratio must be considered. Milder disease is treated with topical emollients, calamine lotion, cool compresses or baths, and topical corticosteroids. Topical corticosteroids (e.g., hydrocortisone and triamcinolone) are classified as FDA pregnancy risk category C drugs, but they are still widely used during pregnancy when the possible benefits outweigh the risks of minimal percutaneous absorption. Some of the very-high-potency topical corticosteroids, such as clobetasol, have potential for significant absorption on large body surface areas.

Many oral antihistamines, including the nonsedating fexofenadine (Allegra) and desloratadine (Clarinex), are labeled as FDA pregnancy risk category C drugs because available data are insufficient. Hydroxyzine (Atarax) is not recommended in the first trimester because it has been associated with a slightly increased rate (5.8%) of congenital malformations, but otherwise, it is in category C.²³ Oral antihistamines classified as category B (e.g., cetirizine [Zyrtec], chlorpheniramine, cyproheptadine [Periactin], diphenhydramine [Benadryl], loratadine [Claritin]) may be worth trying in patients with bothersome pruritus. Cetirizine and loratadine are relatively nonsedating agents. The favorite antihistamine in pregnancy appears to be diphenhydramine, even though it produces annoying drowsiness. One study associated diphenhydramine with cleft palate, but this finding has been disputed in other studies.²³ There has been an increased rate of retrolental fibroplasia reported in premature infants whose mothers took antihistamines within 2 weeks of delivery. No antihistamines are recommended during lactation by the manufacturers, but the American Academy of Pediatrics considers diphenhydramine to be safe during lactation because levels in breast milk are low.

Use of systemic corticosteroids (e.g., prednisone, prednisolone) in patients with severe disease appears to be relatively safe in humans (pregnancy class B). Although cleft palates have occurred in offspring

of pregnant rabbits undergoing such therapy, this relationship has not been demonstrated in humans. Infants of mothers treated with systemic corticosteroids should be monitored for evidence of adrenal insufficiency. Ultraviolet phototherapy can be offered to pregnant women with severe pruritus if the benefits outweigh the risks of burning and excessive heat.²⁴

Pruritus Gravidarum

Pruritus gravidarum is generalized itching during pregnancy without the presence of a rash, although excoriations can occur. Up to 14% of pregnant women complain of itching, but pruritus associated with cholestasis (i.e., intrahepatic cholestasis of pregnancy [see Chapter 50]) occurs in only about 1.5% to 2% of pregnant women, with onset usually in the third trimester. Some authorities seem to confuse definitions by reserving the term *pruritus gravidarum* for patients with cholestasis of pregnancy. Frank clinical jaundice occurs in only 0.02% of pregnancies. Pruritus limited to the anterior abdominal wall is common and is usually caused by skin distention and development of striae rather than cholestasis. Pruritus usually disappears shortly after delivery but recurs in approximately 50% of subsequent pregnancies.

Cholestatic itching correlates better with elevated serum bile acid levels than with other biochemical liver function tests such as alkaline phosphatase, aspartate aminotransferase (AST [SGOT]), alanine aminotransferase (ALT [SGPT]), and bilirubin. Elevated glutathione S-transferase α (GSTA), a specific marker of hepatocellular integrity, identifies women with intrahepatic cholestasis and distinguishes them from those with benign pruritus gravidarum.²⁵ Abnormal plasma lipid profiles are common in those with cholestasis. Biliary obstruction in pregnancy is discussed in more detail in Chapter 50. It has been stressed that some patients with skin lesions indicative of one of the other pregnancy rashes described in this chapter have coexisting cholestasis of pregnancy, and screening with liver function tests may be reasonable for patients with pregnancy-related rashes and for those experiencing pruritus without rash. Pruritus can precede abnormal findings of liver function tests or total serum bile acids, and follow-up testing for obstetric cholestasis may be needed for itchy pregnant patients with initially normal findings.²⁶

Pruritus gravidarum is associated with twin pregnancies, fertility treatments, diabetes mellitus, and nulliparity, but it is not associated with adverse perinatal outcomes for patients without cholestasis.²⁷ Reported increases in rates of premature delivery and perinatal mortality appear to be restricted to those in whom frank clinical jaundice develops.

Treatment is symptomatic, and mild cases usually respond to adequate skin lubrication and topical antipruritics (discussed previously). Oral antihistamines can be of some benefit. Ultraviolet light treatment or judicious sun exposure can decrease pruritus. In more severe cases of cholestasis, phenobarbital or bile-sequestering agents such as cholestyramine (Questran), supplemented with fat-soluble vitamins, can be beneficial, although there is no agreement about efficacy.²⁰ A review of published studies concluded that there is insufficient evidence to recommend corticosteroids, guar gum, activated charcoal, S-adenosylmethionine, and ursodeoxycholic acid.²⁸ Other authorities are convinced that ursodeoxycholic acid reduces premature labor, fetal distress, and fetal deaths.²⁰ It is not clear whether early delivery by 38 weeks' gestation reduces perinatal complications for patients with cholestasis.²⁹

Pruritic Urticarial Papules and Plaques of Pregnancy

Pruritic urticarial papules and plaques of pregnancy (PUPPP)³⁰ is a designation for a rash characterized by erythematous papules, plaques, and urticarial lesions that usually begins in the third trimester. It is the most common pregnancy rash. The rash has also been named polymorphic eruption of pregnancy (PEP) by Holmes and Black in 1982,²⁰ and this term is preferred in Europe. PUPPP is the most popular term in the United States. The eruption was called toxic rash of pregnancy³¹ and late-onset prurigo of pregnancy³² in the older literature.

PUPPP is almost always pruritic, and itching is severe in 80% of patients. The lesions begin on the abdomen in 80% to 90% of patients, often sparing the umbilicus (Fig. 54-1). The striae become involved in 67% of women, suggesting that abdominal distention may contribute to the inflammation occurring with this rash (Figs. 54-2 and 54-3). In many cases, the eruption spreads to the proximal thighs, buttocks, and proximal arms. The face is usually spared. Sometimes, erythema multiforme-like target lesions are present.

FIGURE 54-1 Pruritic urticarial papules and plaques of pregnancy. Lesions commonly begin in the abdominal striae. Confluent, erythematous, urticarial papules and plaques are seen on the thighs in this patient.

The rash usually resolves before or within several weeks after delivery, but, rarely, it may persist or even begin after delivery.³³ Some patients have had significant reductions in serum cortisol levels.³⁴ The disease is most prevalent among primigravidas. There is an association with increased maternal weight gain, increased twin pregnancy rate, hypertension, and induction of labor.³⁵ Unlike most of the other rashes of pregnancy, PUPPP does not tend to recur with subsequent pregnancies. There is no increase in the fetal morbidity or mortality rate.

Routine skin biopsies show nonspecific changes, including variable parakeratosis, spongiosis, acanthosis, dermal edema, and perivascular lymphocytes and eosinophils. Vesicles occur in a minority of cases and can cause confusion with pemphigoid gestationis, but the results of direct immunofluorescence of skin biopsy specimens are usually negative. Treatment depends on the severity of the condition. Topical corticosteroids are adequate for most patients with PUPPP.³⁶

Atopic Eruption of Pregnancy

Atopic eruption of pregnancy is a newly proposed term to encompass what was formerly called prurigo gestationis and folliculitis of preg-

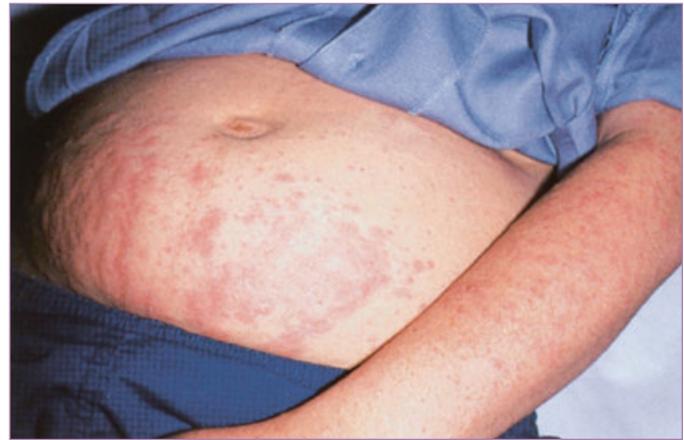

FIGURE 54-2 Pruritic urticarial papules and plaques of pregnancy. Urticarial involvement of striae occurs with papular eruption on the arms.

FIGURE 54-3 Pruritic urticarial papules and plaques of pregnancy. The eruption often begins in itchy, red striae. Notice the linea nigra.

nancy.³⁷ The general term *prurigo* designates an intensely pruritic skin eruption in which excoriation predominates, suggesting a prominent emotional component. Many of these patients have a genetic predisposition for atopic dermatitis (i.e., atopic eczema), and many examples of this disorder may instead be eczema or dermatitis.³⁴ Atopic dermatitis in pregnancy is considered later in this chapter.

Prurigo gestationis was first described by Besnier in 1904 and is similar to the early prurigo of pregnancy later described by Nurse in 1968.^{32,34} The lesions consist of excoriated papules or nodules mostly over the extremities, usually beginning in the middle of pregnancy, whereas most of the other specific pregnancy rashes start later in pregnancy (Figs. 54-4 to 54-6). Elevated liver function test results have been reported in some cases, but this probably represents an overlap of patients with pruritus gravidarum. The eruption usually clears by 3 months after delivery, and the recurrence rate in subsequent pregnancies is low. Treatment depends on the severity of the condition.

Papular dermatitis of pregnancy was designated a distinct entity by Spangler and coauthors³⁸ on the basis of markedly elevated levels of 24-hour urinary human chorionic gonadotropin (hCG) levels for that stage of pregnancy and decreased levels of plasma and urinary estriol and plasma cortisol levels. The lesions were more widespread than

FIGURE 54-4 Prurigo gestationis. The predominant lesions are excoriated papules.

FIGURE 54-5 Prurigo gestationis. Close-up view of excoriated papules on the same patient as in Figure 54-4.

lesions of the other pregnancy rashes. Whether these criteria are sufficient to determine a separate disease is questionable.

There have been few case reports, and some of the reported cases of papular dermatitis have been questionable because of the lack of appropriate laboratory studies to exclude the other pregnancy rashes discussed in this chapter. Vaughan Jones and coworkers³⁴ concluded that papular dermatitis of Spangler is not a separate entity because they were unable to identify any patients with decreased estradiol levels in a large series of patients with pregnancy rashes.

Pemphigoid Gestationis

Pemphigoid gestationis is a rare, autoimmune, blistering dermatosis of pregnancy and the immediate postpartum period.³⁹ It is not related to infection by herpesvirus; the unfortunately common synonym *herpes gestationis* refers to the grouped (herpetiform) nature of the blisters, which often are not herpetiform.²⁰ It is best to avoid the term *herpes gestationis* because of the risk of misleading patients and misinformed health care workers; not using the term avoids potentially inappropriate treatments for herpesvirus. Onset usually occurs during the second or third trimester, but cases beginning in the first trimester or the immediate postpartum period have been well documented. A high frequency of human leukocyte antigen (HLA) haplotypes B8 and DR3/DR4 has been reported.⁴⁰

Lesions often begin around the umbilicus (Fig. 54-7). Other commonly involved areas include the trunk, buttocks, and extremities. The face and mucous membranes are usually not affected. Vesicles and bullae are the most important clinical lesions (Figs. 54-8 and 54-9). Erythematous plaques, often annular or urticaria-like, frequently are present, and they can resemble PUPPP. The extent of the disease process and the degree of accompanying pruritus can be mild to severe.

A mortality rate for infants born to affected mothers has been estimated to be as high as 30%, although this figure has been disputed.⁴¹ Increased likelihood of prematurity has also been reported.⁴² With systemic corticosteroid treatment of severe cases, fetal risk appears to be minimal. There is an increase in premature and small-for-gestational-age infants.⁴¹ Most infants do not have skin lesions, although transient urticarial and vesicular lesions thought to be caused by transplacental antibody transfer have been observed in less than 5% of infants born of affected mothers (Figs. 54-10 and 54-11).

FIGURE 54-6 Prurigo gestationis. Although papules are more common, lesions occasionally coalesce into crusty plaques.

FIGURE 54-7 Pemphigoid gestationis. The patient has characteristic periumbilical urticarial plaque. Blisters may or may not be present.

FIGURE 54-10 Pemphigoid gestationis. Newborn child of the mother seen in Figure 54-8 has urticarial, erythematous patches with rare blisters.

FIGURE 54-11 Pemphigoid gestationis. Close-up view of the erythematous patches seen in Figure 54-10.

FIGURE 54-9 Pemphigoid gestationis. Close-up view of crusts and blisters on the mother seen in Figure 54-8.

Postpartum flares occur in 50% to 75% of patients with pemphigoid gestationis. Exacerbation typically begins within 24 to 48 hours after delivery and can last for several weeks or months. Skin lesions have been reported to persist for more than a year in women who do not breastfeed compared with those who do (average postpartum duration is 1 to 6 months).⁴³ Flares also can occur with subsequent pregnancies, subsequent menses, ovulation, or treatment with estrogen or progesterone. About 20% to 50% of patients who have had pemphigoid gestationis experience recurrent skin lesions when treated with oral contraceptives.

The routine histopathologic location of the blisters is usually subepidermal, but blisters sometimes are intraepidermal as a result of spongiosis. Focal necrosis of basal keratinocytes can occur. There are perivascular lymphocytes in the dermis with a significant number of eosinophils, and those nonspecific dermal changes are found if non-blistering sites are sampled for biopsies. A biopsy for direct immunofluorescence from red macules or perilesional blisters is recommended, because the routine biopsy changes are often not specific.

Immunopathologically, pemphigoid gestationis and bullous pemphigoid (an autoimmune disease most prevalent among the elderly

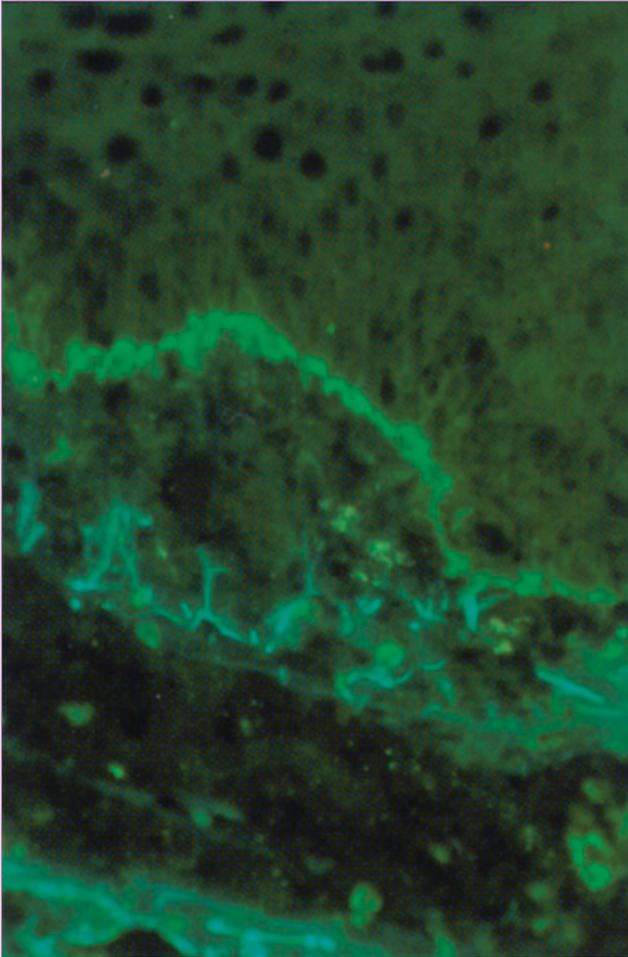

FIGURE 54-12 Pemphigoid gestationis. The skin biopsy specimen taken for direct immunofluorescence assay demonstrates a linear band of C3 at the basement membrane zone.

and with HLA-DQ3) are strikingly similar. Heavy linear deposits of C3 are present in the epidermal basement membrane zone (BMZ) of pemphigoid gestationis perilesional skin (Fig. 54-12), usually in the absence of IgG deposits when direct immunofluorescence staining methods are used. BMZ C3 deposits have also been described in some infants born to affected mothers with pemphigoid gestationis. In contrast, direct immunofluorescence of bullous pemphigoid shows both C3 and IgG.

Unlike cases of bullous pemphigoid, circulating anti-BMZ IgG autoantibodies are measurable in the serum by indirect immunofluorescence in only 10% to 20% of cases of pemphigoid gestationis. When antibodies are present, titers are usually low, in contrast to bullous pemphigoid. Circulating IgG1 autoantibodies (i.e., herpes gestationis factor, also called pemphigoid gestationis factor) avidly fix complement to the BMZ in pemphigoid gestationis. They are present in such low levels, however, that they often escape detection by routine methods. Bullous pemphigoid IgG subclasses are more heterogeneous, with IgG4 predominating over IgG1. Pemphigoid gestationis autoantibodies usually react with the NC16a domain of a 180-kDa protein associated with hemidesmosomes of basal keratinocytes,⁴⁴ whereas bullous pemphigoid autoantibodies potentially react with two protein bands, almost always with a 230-kDa protein (i.e., dystonin [DST],

formerly designated BPAG1) and sometimes with the same NC16a domain of the 180-kDa protein that is the main target in pemphigoid gestationis (i.e., collagen type XVII- α 1 [COL17A1], formerly designated BPAG2). Only a small number of patients with pemphigoid gestationis have autoantibodies directed against the DST protein. Studies have found that immunoblotting and enzyme-linked immunosorbent assay (ELISA) are sensitive methods for detecting the COL17A1 in the sera of patients with pemphigoid gestationis, in contrast to the often negative results obtained with indirect immunofluorescence of sera.⁴⁵ If these tests are made commercially available, they may eliminate the need for skin biopsy for direct immunofluorescence, which has been the standard test required in these patients.

There is an increased incidence of antithyroid antibodies in pemphigoid gestationis, but clinically apparent thyroid dysfunction is rare.⁴⁶ Patients are at an increased risk for Graves disease, but this usually does not occur simultaneously with pemphigoid gestationis.

Because placental antibody deposition may result in placental insufficiency, it has been suggested (based on the study of one patient) that pregnant women with pemphigoid gestationis undergo frequent umbilical artery Doppler studies to document end-diastolic velocity even without the ultrasound finding of intrauterine growth restriction.⁴⁷

Treatment of pemphigoid gestationis should not be designed to suppress the disease process entirely, because the higher doses of therapy needed to suppress disease activity completely can have serious side effects. Instead, therapy should be directed toward suppressing the appearance of new lesions and relieving the intense pruritus. Potent topical corticosteroids can be attempted in mild to moderate cases. In moderate to severe cases, prednisone (20 to 40 mg/day) is often adequate to suppress new blister formation and relieve symptoms. After new blister formation has been suppressed, the prednisone dose can be tapered to lower doses or to just enough to maintain control and relieve symptoms. Eventually, alternate-day therapy may become more appropriate and should be attempted.

If the disease flares in the immediate postpartum period, treatment with prednisone (20 to 40 mg/day) should be reinstated. Higher doses may be instituted at this time if necessary. Infants of mothers treated with prednisone should be monitored for evidence of adrenal insufficiency. Minocycline and nicotinamide have been used anecdotally as alternatives to prednisone in pregnancy.⁴⁸ Plasmapheresis or intravenous immunoglobulin is used for severe cases.⁴⁹ Dapsone is often used for other autoimmune blistering disorders but is contraindicated during pregnancy, because it can cause hemolytic disease of the newborn. Other treatment modalities useful for all pregnancy rashes have been discussed previously.

Impetigo Herpetiformis

First described in 1872 by von Hebra, impetigo herpetiformis is a severe, generalized pustular dermatosis associated with pregnancy.⁵⁰ The name is unfortunate because it is unrelated to bacterial infection (i.e., impetigo) or herpesvirus infection. It probably represents pustular psoriasis in pregnancy, mostly occurring in patients who have never had psoriasis before pregnancy.

Onset of the disease usually occurs in the third trimester, but well-documented cases have occurred as early as the first trimester. The disease usually subsides between pregnancies but can recur with subsequent pregnancies and usually occurs earlier in a subsequent pregnancy. Patients may have hypoparathyroidism, hypocalcemia, hypophosphatemia, decreased vitamin D levels, elevated erythrocyte sedimentation rate, and leukocytosis.⁵¹ The cause remains unknown,

FIGURE 54-13 Impetigo herpetiformis (i.e., pustular psoriasis). The patient has extensive sterile pustules.

FIGURE 54-14 Impetigo herpetiformis (i.e., pustular psoriasis). Close-up view of superficial pustules occurring just beneath the stratum corneum shows the characteristic coalescence into “lakes of pus.”

but it may be a reaction to drugs or occult infection in a genetically predisposed patient.

Clinically, the disease is characterized by hundreds of translucent, white, sterile pustules (Figs. 54-13 and 54-14) that arise on irregular erythematous bases or plaques. These lesions extend peripherally while central pustules rupture because of their superficial locations, leaving denuded surfaces with crusts, as occur in some forms of pemphigus. Common areas of involvement include the axillae, inframammary areas, umbilicus, groin, and gluteal crease. Pustular lesions can also occur on the hands and involve the nails with subsequent nail loss or onycholysis.

Constitutional symptoms are common and include fever, chills, nausea, vomiting, and diarrhea with severe dehydration. Delirium, tetany, and convulsions are rare complications that are usually associated with hypocalcemia. Death may occur in association with these complications and septicemia.

Impetigo herpetiformis is thought to be a form of generalized pustular psoriasis that occurs during pregnancy. The clinical presentation and histopathology of both disease entities are identical. Most pregnant patients do not have a history of psoriasis.

Histopathologically, impetigo herpetiformis is characterized by subcorneal pustules containing neutrophils and degenerated keratino-

cytes. Cultures of pustular lesions are usually negative disease agents unless secondarily infected.

Differential diagnosis includes acute generalized exanthematous pustulosis, which is a severe pustular drug reaction, and it is more likely to have eosinophils in the biopsy specimen. Scabies, bacterial impetigo, fungal infections, folliculitis, and acne can be pustular, but they usually look different to an experienced clinician. Cultures, potassium hydroxide preparations, and biopsies can be done when necessary.

Systemic corticosteroid therapy is the treatment of choice for impetigo herpetiformis. Usually, 20 to 40 mg of prednisone per day is sufficient to control new lesion formation. Systemic antibiotics may help when secondary infection is present. Topical measures, such as wet compresses with or without topical corticosteroid preparations, are also useful as general treatment for itchy pregnancy rashes. Intravenous fluids and electrolytes are important for patients with diarrhea, vomiting, high fever, and extensive skin pustulation. Cyclosporin has been used successfully in pregnancy for severe cases.⁵² Acitretin (a synthetic vitamin A derivative given orally) and methotrexate, both used commonly for generalized pustular psoriasis, are contraindicated during pregnancy.

Autoimmune Progesterone Dermatitis

Autoimmune progesterone dermatitis is a rare, poorly defined, urticarial, papular, vesicular, or pustular eruption thought to be caused by hypersensitivity to progesterone.⁵³ It usually appears as a recurrent, cyclic eruption during the luteal phase of the menstrual cycle.⁵³ It often resembles erythema multiforme. Very few cases have involved onset or worsening of this condition with pregnancy. Two of these cases were associated with spontaneous abortion. In other cases of autoimmune progesterone dermatitis, the rash improved or cleared during pregnancy.

Estrogen dermatitis has been described in seven patients, all of whom had severe premenstrual exacerbations of a variety of skin eruptions.⁵⁴ Skin test results were positive for estrogen in all seven cases.

Autoimmune progesterone dermatitis has been documented by the use of intradermal or intramuscular test injections of progesterone.⁵⁵ Intradermal tests usually produce an immediate local urticarial reaction or a delayed reaction. Intramuscular challenges have caused exacerbations of the rash or even angioedema. Progesterone antibodies have been demonstrated in four cases by indirect immunofluorescence. An indirect basophil degranulation test has also been used, in which the patient's serum is mixed with synthetic progesterone and rabbit basophils.

Specific therapy for autoimmune progesterone dermatitis during pregnancy is unclear. Nonpregnant patients have responded to estrogens (if the allergen was progesterone), birth control pills (e.g., Loestrin, which contains ethinyl estradiol plus norethindrone), the antiestrogen tamoxifen, the anabolic androgen danazol, thalidomide, or oophorectomy.⁵⁶ Spontaneous remission can occur after successful treatment.²⁰ Regional anesthesia may be preferred over general anesthesia for patients with progesterone dermatitis who are also prone to angioedema and need to undergo obstetric procedures.⁵⁷

Skin Disorders Affected by Pregnancy

The effect of pregnancy on preexisting skin diseases varies.⁵⁸ Table 54-2 lists some skin diseases that improve or become aggravated by preg-

TABLE 54-2 EFFECT OF PREGNANCY ON SKIN DISEASES**Usually Improved by Pregnancy**

Fox-Fordyce disease
Hidradenitis suppurativa

Usually Aggravated by Pregnancy

Condylomata acuminata
Ehlers-Danlos syndrome
Erythema multiforme
Erythema nodosum
Herpes simplex
Lupus erythematosus
Neurofibromatosis
Pemphigus
Pityriasis rosea
Porphyrias
Pseudoxanthoma elasticum
Scleroderma (increased renal disease)
Tuberous sclerosis (increased seizures)

Unpredictable Response to Pregnancy

Acne
Acquired immunodeficiency syndrome
Atopic dermatitis
Dermatomyositis
Melanoma
Psoriasis

nancy, although the course of a disease in a given patient is not always predictable.^{29,59} Most skin diseases do not affect fetal outcome.⁶⁰ Cutaneous infections are discussed in Chapter 38, and connective tissue diseases involving the skin are discussed in Chapter 51. Some infectious, autoimmune, or rheumatic diseases tend to worsen during pregnancy.

Acne

Acne is a disease of the pilosebaceous unit. It is partially influenced by androgens such as testosterone and dehydroepiandrosterone sulfate (DHEAS), which increase sebaceous gland activity. Estrogen reduces sebaceous gland size and activity, but this is probably a function of negative feedback on androgen production by the ovary. Sebaceous gland activity is increased during pregnancy. Montgomery tubercles are small sebaceous glands on the areolae of the breasts, and their papular enlargement is one of the first signs of pregnancy.

Acne consists of erythematous papules, pustules, comedones, and cysts on the face, back, and chest. Some cases reported as “pruritic folliculitis of pregnancy” of widespread locations may represent hormonally induced acne.⁶¹ Pregnancy has a variable effect on acne, probably because many other factors are involved in its pathogenesis besides the hormonal influences discussed.

Acne can be controlled during pregnancy or lactation with topical benzoyl peroxide (category C), salicylic acid, azelaic acid (Azelex, category B), or topical antibiotics such as erythromycin (category B) or clindamycin (Cleocin T, category B).⁶² Topical and oral sulfonamides should be avoided near term. Forms of topical metronidazole (Metro-Lotion, MetroGel, MetroCream, and Noritate cream, all category B) typically are used if other alternatives have failed. More severe disease can be treated with the apparent oral antibiotic of choice, erythromy-

cin, starting with 1 g daily (category B), even though its efficacy has been dwindling because of the increasing resistance of bacterial flora. It appears to be safe during lactation. Erythromycin estolate has been implicated as a cause of hepatotoxicity in pregnancy after prolonged use, and it should be avoided. Tetracycline should be avoided because of its potential risk of fatty liver of pregnancy and adverse effects on fetal dentition. Vitamin A derivatives (i.e., retinoids) such as oral isotretinoin are contraindicated because of teratogenic effects. Topical retinoids such as tretinoin (Retin-A or Avita, category C) or topical adapalene (Differin, category C) are not contraindicated, but different topical drugs are probably better during pregnancy. Topical tazarotene is a category X drug, but healthy infants have been born to six women using it.

Atopic Dermatitis

Atopic dermatitis is an allergic skin disease characterized by intensely pruritic, eczematous lesions that become lichenified when patients are caught in a scratch-itch cycle.⁶³ There appears to be an inherited irritability of the skin (i.e., the “itch that rashes” instead of the rash that itches), and many patients have a personal or family history of eczema, asthma, hay fever, food allergies, or allergic rhinitis beginning in childhood. This disease can worsen (52%) or improve (24%) during pregnancy.⁶⁴ Exacerbation of atopic dermatitis changes in pregnancy has been called *atopic eruption of pregnancy* (previously discussed).

Some studies show that breastfeeding reduces the incidence of atopy in infants because cow’s milk has been implicated as a significant aggravating factor. Soya milk is often substituted, but it also can be allergenic.⁶⁵ The mother’s diet has not been shown to make a significant difference during pregnancy and breastfeeding.⁶⁶ An increased incidence of atopy in children has been associated with a wide variety of confusing factors in various studies, such as increased fetal growth and a larger head circumference,⁶⁷ increased gestational age,⁶⁸ low parity, febrile infections in pregnancy, the use of contraceptives before pregnancy,⁶⁹ and maternal smoking.⁷⁰

Treatment with topical emollients, topical corticosteroids, and oral antihistamines is usually effective. If the skin is extremely dry and scaly, greasy ointments may be more effective than creams. Patients should be instructed to use soap sparingly and should always apply topical emollient lotions or creams after bathing. The newer immunomodulators, topical pimecrolimus (Elidel cream) and tacrolimus (Protopic ointment), are FDA pregnancy category C drugs. Exceptional patients may require systemic corticosteroids.

Erythema Nodosum

Erythema nodosum is characterized by tender nodules on the anterior lower legs, usually considered to be a reaction to a drug or an infection somewhere else, such as streptococcal pharyngitis or coccidioidomycosis.⁷¹ Sarcoidosis and inflammatory bowel disease are also common causes.⁷² Women account for 90% of patients. Erythema nodosum is known to be precipitated by pregnancy and by oral contraceptives,⁷³ which suggests an estrogen influence on this disease.⁷⁴

Treatment begins with specific therapy for the underlying inciting cause. Nonsteroidal anti-inflammatory agents other than acetaminophen are usually not recommended because they can constrict the ductus arteriosus or cause prolonged labor because of prostaglandin synthesis inhibition. Systemic corticosteroids may be used in more severe noninfectious cases.

Fox-Fordyce Disease

Fox-Fordyce disease is a rare entity, often called apocrine miliaria because it can be similar to the prickly heat or heat rash involving eccrine glands. Fox-Fordyce disease occurs mainly in women, with onset occurring usually shortly after puberty.⁷⁵ Many pruritic, dome-shaped, follicular papules develop in the axillae and anogenital region, areas rich in apocrine glands.

The disease usually improves during pregnancy or with oral contraceptive therapy, probably because of an estrogen effect. Apocrine activity, unlike eccrine activity, appears to be decreased during pregnancy. Response to topical corticosteroids or pimecrolimus varies.

Genodermatoses

A long list of inherited severe cutaneous diseases involving the mother or other family members can affect fetal mortality or morbidity. Newer techniques that make it possible to study the molecular, enzymatic, and ultrastructural basis of these conditions are continually evolving. It is impossible to provide up-to-date information on this rapidly changing field in a textbook. More details of prenatal diagnosis are given in Chapter 17.

Modalities useful for detecting severe fetal skin diseases include chorionic villus sampling, amniocentesis, fetal skin biopsy,⁷⁶ and pre-implantation genetic diagnosis. DNA-based tests involve screening by nucleotide sequencing, restriction enzyme digests, or linkage analysis.⁷⁷ Although ichthyosis and epidermolysis bullosa are the two most important groups of disorders, prenatal diagnosis has been successful in many other skin diseases.⁷⁸

There are many types of ichthyosis, all of which cause extensively thickened, scaly skin resembling the scales of a fish. A variety of ichthyotic syndromes have been described that involve abnormalities other than the skin. Ichthyosiform erythroderma is subdivided into dominant and recessive forms, and generalized involvement is usually present at birth. The collodion and harlequin fetuses are severe examples of ichthyosis in which an infant with grotesque deformities, often resulting in death, is born encased in a horny sheet. Genetic defects have been discovered in many forms of ichthyosis.⁷⁹⁻⁸¹

The many forms of epidermolysis bullosa are characterized by extensive blistering that can contribute to excessive fluid loss or predispose to scarring, deformities, and fatal neonatal infection. The dystrophic and letalis forms of the disease can be distinguished from the less severe simplex form by using electron microscopy or immunofluorescent staining of BMZ antigens to determine the level of blistering in the skin.⁸² DNA-based prenatal diagnosis also has been used.⁸³

Psoriasis

Psoriasis is a papulosquamous skin condition found in 1% to 3% of the population.⁸⁴ It is usually mild but sometimes can become severe, generalized, or associated with psoriatic arthritis. The pustular form of psoriasis was discussed earlier in the section on impetigo herpetiformis. In one study, psoriasis remained unchanged during pregnancy in 43% of patients, improved in 41%, and worsened in 14%. In the postpartum period, it remained unchanged in 37%, improved in 11%, and worsened in 49%.⁸⁵

Psoriasis in pregnancy is commonly treated with topical corticosteroids (mostly category C agents). Low-potency hydrocortisone is used commonly on delicate skin areas such as the face and intertriginous areas, and medium-potency triamcinolone is used on most other areas. The topical vitamin D derivative calcipotriene (Dovonex, category C)

has not been evaluated during pregnancy or lactation, and use of large quantities can result in hypercalcemia. The topical retinoid tazarotene is a category X agent. For severe disease, oral cyclosporin (category C) has been used without an apparent increase in problems. Ultraviolet B light therapy is safe in pregnancy. Oral psoralen combined with ultraviolet A light (PUVA) has a category C designation. The oral retinoid acitretin and the antimetabolite methotrexate are both category X drugs and should not be used during pregnancy.

Chapter 55

Benign Gynecologic Conditions in Pregnancy

Alessandro Ghidini, MD, and Patrizia Vergani, MD

Pathologies involving the genital organs are often detected for the first time during pregnancy because of the closer clinical and ultrasonographic surveillance that is usually instituted during gestation. Diagnosis of uterine or ovarian pathology, although benign in nature, can engender concern among the affected women and health care providers. When such pathologies are diagnosed before pregnancy, providers must carefully weigh the risks and benefits of interventions (e.g., surgical removal of myomas) before attempting conception.

Uterine Leiomyomas

Epidemiology

Leiomyomas are the most common uterine solid masses. Their prevalence ranges between 1.6% and 4%, according to series that used routine ultrasound screening in cohorts of women who presented for prenatal care.^{1,2} The prevalence of leiomyomas primarily correlates to maternal age and African-American ethnicity.^{3,4} Reported associations between leiomyomas and other risk factors, such as tobacco use, parity, history of diabetes mellitus, or chronic hypertension, are possibly mediated by the confounding effects of race and age.

Pathogenesis

Effect of Pregnancy on Myomas

It has been hypothesized that several changes in the myometrium associated with pregnancy can affect the size of uterine myomas, including hypertrophy, edema, stretching of the myometrium due to progressive expansion of the amniotic cavity, and degenerative changes related to ischemia. Whereas approximately 40% (range, 25% to 60%) of myomas remain stable in size during pregnancy, the remaining myomas demonstrate an increase or decrease by more than 10% of the original size. One third of myomas larger than 5 cm grow during pregnancy, in contrast to less than 10% of myomas smaller than 5 cm.¹ An increase in size occurs most commonly in the first trimester, independent of the original size of the myoma.⁵⁻⁷ This may be related to the effect of the hormone human chorionic gonadotropin (hCG), receptors for which have been found in leiomyoma cells.⁸ Rapid growth of the myoma does not suggest an underlying sarcoma, because most leiomyosarcomas occur in women beyond

reproductive years and they originate from myometrial cells outside of myomas.⁹

Effects of Myomas on Pregnancy

Conflicting evidence has associated the presence of myomas with increased rates of infertility and obstetric complications, including spontaneous abortion, preterm delivery, placental abruption, fetal growth restriction, and malpresentation. The most reliable conclusions are derived from prospective cohort studies of women in whom myomas are detected at routine ultrasound screening in early pregnancy, allowing inclusion of asymptomatic women and of myomas of any size. Not surprisingly, the frequency of myoma-related obstetric complications is generally lower among cohorts of women identified with myomas at ultrasonographic screening than from series derived from referral radiology centers or registries of hospital admissions during pregnancy, with the inherent potential biases associated with the latter reports.

Several mechanisms have been suggested to explain the association between uterine fibroids and pregnancy complications:

- A large submucous fibroid projecting into the uterine cavity may lead to spontaneous pregnancy loss by disturbing perfusion of the endometrium at the site of blastocyst implantation, or it may interfere with normal placentation and development of the uteroplacental circulation.¹⁰
- Rapid fibroid growth may lead to increased uterine contractility or decreased placental oxytocinase activity,¹⁰ both of which may disrupt placentation, or may result in a localized increase in oxytocin levels and preterm contractions
- As blood flow has been shown to be reduced within fibroids and the adjacent myometrium, it has been hypothesized that myomas may cause placental ischemia and decidual necrosis, which may lead to abruption.¹¹
- Large myomas distorting the shape of the uterine cavity may cause fetal malpresentation and placenta previa.
- By decreasing the force and coordination of uterine contractions, fibroids may predispose to postpartum hemorrhage and uterine atony.¹²

INFERTILITY

There are no randomized, controlled trials testing the benefit of pre-conceptual removal of myomas on fertility. Case series have

reported an improved conception rate after removal of myomas, suggesting that myomas may be associated with infertility.¹³ A meta-analysis has shown that in infertile women with no identifiable infertility factors, submucous myomas are associated with lower pregnancy rates compared with infertile women without myomas (relative risk [RR] = 0.32; 95% confidence interval [CI], 0.13 to 0.70), whereas there was no effect of intramural or subserosal myomas.¹⁴ However, subsequent retrospective and prospective observational studies have suggested that subserosal or intramural myomas without intracavitary involvement also may affect fertility.¹⁵

SPONTANEOUS ABORTION

Although most reviews on the effects of myomas on pregnancy quote an increased risk of miscarriage associated with myomas, the supporting evidence is scant and mostly based on case series often biased by a retrospective design, a lack of control groups, and the presence of multiple confounders. Although studies using control populations have found increased rates of threatened abortion in women with myomas compared with controls without myomas,² no significant differences have been reported in rates of first-trimester losses,^{2,16} even in women with a history of miscarriages. The largest study found significantly increased rates of miscarriage among women with myomas compared with controls (14% versus 8%) had significantly higher rates of assisted reproductive techniques among women with myomas (15% versus 6%), an important confounder.¹⁷ There is no conclusive evidence that number, size, or location of myomas influences rates of spontaneous abortions.

FETAL DEATH

In one small study with design limitations, the rate of second-trimester losses was significantly higher before than after myomectomy (7 of 14 versus 0 of 6; $P = .04$).¹⁸ Another study found increased rates of second-trimester fetal losses between 18 and 23 weeks' gestation in two groups of 128 women with myomas undergoing (group 1) or not (group 2) genetic amniocentesis compared with controls without myomas (group 3) undergoing amniocentesis that were matched for maternal age, nulliparity, prior abortion or preterm birth, and gestational age at amniocentesis or sonogram (6%, 7%, and 1%, respectively; $P = .02$).¹⁹ Although the investigators concluded that the presence of myomas increases the risk of second-trimester fetal losses, the strength of the conclusions is weakened by several biases, such as lack of information on the criteria for the choice of controls and on the indications for sonogram or amniocentesis.

PRETERM DELIVERY

Women with myomas seem to have higher rates of hospital admissions for preterm labor,^{2,11,20} and the risk of preterm uterine activity has been correlated with the size of the myoma.^{2,11} It is controversial, however, whether this increase in uterine contractility leads to higher rates of preterm delivery. After exclusion of series without control groups, only a few studies have dealt with the risk of preterm delivery for women with myomas (Table 55-1). The three series that observed a significant increase in risk for preterm delivery in the presence of myomas deserve special comment. Two of them^{4,21} used the hospital discharge diagnosis of myoma to identify cases, a design prone to potential ascertainment biases. In the third series, logistic regression analysis demonstrated that presence of uterine myomas remained significantly associated with risk of preterm delivery after controlling for several potential confounders, including maternal age, body mass index, race, parity, insurance status, diabetes, and chronic hypertension (odds ratio [OR] = 1.4; 95% CI, 1.1 to 2.0).³ However, the study showed no correlation between the number of myomas or myoma size and the risk of preterm delivery. In a later series of almost 25,000 women, no association was reported between presence of myomas larger than 5 cm and preterm delivery compared with women without myomas (7.6% versus 7.3%).²²

PLACENTAL ABRUPTION

An increased rate of placental abruption has been described among women with myomas admitted to antepartum hospital care compared with those without myomas (10 [11%] of 93 versus 48 [0.7%] of 6613).¹¹ The study authors found that the risk of abruption was associated with myomas larger than 3 cm in diameter and with those with a retroplacental location. Similarly, Coronado and colleagues,⁴ using hospital ICD9 codes and multivariate analysis to control for confounders, found that a diagnosis of abruption was significantly associated with a code for myomas compared with the absence of such a code (OR = 3.8; 95% CI, 1.6 to 9.2). Sheiner and associates,²¹ using a similar design, found an odds ratio of 2.6 (95% CI, 1.6 to 4.2) for abruption in the presence of myomas. A subsequent large cohort study in which abruption was defined as placental separation at ultrasonographic examination or based on histopathologic placental examination, with or without vaginal bleeding or fetal compromise, confirmed an association between abruption and myomas (7.5% versus 0.9%) and reported that abruption was more common with large than small myomas and with submucosal myomas than myomas in other locations.²

TABLE 55-1 PRETERM DELIVERY IN WOMEN WITH MYOMAS

Study	Definition of PTD	Type of Study	Myomas	No Myomas	OR (95% CI)
Rice et al, 1989 ^{11,*}	<36 wk	Cohort	12% (11/93)	7% (440/6613)	1.9 (1.0-3.5)
Davis et al, 1990 ^{19,*}	<37 wk	Case-control	12% (10/85)	6% (5/85)	2.1 (0.7-6.2)
Exacoustos and Rosati, 1993 ^{2,*}	<37 wk	Cohort	9% (46/492)	9% (1099/12,216)	1.0 (0.8-1.4)
Vergani et al, 1994 ^{22,*}	<37 wk	Cohort	10% (16/167)	10% (537/5595)	1.0 (0.6-1.7)
Coronado et al, 2000 ^{4,†}	<38 wk	Case-control	12% (242/2065)	8% (305/4,243)	1.7 (1.4-2.0)
Sheiner et al, 2004 ^{20,†}	<2500 g	Cohort	15% (101/690)	8% (7845/105,219)	2.1 (1.7-2.6)
Qidwai et al, 2006 ^{3,*}	<37 wk	Cohort	19% (77/401)	13% (1867/14,703)	1.6 (1.3-2.1)

*Cases identified with ultrasonography.

†Cases identified using hospital discharge codes (ICD9) after delivery.

*Cases identified from database of antepartum admissions.

CI, confidence interval; OR, odds ratio; PTD, preterm delivery.

At variance with these findings, two large cohort studies of myomas detected prospectively at ultrasonography^{3,23} found no significant association between presence of myomas and occurrence of abruption (Vergani and colleagues²³: 1.2% versus 0.4%; Qidwai and coworkers³: 2.2% versus 1.8%). Moreover, a case-control study of myomas larger than 5 cm detected prospectively at routine sonographic screening found no significant association between myomas and abruption.²² Another case-control study found no association between abruption and retroplacental location of myomas.²⁰ In summary, there is conflicting evidence about a possible association between myomas and abruption.

PLACENTA PREVIA

Presence of uterine myomas may facilitate an abnormally low placental implantation. A large sonographic series of almost 15,000 women found significantly higher rates of placenta previa among patients with myomas (3.5% versus 1.8%), and a trend was identified between myoma size (≥ 10 cm) and risk of placenta previa.³ In line with these findings, a cohort of almost 25,000 women undergoing sonographic screening reported significantly higher rates of placenta previa among women with myomas larger than 5 cm in diameter than among those without myomas (2.4% versus 0.6%).²² Unlike size, the number of myomas does not seem to correlate with occurrence of placenta previa.³

FETAL MALPRESENTATION

A significant association (odds ratios of 1.6 to 4.0) between myomas and fetal malpresentation has been reported in large, prospective series in which multivariate analysis was used to control for confounders, including gestational age and parity.^{3,4,22} Size of the myoma plays an important role. One series reported significantly higher rates of malpresentation at term in women with myomas larger than 5 cm than in controls without myomas (12% versus 5%).²² Other investigators found a progressive increase in rates of malpresentation with myoma size: 8% in women without myomas, 10% in those with myomas smaller than 10 cm, and up to 23% in those with myomas larger than 10 cm.³ Unlike myoma size, the number of myomas does not seem to affect the risk of fetal malpresentation.³

LABOR COMPLICATIONS

A large series using ICD9 codes found increased rates of labor complications (OR = 1.9; 95% CI, 1.6 to 2.2) in women with leiomyomas after controlling for maternal age, parity, and previous cesarean delivery.⁴ Labor complications were mainly limited to dysfunctional labor (OR = 1.8; 95% CI, 1.3 to 2.7), because rates of prolonged labor were not significantly different between the two groups.⁴ However, a large cohort of cases with myomas diagnosed prospectively at the second-trimester sonographic screening did not find an association between presence of myomas and duration of first or second stage of labor.³ That leiomyomas do not disrupt uterine contractility is further supported by the observation that even women with large tumors (≥ 10 cm) have similar durations of first and second stage of labor and similar rates of cesarean delivery among labor-eligible women as women with small myomas.³ Similar rates of cesarean delivery for dystocia (OR = 1.1; 95% CI, 0.4 to 2.3) and fetal distress (OR = 0.9; 95% CI 0.3 to 1.9) have been reported for women with myomas larger than 5 cm compared with those without myomas.²² In summary, women with leiomyomas of any size can be reassured that if they are eligible for vaginal delivery and they initiate labor, they can expect similar rates of vaginal delivery as the general obstetric population.

CESAREAN SECTION

An increased rate of cesarean delivery is the obstetric complication most frequently observed for women with leiomyomas.^{2,11,23,24} Consistent and cumulative evidence suggests that malpresentation,^{3,4,21} placenta previa,^{3,4,21} and location of the tumors in the lower uterine segment below the presenting fetal part²¹ are the most common indications for cesarean delivery in women with leiomyomas. However, presence of leiomyomas remains significantly associated with increased risk for cesarean delivery before labor, even after correcting for these indications.²²

POSTPARTUM HEMORRHAGE

Although one report⁴ using ICD9 discharge codes found no relation between myomas and postpartum hemorrhage, more robust studies have reported an increased risk.^{3,22,25} Size of myomas does not seem to play a role in the risk, because women with myomas 10 cm or larger have rates of postpartum hemorrhage similar to rates for those with smaller myomas.³

PERINATAL OUTCOME

Women with myomas can be reassured that adverse perinatal outcomes (i.e., neonatal death, small size for gestational age, low Apgar scores, and malformations) are not affected by the presence of uterine myomas.^{2,4,11,22,23,26} The purported fetal compression syndrome, caused by the pressure effects of large myomas on fetal parts, is limited to isolated case reports, such as one in which a fetus born with severe oligohydramnios and fetal growth restriction had dolichocephaly, which the study authors ascribed to the presence of a large myoma.²⁷

Diagnosis

Ultrasonographic diagnosis of leiomyoma rests on visualization of persistent, hypoechoic, spherical masses distorting the myometrial contour. When located within the myometrium, they should be differentiated from focal myometrial contractions, which tend to disappear during the examination or at follow-up scans. The hypoechoic sonographic appearance of leiomyomas may change when the masses undergo degeneration, which may lead to the appearance of cystic spaces or a coarse heterogeneous pattern consisting of hyperechogenic clusters within the myomas (Fig. 55-1). In such cases, myomas may have a worrisome appearance, and they can be mistaken for ovarian neoplasms or other intra-abdominal masses. When in doubt, magnetic resonance imaging (MRI) may help to confirm the diagnosis of a large, degenerating leiomyoma.²⁸ Pedunculated myomas can be differentiated from other pelvic masses by visualization of the blood supply by using color flow mapping (Fig. 55-2).

Myomas are often classified on the basis of their location in relation to the uterine cavity (i.e., submucosal if they distort the uterine cavity, intramural if they are predominantly located within the myometrial layer, and subserosal if they predominantly protrude out of the serosal surface of the uterus); in relation to the anatomic location within the uterus (i.e., fundal, corporal, isthmic, or cervical); and in relation to the placental insertion site (i.e., retroplacental or not). Such classifications are often difficult to apply in pregnancy because of uterine enlargement. Moreover, the location of a myoma can change during pregnancy because of changes in uterine size, so-called placental migration, and development of the lower uterine segment. Despite these difficulties, several series have attempted to correlate the location of myomas with the subsequent occurrence of pregnancy complications. The evidence for such associations is discussed subsequently.

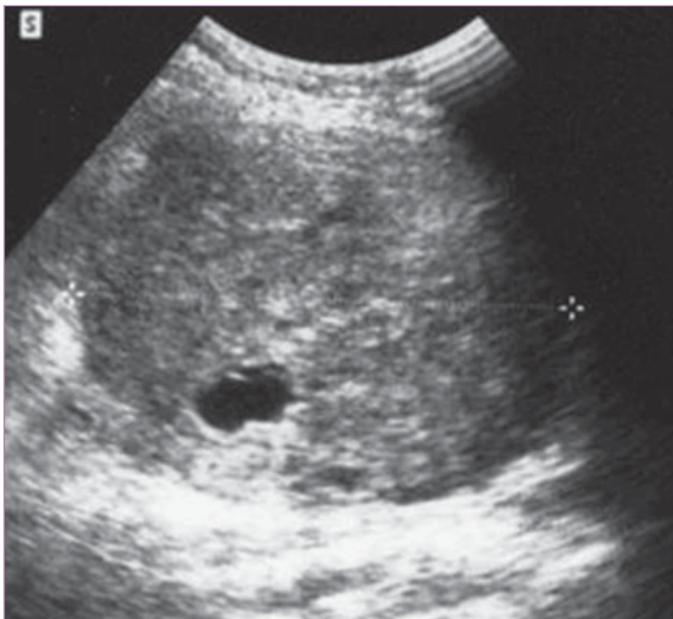

FIGURE 55-1 Degenerated myoma. Degenerated myomas have a heterogeneous echogenic pattern, with hypoechoic and hyperechoic areas seen within the myoma.

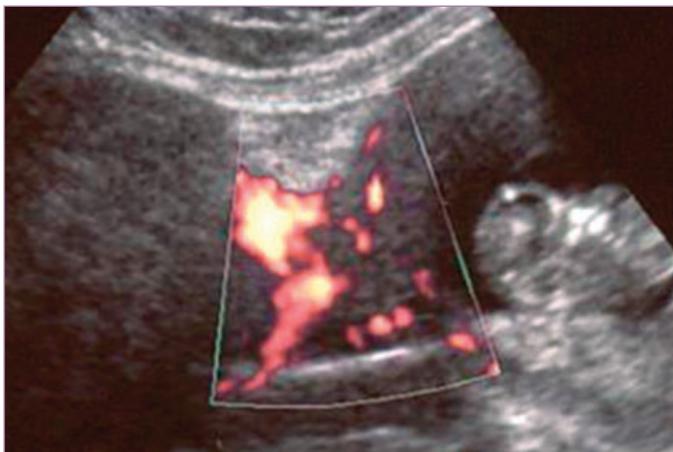

FIGURE 55-2 Pedunculated myoma. The arterial blood supply from the uterus can be demonstrated using color flow mapping.

Management

Fertility

A meta-analysis has shown that in infertile women with no identifiable infertility factors and submucous myomas, resection of the submucous myomas is followed by increased fertility rates (RR = 1.72; 95% CI, 1.13 to 2.58),¹⁴ suggesting that resection of submucous myomas may be a treatment for infertility in selected cases.¹⁵ Moreover, women with infertility due to submucous myomas who conceive spontaneously after myoma resection have higher pregnancy rates than those who conceive with assisted reproductive techniques.¹⁴ Retrospective and prospective observational studies have suggested that subserosal or intramural myomas without intracavitary involvement may affect fertility and that myoma resection in such cases may improve fertility.¹⁵ This hypothetical benefit must be weighed against the surgical risks to

the woman, increased risks for future pregnancies due to the presence of the uterine scar, and risks of recurrence of myomas. Until randomized clinical trials demonstrate benefits from myoma resection in infertile women with intramural or subserosal myomas, the procedure should not be recommended.^{15,29}

Miscarriages

Because of the known risks of myomectomy, the procedure should not be offered to women with myomas and history of miscarriages until prospective, observational studies with appropriate controls demonstrate an independent association between myomas and miscarriages and randomized, controlled trials document a beneficial effect of myoma resection on the risk for recurrent miscarriages.

Syndrome of Painful Myomas

The changes caused by large myomas during pregnancy may lead to the syndrome of painful myomas (i.e., red degeneration, carneous degeneration, hemorrhagic infarction, and aseptic necrobiosis) in less than 5% of patients.^{1,30} The pathogenesis of the pain is unclear, although it has been attributed to ischemia and necrosis caused by rapid growth of the myoma outpacing its blood supply or acute disruption of the blood supply leading to hemorrhagic necrosis. The exquisite response of the myoma pain to cyclooxygenase inhibitors (i.e., indomethacin or ibuprofen) suggests that release of prostaglandins plays an important role in the genesis of the pain.

Clinically, the diagnosis should be considered if there is localized tenderness over the myoma; in rare cases, the syndrome may be associated with low-grade pyrexia, mild leukocytosis, nausea, and vomiting. The differential diagnosis is extensive because of the lack of specificity of the symptoms, and it includes appendicitis, ureteral stones and pyelonephritis, adnexal torsion, and preterm labor. Ultrasonography plays a critical role in establishing a correct diagnosis by demonstrating the topographic association between the site of pain and the myoma, as well as the presence of cystic areas related to myoma degeneration in 70% of cases. If the diagnosis is uncertain, MRI may be indicated.³¹

Experts' opinions and case series suggest that nonselective cyclooxygenase inhibitors are more effective in the treatment of myoma-related pain than standard analgesics or narcotics.^{24,32} Use of indomethacin (25 mg every 6 hours) or ibuprofen (600 to 800 mg every 6 hours) usually leads to resolution of the symptoms within 48 hours. Intravenous therapy with ketoprofen (100 mg every 6 hours) is similarly useful, particularly in cases with gastrointestinal symptoms. An infected myoma (i.e., pyomyoma) is a rare cause of syndrome of painful myoma. It can be suspected in the presence of fever, moderate leukocytosis, and lack of response to appropriate medical therapy.³³⁻³⁵ Most cases are associated with termination of pregnancy or occur in the puerperium. Intravenous antibiotics together with myomectomy^{33,36} or hysterectomy³⁴ are the mainstays of therapy in such cases.

Myomectomy during Pregnancy

Myomas in pregnancy are best treated conservatively because of the risks of myomectomy in a pregnant uterus (chiefly bleeding and preterm delivery). Surgery should be reserved to cases of syndrome of painful myomas refractory to medical therapy. Because these cases are frequently related to torsion of pedunculated subserosal myomas, surgery is relatively safe and facilitated by clamping of the myoma pedicle.³⁷ A few small series have explored the effects of myomectomy in pregnancy for rapid myoma growth or recurrent myoma pain.^{26,30,38} Their conclusions have been contradictory, with some finding improved pregnancy outcome with myomectomy, and others reporting higher

rates of preterm delivery. The small sample size of the reports, with the associated lack of adequate statistical power, does not allow firm conclusions.

Cesarean Myomectomy

Occasionally, myomas need to be removed at the time of cesarean section to facilitate closure of the uterine incision or, rarely, to facilitate access to the fetus. With the exception of pedunculated myomas, which can be safely removed at the time of cesarean section, cesarean myomectomy carries significant risks of hemorrhagic complications. Bleeding significant enough to require transfusion, uterine artery ligation, embolization, or hysterectomy has been reported for an average of 11% of cases of myomectomy at cesarean section (range, 0% to 33%) in published series, with the number of cases ranging from 5 to 25.^{2,37,39-43}

In light of the risk of severe bleeding, appropriate planning is desirable for women with large uterine myomas located in the anterior uterine wall or lower uterine segment, including careful ultrasound mapping of the myoma location in relation to placental insertion and fetal position before surgery and the availability of blood products and appropriate support personnel in case of complications. Extensive cesarean myomectomies with removal of many myomas should be seen as an elective procedure to be discouraged because of the risk of bleeding and the natural history of myomas, which tend to undergo involution after delivery.

Pregnancy after Myomectomy

The main concern for pregnancies after any type of myomectomy is the risk of uterine rupture before or during labor. The risk seems to depend on the location of the myoma and the type of surgery. After *laparotomic myomectomy*, the risk of uterine rupture is mainly limited to myomectomies with entry into the uterine cavity. After *laparoscopic myomectomy*, the risk of uterine rupture seems to be related to the location of the myoma and to inadequate suturing. Uterine rupture in pregnancies after *hysteroscopic myomectomy* is a rare event, and it has been reported only in cases of uterine perforation at the time of the procedure.

Particular risks may affect pregnancies after uterine artery embolization for myomas. A total of 144 pregnancies have been reported in women after uterine artery embolization, resulting in 83 deliveries.⁴⁴⁻⁴⁶ The preterm delivery rate was 20% (17 of 83), and the average cesarean section rate was in excess of 50%. Rates of fetal growth restriction and birth weight were not consistently reported, but they did not seem to be significantly affected.⁴⁵ Several series reported occurrences of abnormal placentation (including accreta and previa) in pregnancies after uterine artery embolization, which contributed to increased rates of severe postpartum hemorrhage. Although these complications should be kept in the context of additional risk factors, including advanced maternal age, previous uterine surgeries, and presence of residual myomas, they raise serious concerns that uterine artery embolization may permanently alter myometrial function and induce changes in the uterine vasculature. Only one case of uterine rupture has been reported in a woman after uterine artery embolization, and it occurred at the scar of a previous cesarean section.⁴⁵

In summary, the available evidence suggests that pregnancy and delivery can be achieved after uterine artery embolization in most cases, but the risks of complications, including prematurity and placental abnormalities, may be higher than expected for the general population. Because of the generally benign outcome associated with untreated myomas in pregnancy, uterine artery embolization should be proposed cautiously for women planning future pregnancies.

Adnexal Masses

The detection of ovarian cysts in pregnancy is not uncommon. Small cysts discovered in early pregnancy are often functional, and expectant management is recommended because most of them resolve spontaneously and do not pose a risk to the pregnancy. Larger or complex cysts pose more of a clinical dilemma. Although some clinicians often remove them in the second trimester because of the risk for complications, even large and complex masses may be followed expectantly if they appear to be benign.^{47,48}

Epidemiology

The prevalence of adnexal masses depends on the gestational age. During the first 5 weeks of pregnancy, adnexal masses have been reported in 8.8% of women undergoing ultrasonographic examination; the rate decreases to 0.4% by 16 to 20 weeks.^{47,49} Similarly, Condous and associates⁵⁰ identified ovarian cysts in 6.2% of pregnant women examined before 14 weeks.

Spontaneous resolution during pregnancy occurs for most adnexal masses.^{47,50} In a series of 123 asymptomatic ovarian cysts detected at prenatal ultrasound examinations and followed conservatively, complete resolution was observed in 89% of cases, including 82% of the cysts larger than 6 cm in diameter.⁵¹ Similarly, spontaneous resolution was reported for 72% (119 of 166) of ovarian cysts followed with ultrasonography⁵⁰ and for 69% (70 of 102) of simple or complex adnexal masses larger than 5 cm in diameter.⁴⁷ The high rate of resolution reflects the physiologic nature of most ovarian masses detected early in pregnancy; expectancy is a reasonable management option.^{47,52}

Pathogenesis

The frequency and classification of persistent ovarian masses is limited to masses removed during or immediately after pregnancy, generating an inevitable bias because most ovarian masses with a benign appearance are not surgically removed. A review of the latest series reveals that three types of benign ovarian pathology account for most ovarian masses in pregnancy: corpus luteum cysts, mature teratomas, and cystoadenomas (Table 55-2).

TABLE 55-2 HISTOLOGIC PREVALENCE OF OVARIAN CYSTS IN PREGNANCY

Behavior	Type of Pathology	Frequency (%)
Benign	Corpus luteum	15-20
	Mature teratoma	7-42
	Luteoma or functional cyst	11-19
	Endometrioma	1-5
	Leiomyomas or adenofibromas	4-5
Borderline	Serous and mucinous cystoadenomas	9-16
	Borderline (serous, mucinous, other)	1-2
Malignant	Epithelial ovarian cancer, germ cell tumor, sex-cord stromal tumors	2-7

Data from references 52, 59, 82, 83.

Diagnosis

Most functional cysts are asymptomatic. Older series reported 10% to 30% rates of symptomatic or complicated adnexal masses during pregnancy. However, such series were prone to ascertainment bias because screening ultrasonography was not performed.^{53,54} In one series of ovarian cysts detected during the course of ultrasonographic examination in the first trimester, the rates of complications were much lower (7 [4%] of 166).⁵⁰ The most common complications of adnexal masses in pregnancy are malignancy; torsion, rupture, or hemorrhage; and dystocia at delivery.

Malignancy

The potential for malignancy is the paramount concern for the managing clinicians. Among women of reproductive years, germ cell tumors are common in young women, whereas epithelial ovarian cancers occur more frequently in older patients. The rate of malignancy for adnexal masses identified during pregnancy is commonly reported as 2% to 3% of surgically removed ovarian masses. The largest series on the subject, involving 9375 patients with a hospital discharge diagnosis of an ovarian mass, found a 2.1% incidence of malignancy, including 87 (0.9%) ovarian cancers of various histologic types and 115 (1.2%) ovarian tumors of low malignant potential.⁵⁵

Several algorithms have been proposed to differentiate benign from malignant ovarian tumors and to stratify the risk of malignancy using ultrasonographic characteristics.

Ultrasound Characteristics

Although malignant masses tend to be larger than benign ones, the size of an ovarian mass in pregnancy cannot be used to predict malignancy. In a case-control series, the average size of nonmalignant tumors was 7.6 cm and that of malignant neoplasms was 11.5 cm.⁵⁶ All masses smaller than 6 cm were benign.

Zanetta and colleagues⁴⁸ proposed a triage system to identify those who were candidates for expectant management (Table 55-3 and Fig. 55-3). The system was applied to 79 pregnant women with adnexal masses followed prospectively. Only pregnant patients with suspicious masses were triaged to surgical intervention at diagnosis, and women with masses of all the other categories were considered candidates for expectant management. There were no malignant tumors among the

23 women who underwent surgery because of persistent masses, torsion or rupture, or nonreassuring ultrasonographic findings, and all three borderline tumors were correctly suspected prenatally. Similarly, in a series of 131 tumors, ultrasonography accurately identified 95% of dermoid cysts, 80% of endometriomas, and 71% of simple cysts during pregnancy, and, more importantly, it correctly suspected the only case of malignancy.⁵² In a case-control study of 40 patients (Table 55-4), 3 of whom had malignant neoplasms and 5 of whom had tumors of low malignant potential, a uniform cystic appearance of the tumors had high specificity, whereas the presence of internal papillary excrescences had high sensitivity for diagnosis of malignancy.⁵⁶

Wheeler and Fleisher⁵⁷ prospectively investigated 34 ovarian masses with ultrasonography and color Doppler sonography, and compared their results with histologic diagnoses (Fig. 55-4). The mean pulsatility index in morphologically suspect areas within the tumor was significantly lower for malignant than for benign masses (0.7 [range, 0.4 to 1.3] versus 1.2 [range, 0.4 to 2.8]; $P = .03$), suggesting low impedance to flow in malignant masses. A pulsatility index less than 1.0 correctly identified three malignant ovarian lesions and five tumors of low malignant potential, with a sensitivity of 89%, positive predictive value of 42%, and negative predictive value of 93%. However, the overlap in blood flow patterns between benign and malignant tumors was such that the false-positive rate was almost 48%, causing incorrect assignment of malignant potential to some benign lesions and offering no advantage over the use of sonographic morphology indexing alone.

Other studies of nonpregnant women with ovarian masses have confirmed a partial role for Doppler sonography in differentiating benign from malignant ovarian tumors. However, the wide range in values makes the use of Doppler in differentiating benign from malignant perhaps most useful as an adjunct to morphologic assessment.

Serologic Markers

Serum tumor markers are primarily used for surveillance of known, treated ovarian malignancies, but they are of limited benefit in the initial assessment of ovarian masses. The level of cancer antigen 125 (CA 125) is elevated in 80% of women with epithelial ovarian malignancies, with mucinous adenocarcinomas being a notable exception. CA 125 has inadequate diagnostic accuracy in premenopausal women

Category	Sonographic Features
Simple cyst	Anechoic cyst without septa or vegetations
Endometriosis-like or corpus luteum-like	Hypoechoic content, homogeneous or trabecular, no papillae
Dermoid-like	Combination of hyperechogenic and hypoechoic content, shadows
Complex benign	Septa, thick content but no papillae
Borderline-like	Smooth capsule, presence of intracystic papillae, absence of gross solid parts
Suspicious	Solid parts, irregular capsule or border, ascites, irregular vascularization

Modified from Zanetta G, Mariani E, Lissoni A, et al: A prospective study of the role of ultrasound in the management of adnexal masses in pregnancy. *BJOG* 110:578-583, 2003.

Characteristic	Benign <i>n</i> = 32	Malignant <i>n</i> = 8
Morphology		
Complex	66% (21)	87% (7)
Solid	13% (4)	12% (1)
Cystic	22% (7)	0%
Discriminator		
Internal excrescences	0%	50%
Echogenic focus	3% (1)	0%
Septate	9% (3)	13% (1)

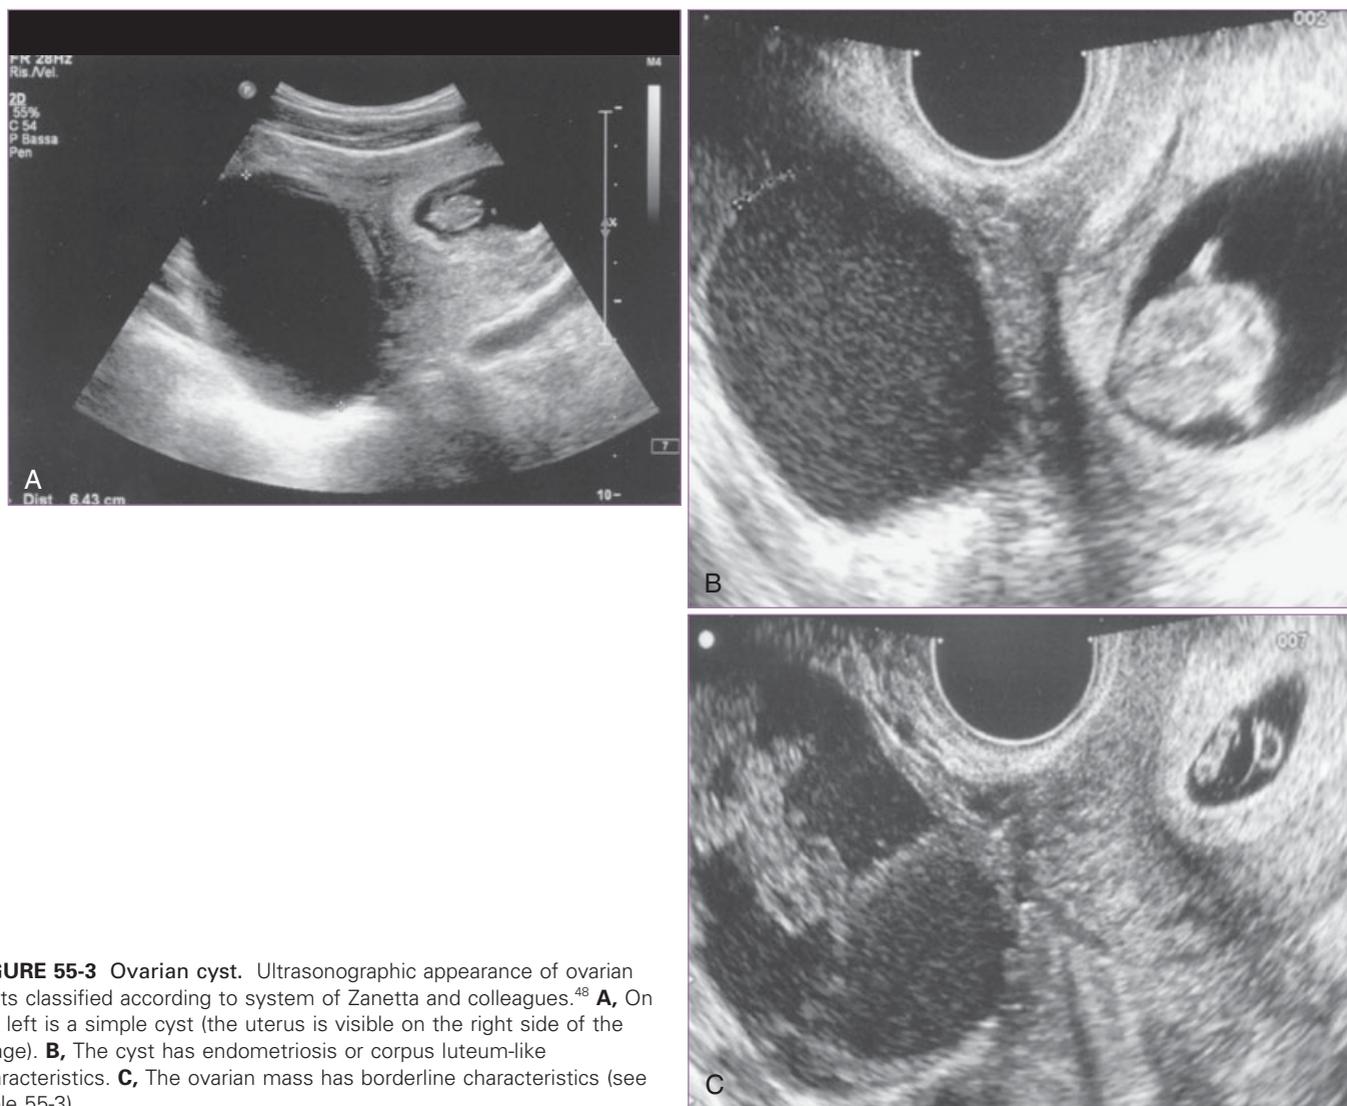

FIGURE 55-3 Ovarian cyst. Ultrasonographic appearance of ovarian cysts classified according to system of Zanetta and colleagues.⁴⁶ **A**, On the left is a simple cyst (the uterus is visible on the right side of the image). **B**, The cyst has endometriosis or corpus luteum-like characteristics. **C**, The ovarian mass has borderline characteristics (see Table 55-3).

because many benign gynecologic conditions, such as uterine fibroids, and especially pregnancy, are associated with elevated values. When elevated, the CA 125 level can provide a baseline value before treatment of ovarian cancer, but it does not help to differentiate benign from malignant masses during pregnancy.

Various other tumor markers are used to monitor germ cell tumors: α -fetoprotein (AFP) for endodermal sinus tumor, hCG for choriocarcinoma, and lactate dehydrogenase for dysgerminoma. Although germ cell tumors are among the most common ovarian malignancies seen in pregnancy, hCG and AFP have very limited use as tumor markers during pregnancy. Levels of tumor markers should be obtained before any surgical intervention when there is a suspicion of ovarian malignancy to provide a baseline value in case a malignancy is diagnosed. Any elevation in the levels of tumor markers should be considered in conjunction with the results of the imaging tests to avoid unnecessary intervention when possible.

Magnetic Resonance Imaging

MRI can be safely used during pregnancy to evaluate adnexal masses. The primary advantages of MRI are its capacity to develop three-dimensional planar images, delineate tissue planes, and characterize

tissue composition. This is particularly helpful for lesions in the pelvis, where ultrasonography has a limited role in assessing the bony and muscular structures. Kier and colleagues⁵⁸ reported that MRI is a useful complement to ultrasonography for patients with adnexal masses in pregnancy. In their series of 17 patients, MRI correctly identified the cause in 17 (100%) of 17, whereas ultrasonography was accurate in 12 (71%) of 17.⁵⁸ Three patients with ultrasonographic findings of suspicious ovarian masses were found to have pedunculated uterine leiomyomas on MRI, and unnecessary surgery was avoided.

MRI can be considered as an alternate imaging strategy when the ultrasound diagnosis is uncertain, if ultrasonography raises suspicion of uterine leiomyoma or shows a solid adnexal mass, and when a radiologist experienced in interpreting MRI of adnexal masses and pregnancy is available. Both ultrasonography and MRI greatly depend on the experience of the operator.

Complications

TORSION AND RUPTURE

During pregnancy, the progressive enlargement of the uterus displaces the ovaries and fallopian tubes out of the pelvis. This phenomenon and the rapid return of these structures to their normal anatomic

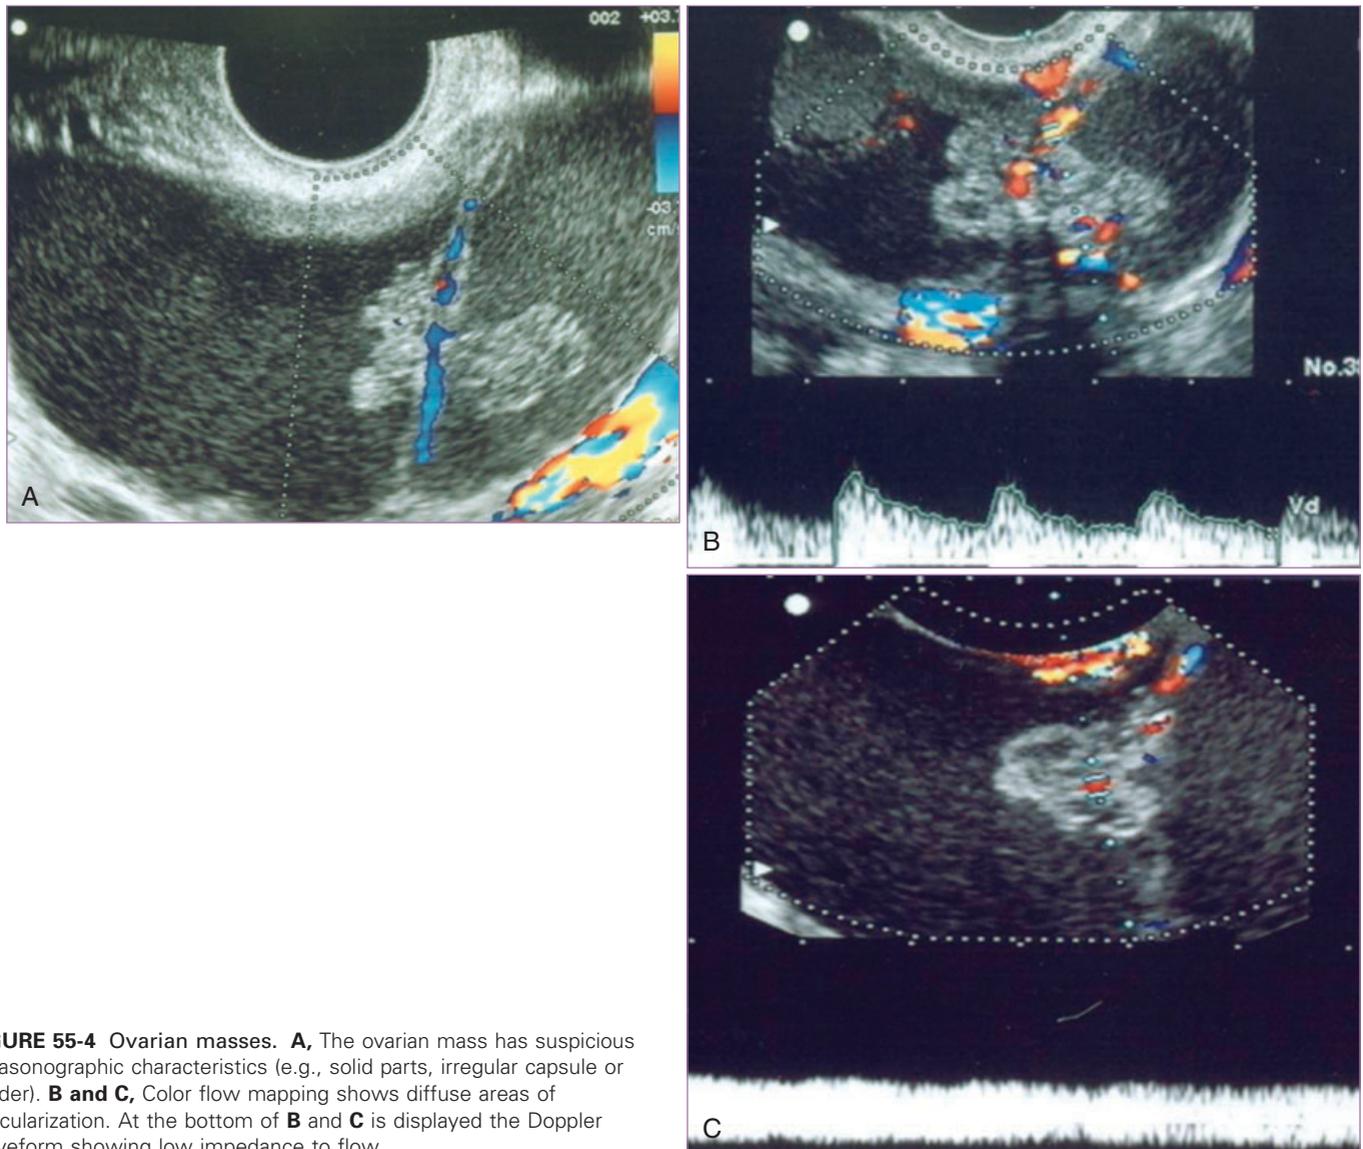

FIGURE 55-4 Ovarian masses. **A**, The ovarian mass has suspicious ultrasonographic characteristics (e.g., solid parts, irregular capsule or border). **B and C**, Color flow mapping shows diffuse areas of vascularization. At the bottom of **B** and **C** is displayed the Doppler waveform showing low impedance to flow.

location after parturition place adnexal masses at increased risk of torsion, particularly at the beginning of the second trimester and during postpartum involution. The rate of torsion in published series varies from 1% to 22%.^{50,52} Rupture appears to be less common, with rates ranging from 0% to 9%.^{52,59,60} Less frequent complications include bleeding and infection.

In a series of 130 women with adnexal masses, 16 required emergency laparotomy for acute abdominal pain, and 11 of 16 had documented or presumptive ovarian torsion.⁵⁹ Struyk and Treffers⁶⁰ observed a relationship between tumor size and the risk of complications; complications occurred in 35% of tumors between 5 and 6 cm in diameter and in up to 85% of larger tumors.⁶⁰ Overall, torsion occurred in 12% and rupture in 9%. A far lower rate of antepartum complications was reported by Bromley and Benacerraf⁵² in a series of 131 ovarian masses among 125 pregnant women; only one patient had an ovarian torsion, and another patient underwent exploratory laparotomy. Similarly, Bernhard and coworkers⁴⁷ reported a 1% risk of torsion in their series of 102 ovarian masses; the only torsion occurred in a patient with a palpable mass.

Overall, it appears that later studies report lower risks of torsion and rupture than earlier ones. This may reflect a higher proportion of asymptomatic, ultrasound-detected ovarian masses and therefore may more accurately reflect the risk of this complication in pregnancy.

RISK OF DYSTOCIA AT DELIVERY

Obstruction of labor is a complication that can occur when large adnexal masses are lodged between the presenting fetal part and the birth canal. Obstruction of labor occurs in 2% to 17% of patients with large adnexal masses.^{60,61}

Management

Optimal management of adnexal masses should be based on an accurate assessment of the risks of the complications previously outlined. Ultrasonographic criteria can successfully stratify the risk by identifying the few masses with suspicious complex features that warrant surgical management. Most masses have a benign ultra-

sonographic appearance, and they are suitable for conservative (expectant) management.

Surgical Management

Surgical management of adnexal masses during the first trimester should be limited to lesions with complications (i.e., torsion or rupture). Persistence of adnexal pathology during the second and third trimester may warrant intervention in if there is a strong suspicion of malignancy or large size (>6 cm) or there are symptomatic complaints. A large size may signal increased risk of torsion, rupture, or obstruction during labor. Before undergoing surgical removal, patients should be appropriately counseled about the possibility of an underlying malignancy and be prepared for possible ovarian cancer staging and related evaluation of tumor serum markers. Although the risks to mother and fetus have been substantially reduced with the improvement of anesthesia, intraoperative and postoperative care, and prenatal care, surgery during pregnancy requires a trained team of surgeons and anesthesiologists and close monitoring postoperatively.

Laparoscopy offers clear advantages to exploratory laparotomy for surgical management of adnexal masses, including less invasive surgical management and a shorter postoperative course with fewer complications.⁶² Patients with an ovarian mass that is not suspected to be malignant in the first or second trimester of pregnancy potentially benefit the most by laparoscopic surgery. Sound clinical judgment is critical for patient selection, and caution is strongly advised when considering laparoscopic management of possible ovarian cancer. Although many case series proposed aspiration of simple unilocular cysts to avoid the need for major surgery, provide symptomatic relief, or allow these masses to fit into endoscopic bags, aspiration of a complex ovarian cyst runs the potential risk of malignant fluid spillage, which is associated with decreased survival.⁶³ Ovarian masses, especially those suspicious for cancer, should be removed intact when possible, and surgical intervention for large, complex ovarian masses should be performed by laparotomy.

Whether by laparoscopy or laparotomy, consideration can be given to ovarian cystectomy if the imaging criteria for a benign mass are met. Otherwise, oophorectomy is appropriate.

Timing of Surgery

Delaying surgery because of fear about the risks of the operation may potentially lead to increased fetal and maternal complications. Adverse fetal outcomes associated with abdominal surgery are most commonly the result of an abdominal catastrophe, such as ovarian torsion or rupture as indications for the surgery. In elective surgical cases, there seems to be no association between surgery and adverse perinatal outcome. Hess and colleagues⁶⁴ reported that patients who underwent emergency surgery because of adnexal torsion or hemorrhage had a greater incidence of abortion and preterm delivery compared with patients who underwent elective laparotomy. Elective surgical intervention is preferably timed for the second trimester, when the risk of fetal loss is minimal. Whitecar⁵⁹ found that adverse pregnancy outcomes, including preterm deliveries and fetal loss, were significantly less common if laparotomy occurred before rather than after 23 weeks' gestation (OR = 0.15; $P = .005$). Laparotomy in the third trimester was associated with a 50% risk of preterm delivery.

Other Management Considerations

If there is a risk of disrupting a corpus luteum cyst at up to 12 weeks' gestation, progesterone supplementation is indicated. The effectiveness of tocolytics for suppression of preterm delivery associated with

adnexal surgery is similar to that of tocolysis administered for preterm labor. In Whitecar's series,⁵⁹ tocolytics were administered to 13 patients who had operations in the second and third trimesters; 6 of 13 had preterm deliveries, although only 2 delivered within 2 weeks of laparotomy. Given the potential for preterm delivery unresponsive to tocolysis and the negligible risks of steroids, consideration may be given to a prophylactic course of steroids for fetal maturity enhancement if the surgery is performed between 24 and 34 weeks' gestation.

Congenital Uterine Anomalies

Epidemiology

The mean overall prevalence of uterine malformations in the general population and the population of fertile women is 4.3%.⁶⁵ The mean incidence of müllerian defects in infertile patients is 3.4%, which is similar to the prevalence of 4.3% found in the general population and in fertile women. This is an indirect indication that müllerian defects have no impact on women's fertility.⁶⁵ Congenital uterine malformations complicate 1 in 594 pregnancies.⁶⁶

Pathogenesis

Uterine malformations consist of a group of congenital anomalies of the female genital system. They are the result of disturbances in the development, formation, or fusion of the müllerian or paramesonephric ducts during fetal life. They are usually classified as six major anatomic types:

- Type I: hypoplasia or agenesis (usually with infertility)
- Type II: unicornuate uterus (i.e., normal differentiation of only one müllerian duct), often with a contralateral communicating or noncommunicating rudimentary horn
- Type III: didelphys uterus (i.e., complete failure of the müllerian ducts to fuse in the midline)
- Type IV: bicornuate uterus (i.e., two normally differentiated ducts are partially fused in the region of the fundus)
- Type V: septate uterus (i.e., failure of resorption of medial segment of the müllerian ducts)
- Type VI: arcuate uterus (i.e., minor change in the uterine cavity shape with no external dimpling)

Table 55-5 shows the prevalence of the different types of uterine anomalies.

Uterine malformations result in an abnormal uterine cavity, which is thought to impair the reproductive performance by increasing the incidence of early and late abortions, preterm deliveries, and obstetric complications. Other factors may be associated with the anatomic anomalies and may have the potential to affect pregnancy outcomes. Anomalies in uterine arterial circulation may result in uterine hypoperfusion; abnormalities in thickness of uterine walls may affect blastocyst implantation and result in poor decidualization and placentation; and associated cervical structural or functional anomalies may result in cervical incompetence. Such factors may explain why even a minor uterine anomaly, such as arcuate uterus, has been found by some investigators to result in an excess of spontaneous abortions, second-trimester losses, and preterm deliveries.^{65,67} One study⁶⁸ reported sig-

nificantly higher blood pressure values and higher rates of fetal growth restriction among 16 primigravidas with congenital uterine malformations compared with controls matched for parity, age and gestation, suggesting altered uteroplacental circulation in pregnancies with uterine anomalies.

Diagnosis

Diagnosis of uterine anomalies is usually made after a workup for recurrent pregnancy losses. The rates of uterine malformations in patients with recurrent pregnancy losses range from 1.8% to 37.6%,^{67,69} with a mean overall rate of 12.6%.⁶⁵ Less commonly, a diagnosis of uterine anomaly is made during the course of sonographic evaluation of an ongoing pregnancy, serendipitously during the course of imaging testing, or at laparoscopy or laparotomy.

Accurate identification of the type of uterine malformation is important because each type of uterine anomaly is associated with different rates of obstetric complications.^{65,67,70-72} Visualization of the uterine cavity and the fundal uterine contour is essential to differentiate uterine anomalies (e.g., between septate and bicornuate uteri). Traditionally, diagnosis rested on hysteroscopy, chromotubation, or sonohysterography for visualization of the uterine cavity and laparoscopy or laparotomy for intra-abdominal views. Three-dimensional ultrasound and saline contrast sonohysterography appear promising for reliable diagnosis and classification of congenital uterine anomalies in a noninvasive way. Although MRI is often helpful, incorrect diag-

noses have been reported with the use of MRI alone, frequently mistaking a unicornuate uterus that has an associated contralateral rudimentary horn for a bicornuate or didelphys uterus. Because urinary tract anomalies occur in about 60% of congenital uterine anomalies, imaging of the urinary tract is indicated.

Management

Certain complications seem to be more common or unique in certain types of malformations (Table 55-6). For women with bicornuate uteri, some investigators have found poorer pregnancy outcomes when the division is partial rather than complete,⁶⁷ whereas others have been unable to confirm a difference between these two types.⁷² The septate uterus has been associated with the poorest reproductive outcome, mainly because of a high rate of spontaneous abortions.^{71,73-75} Didelphys, bicornuate uteri, and septate uteri are associated with rates of preterm delivery that are two to three times higher than expected in the general pregnant population.⁶⁵ Uterine rupture is a frequent complication (about 50% of cases) in pregnancies in rudimentary horns, which are frequently associated with a unicornuate uterus.⁷⁶ Although prophylactic tocolysis has been suggested for pregnancies in rudimentary horns to minimize uterine contractility and attainment of fetal viability,⁷⁶ its efficacy has not been adequately tested. A rare complication specific to uterus didelphys is hemiuterus torsion.⁷⁷

Approaching delivery, women with uterine anomalies are at increased risk for fetal malpresentation, and fetal presentation should be verified with ultrasonography. Because major uterine anomalies (i.e., types II to IV) are associated with an increased risk for uterine rupture,⁷⁸ induction of labor should be undertaken cautiously.

Prevention

Hysteroscopic metroplasty offers the possibility of correction of the uterine cavity, mainly in cases of septate and arcuate uterus and in some cases of partial bicornuate uterus. Hysteroscopic metroplasty is associated with a significant decrease in the abortion and preterm delivery rates.^{65,79,80} Transabdominal metroplasty remains the only approach in cases of bicornuate uterus.⁸¹

It is not known whether closer sonographic surveillance of fetal growth and mid-trimester sonographic assessment of cervical length in women with uterine anomalies may improve outcome by identification of fetal growth restriction in a timely fashion and recognition of increased risk for preterm delivery.

TABLE 55-5 UTERINE MALFORMATIONS: PREVALENCE OF THE DIFFERENT TYPES

Type of Malformation	Cases <i>N</i> (%)
Arcuate	255 (18.3)
Septate	486 (34.9)
Bicornuate	362 (26.0)
Unicornuate	134 (9.6)
Didelphys	114 (8.2)
Agenesis	40 (2.9)
Total	1392

Chapter 56

Anesthetic Considerations for Complicated Pregnancies

Krzysztof M. Kuczkowski, MD

The physiologic changes that occur during normal pregnancy must be considered by the anesthesiologist to facilitate selecting the most appropriate and safest anesthetic drugs and techniques. When pregnancy is complicated by a significant medical disorder, the anesthetic considerations are even more challenging. This chapter reviews the special concerns posed by the more common and complex medical disorders superimposed on pregnancy and the most prudent technical solutions to the specific problems. Epidural and combined spinal-epidural analgesia and anesthesia frequently are recommended for the parturient with medical or obstetric complications because of the great flexibility and utility of these techniques for virtually any obstetric procedure.

Preeclampsia

The patient with preeclampsia has multiple organ system alterations that affect the selection of analgesia and anesthesia for labor and delivery.¹ The patient with mild preeclampsia rarely poses a major problem regarding anesthesia. Consequently, the focus here is on the patient with severe preeclampsia and eclampsia. Throughout this chapter, intensive care monitoring and the use of pulmonary artery occlusion pressure monitoring are emphasized (see Chapter 57).

Intravascular Volume Depletion

Intravascular volume depletion is a well-recognized occurrence in women with severe preeclampsia.^{1,2} The anesthesiologist is concerned about inducing epidural, combined spinal-epidural, or spinal anesthesia in the patient with relative hypovolemia because the ensuing sympathetic blockade can lead to precipitous declines in blood pressure, which can seriously impair critical organ and uteroplacental blood flow. Preanesthetic volume expansion is used with caution to prevent this undesired effect. Replacement may require the use of central venous pressure or pulmonary artery pressure monitoring.^{1,3} Because many patients with preeclampsia have low central filling pressures, they often require large volumes of fluid to bring the pressures into the middle of the normal range. This measure, however, can result in pulmonary edema in the postpartum period, when colloid osmotic pressure reaches its nadir.⁴ More judicious fluid management with slow advancement of an epidural block, particularly for those under-

going cesarean delivery, is proving effective at maintaining maternal blood pressure while minimizing the risk of fluid overload.

The choice of fluid—crystalloid or colloid—remains controversial. Studies have demonstrated the beneficial effects of albumin administration for these patients.⁵ Its use is justified in part by the fact that preeclamptic women tend to demonstrate significant reductions in plasma protein levels and colloid osmotic pressure as a result of protein loss through the kidney. Arguments against the routine use of albumin emphasize that the functional changes in membranes that allow edema to occur also allow protein to leak into the tissues, making removal of interstitial fluid more difficult. To avoid volume overload, the judicious administration of crystalloid solution (up to 2000 mL) is guided by central venous or pulmonary artery occlusion pressure monitoring. This is accomplished with simultaneous advancement of the regional block, thereby titrating the effects of one against the other. If the patient has marked edema or low colloid osmotic pressure or has not responded to crystalloid infusion, 25% salt-poor albumin is administered to maintain intravascular volume. The objective is to provide sufficient volume to allow the patient to undergo anesthesia and maintain an adequate urine flow rather than totally correct an estimated volume deficit.¹

Vascular Reactivity

Vascular reactivity is enhanced in preeclampsia, and the increased sensitivity to vasopressor agents such as angiotensin II and catecholamines is well documented.^{6,7} Systemic vascular resistance (SVR) can be increased, and uteroplacental crucial organ blood flow can be compromised. The anesthesiologist must consider the possibility that the administration of regional anesthesia and its attendant sympathetic blockade to a patient who is already experiencing volume depletion and vasoconstriction may result in sudden hypotension. The initiation of epidural blockade with maintenance of an acceptable maternal blood pressure, however, results in increases in uteroplacental blood flow.¹ An acceptable maternal blood pressure is defined as no more than a 25% reduction in systolic blood pressure.

Vasoreactivity alerts the anesthesiologist to use lower doses of vasopressors to correct maternal hypotension. An arterial catheter can be helpful in monitoring beat-to-beat blood pressure responses in patients requiring aggressive therapy. Patients who undergo general anesthesia for cesarean delivery are at risk for hypertensive crisis at the time of laryngoscopy and intubation as a result of the associated increase in

sympathetic tone. This can lead to intracranial hemorrhage or pulmonary edema, and measures should be taken to block this response when general anesthesia is required.^{4,8}

Coagulation

Coagulation system changes are frequently observed in patients with severe preeclampsia. The most common alteration is a decrease in platelet count. This is usually not a concern unless the level falls below 100,000/mm³. Many anesthesiologists are reluctant to administer regional anesthesia when the platelet count is at or below this level for fear that an epidural hematoma may occur.^{9,10} A possible platelet functional defect has also been identified in these patients.¹¹ This results in a prolonged bleeding time by the Ivy method (<5 minutes from the stab until all bleeding from the wound stops) despite a normal platelet count. The absolute limit beyond which it is thought unwise to perform regional anesthesia is arbitrary and variable, because there are no documented reports of an epidural hematoma occurring in association with epidural anesthesia in preeclamptic patients with lowered platelet counts or a prolonged Ivy bleeding time, and some have questioned the diagnostic and predictive ability of the bleeding time.¹²

There is retrospective evidence to suggest that many epidural agents have been placed in such patients without incident.¹³ Nevertheless, the potential complication is so serious that the arbitrary limit generally used is as follows. If the bleeding time is less than 12 minutes or if another test of primary hemostasis indicates good platelet function, it is probably safe to use regional anesthesia even if the platelet count is below 100,000/mm³. Other tests of whole-blood clotting (e.g., thromboelastogram, Sonoclot, Platelet Function Analyzer-100) have been evaluated in preeclamptic and healthy parturients, but their usefulness as predictors of surgical or epidural bleeding remains to be defined. Disseminated intravascular coagulation is an infrequent occurrence in preeclamptic patients, but it significantly alters other tests of coagulation.

Edema

Edema is a frequent finding in patients with preeclampsia. Limb edema can make vascular access difficult. Edema in the neck can obscure landmarks for performing internal jugular vein cannulation for central line insertion. The most worrisome edema for the anesthesiologist is that which can occur in the pharynx and larynx. Difficult or impossible intubation has been encountered, with severe maternal consequences. General anesthesia for markedly edematous preeclamptic patients should be avoided, and when absolutely necessary, preparation for alternative methods of securing the airway must be made.¹ Postextubation airway obstruction resulting from edema at the level of the glottis is a serious complication that occurs frequently in these patients.

Pulmonary edema is another complication of preeclampsia. Most of these patients have normal cardiac function with imbalances in pulmonary artery pressure and colloid osmotic pressure.⁴

The observed reduction of colloid osmotic pressure in normal pregnancy is further decreased in preeclampsia. This results from the loss of albumin, which is the major contributor to colloid osmotic pressure. Modest elevations in pulmonary artery occlusion pressure from exogenous fluid administration and mobilization of endogenous fluid alter the gradient between colloid osmotic pressure and pulmonary artery pressure so that transudation of fluid into the interstitium is likely.

Drugs

Pharmacologic agents are often required to treat patients with preeclampsia. These drugs can interact with anesthetic agents to produce an undesired effect, and the obstetrician and anesthesiologist should be aware of the pharmacology of the drugs employed, their dosages, and the time of administration.¹⁴

Magnesium sulfate is the most commonly administered agent in the management of preeclampsia. Adverse effects are few when it is administered appropriately, and overdose is treated easily with intravenous calcium. Magnesium exerts several important effects at the neuromuscular junction. It inhibits the release of acetylcholine from the presynaptic nerve terminal, depresses the postjunctional membrane response, and depresses the response of the underlying myofibrils.¹⁴ These effects are responsible for the muscle weakness and respiratory depression observed with overdose. Neuromuscular blocking agents are used to facilitate endotracheal intubation and to maintain a relaxed surgical field when general anesthesia is provided for cesarean delivery.¹⁵ Magnesium potentiates and prolongs the action of depolarizing agents (e.g., succinylcholine) and nondepolarizing agents (e.g., rocuronium, vecuronium, atracurium).¹⁶ Lower doses of these drugs are necessary, and electronic monitoring of the neuromuscular junction is helpful.¹⁷

The patient must be evaluated carefully at the end of the procedure to ensure that she has regained sufficient muscle strength to maintain and protect her airway and to sustain adequate ventilation. Because drugs used to provide anesthesia are anticonvulsant in nature, it is prudent to discontinue magnesium sulfate therapy in the operating room when general anesthesia is used and to reinstate use after the patient has regained full neuromuscular function.

The anesthetic options for a patient with severe preeclampsia depend on the mode of delivery. Analgesia for the first stage of labor reduces maternal catecholamine output and perhaps maintains or improves uteroplacental blood flow. Systemic analgesia with narcotics is acceptable, although continuous lumbar epidural analgesia provides the best pain relief with minimal or no sedation.¹⁸ The use of segmental epidural analgesia avoids extensive sympathetic blockade. Opioids may be added to the local anesthetic solution to enhance the quality of pain relief without additional sympathetic or motor blockade. If sympathetic blockade must be totally avoided, intrathecal narcotics (e.g., morphine, fentanyl, sufentanil, meperidine) can be administered by single injection or continuous technique. Anesthesia for vaginal delivery may be provided by pudendal nerve block, low spinal anesthesia, or lumbar or caudal epidural anesthesia. Although the choice of anesthetic in the patient who is to undergo cesarean delivery has been controversial, the careful use of epidural anesthesia, with meticulous attention to left uterine displacement and fluid management, is associated with good maternal and fetal outcomes and is the preferred approach.^{1,4}

When general anesthesia is required, measures must be taken to avoid the hypertensive response to laryngoscopy and to intubation and extubation. Labetalol administered just before induction in doses up to 1 mg/kg have proved effective in reducing this response. Alternative or adjunctive drugs, such as sodium nitroprusside and nitroglycerin, may also be used. Sodium nitroprusside, because of its short half-life, provides the advantage of allowing for minute-to-minute blood pressure control.

Inability to intubate the trachea is the leading cause of maternal death associated with general anesthesia. Alternative means of providing oxygenation and ventilation (e.g., laryngeal mask airway, the Combitube, transtracheal jet ventilation) must be readily available.^{19,20}

Transtracheal jet ventilation provides adequate oxygenation and ventilation to pregnant patients.^{20,21} If airway difficulty is anticipated, an awake intubation, perhaps aided by a fiberoptic bronchoscope, may be necessary.

In the past, spinal anesthesia was usually avoided for cesarean delivery of patients with severe preeclampsia because of concern about rapid onset of profound sympathetic blockade, which resulted in catastrophic hypotension difficult to treat.²² As a result, epidural anesthesia became the preferred regional technique for cesarean section in women with severe preeclampsia because of a more gradual onset of sympathetic block.^{1,23,24}

In 2003, Aya and colleagues²⁵ demonstrated that severely pre-eclamptic patients receiving spinal anesthesia for cesarean delivery were at no greater risk for profound hypotension than normotensive patients when using a standard single dose of spinal anesthesia.²⁵ In 2005, two more studies^{26,27} supported the use of single-dose spinal anesthesia in women with severe preeclampsia.

Although the optimal anesthetic technique for cesarean section in women with severe preeclampsia still poses a dilemma for some obstetricians and obstetric anesthesiologists, it appears that spinal anesthesia in stable and noncoagulopathic parturient may be a reasonable alternative to epidural anesthesia, especially in emergency situations and particularly if it avoids the use of general anesthesia. The lower arterial blood pressure that follows induction of spinal anesthesia is far less a concern than the risk of failed ventilation, intubation, and the risk of hypertensive crisis during laryngoscopy when general anesthesia is selected for women with severe preeclampsia.^{1,24}

Neurologic Disorders

Multiple Sclerosis

Multiple sclerosis is a disease of young adults that may occur in pregnant women. The disease process is characterized by chronic inflammation, demyelination, and gliosis in the central nervous system. The cause of multiple sclerosis is not known, and there is no curative treatment. Pregnancy does not negatively affect the long-term prognosis of multiple sclerosis.^{28,29}

Although there have been many attempts to associate anesthesia and surgery with relapses of symptoms, no controlled studies have directly linked any form of anesthesia to exacerbation of multiple sclerosis.³⁰ Nevertheless, the routine administration of anticholinergic agents is not recommended because they may induce an elevation in body temperature, known to be associated with exacerbations of multiple sclerosis. Concern has been raised that local anesthetics may be more histotoxic to neural tissue already compromised by multiple sclerosis. All local anesthetic agents are potentially neurotoxic in doses that far exceed those used clinically. Neurotoxicity from local anesthetic drugs has not been demonstrated in patients with multiple sclerosis, and epidural analgesia and anesthesia have been safely and successfully used for labor and delivery in these patients.^{30,31} The lowest concentration of local anesthesia capable of producing the desired effect should be selected.^{30,31} Epidural and intrathecal narcotics have also been administered without apparent adverse effect. Although peripartum and surgical stress (and general anesthesia) have been linked to exacerbation of symptoms of multiple sclerosis, published data regarding this association are limited. Diagnostic lumbar puncture is not associated with an increased rate of relapse.³²

In summary, the review of published data does not contraindicate the use of regional anesthesia for labor, vaginal delivery, and cesarean

section in patients with multiple sclerosis.^{31,32} However, it is important to inform the patient that there is a high incidence of disease relapse during the postpartum period, regardless of the choice of anesthesia and mode of delivery.³²

Paraplegia

Each year, more than 2000 women of childbearing age in the United States sustain a spinal cord injury.³³ As a result of increased survival rates for women with spinal cord injury, the number of parturients with paraplegia is increasing. The level and extent of the lesion determine the patient's response to labor. If the spinal cord lesion is below the 10th thoracic dermatome, the patient will have the sensation of labor.³³ If it is above this level, she will have minimal or no awareness of contractions. Paraplegic parturients tend to have a normal course of labor but a higher percentage of forceps-assisted deliveries because of weakness of the abdominal muscles and consequent impairment of the ability to bear down effectively in the second stage.³⁴ The major anesthetic issues are the management of analgesia and anesthesia for labor and delivery, the possibility of autonomic hyperreflexia, and hyperkalemia with the administration of succinylcholine.

The phenomenon of autonomic hyperreflexia occurs in patients whose spinal cord lesion is at the seventh thoracic dermatome or higher.^{35,36} This condition is characterized by severe hypertension, bradycardia, headache, premature ventricular contractions, flushing, sweating, and priapism. The hypertension can be severe and, if uncontrolled, can lead to central nervous system hemorrhage, cardiac decompensation, or death. It is triggered by stimulation below the level of the spinal cord lesion.^{35,36} Common initiating events include bladder or rectal distention, rubbing of the skin, genital stimulation, and contraction of any hollow viscus, including the uterus. The triggering impulse is conducted to the spinal cord, where a reflex response occurs that cannot be modulated or inhibited by higher centers because of the isolation invoked by the cord lesion. This results in an uncontrolled adrenergic discharge with norepinephrine release from the peripheral sympathetic nerve endings.³⁵ The release of adrenal catecholamines may also be involved.

Although a large percentage of patients at risk do exhibit this reflex, some do not. A careful history should reveal those who exhibit such a response. Because preterm labor may be unrecognized by these patients, the sudden onset of paroxysmal hypertension should prompt a search for uterine contractions before the diagnosis of pregnancy-induced hypertension is considered.

During labor, adequate blockade of the afferent impulses can be provided by regional anesthesia, even if no pain is perceived by the patient. Continuous epidural anesthesia with a local anesthetic and narcotic agents has been employed successfully to treat autonomic hyperreflexia during labor and delivery.^{35,36} Spinal anesthesia in single-injection and continuous forms has been used to control blood pressure.³³⁻³⁶ With regional anesthesia, it is difficult to determine whether an adequate block is present, because the usual sensory tests are useless below the level of the lesion. The anesthetic block must therefore be titrated to just above the existing sensory level. Autonomic hyperreflexia can be controlled by a variety of antihypertensive agents, such as phentolamine and sodium nitropruside.

General anesthesia can effectively inhibit the hyperreflexia response.^{35,36} If general anesthesia is required for a complex vaginal or cesarean delivery, however, the anesthesiologist must determine when the spinal cord injury initially occurred, because there is a significant release of potassium from the denervated muscle after the use of succinylcholine for endotracheal intubation if it is administered 6 months

to 1 year after the injury. The elevation in serum potassium can reach life-threatening levels.³³

Ordinarily, although a general anesthetic agent may be used safely, an epidural anesthetic agent is preferred. Regional anesthesia has the advantage of blocking afferent input, thereby avoiding autonomic hyperreflexia. If the lesion is in the upper thoracic region, the patient will have weak abdominal and thoracic musculature. The use of epidural anesthesia is preferable to spinal anesthesia because the degree of motor impairment is less and profound muscle relaxation is not required. The block can be advanced gradually, avoiding sudden hypotension from a rapid extensive sympathetic blockade.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage from an intracranial vascular lesion is an uncommon but serious complication of pregnancy.³⁷⁻³⁹ The stress induced by the increased cardiac output and blood volume, combined with the softening of vascular connective tissue by the hormonal changes of pregnancy, may predispose a patient to such an event. The diagnosis can be obscured initially because nausea and vomiting are common findings during pregnancy.

Treatment is usually surgical if the lesion is an aneurysm because this approach significantly improves maternal chances of survival. The decision to treat surgically should be influenced not by the pregnancy but by the site and type of lesion, the clinical condition of the patient, and the presence or absence of vasospasm. Medical management appears to be as effective as surgical management for arteriovenous malformations during pregnancy. After a patient has undergone surgical correction of an aneurysm, there are no special considerations for anesthetic management of labor and delivery.³⁹

The anesthetic concerns regarding the patient *without* surgical correction are focused on two different clinical situations. The first relates to the patient undergoing neurosurgery for a ruptured aneurysm; the second is anesthetic management of labor and delivery for a patient who has not undergone surgical repair. Anesthesia for the patient having a neurosurgical procedure has the same primary goals as for all patients having surgery during pregnancy—maintaining uteroplacental blood flow and fetal oxygenation and preventing preterm delivery.⁴⁰⁻⁴²

The usual neurosurgical anesthetic approach to patients with these types of lesions includes the following:

- Deliberate hypotension to reduce the risk of cerebral hemorrhage
- Hypothermia to reduce cerebral metabolism
- Hyperventilation to reduce cerebral blood flow and brain size
- Diuresis to promote shrinkage of the brain

Deliberate hypotension can be produced with a volatile anesthetic, sodium nitroprusside, or nitroglycerin. Each agent carries its own potential hazards in addition to reduction in uteroplacental blood flow. A reduction in systolic blood pressure of 25% to 30% or a mean arterial blood pressure of less than 70 mm Hg leads to reductions in uteroplacental blood flow.⁴⁰ The hypotensive agents also cross the placenta and can induce hypotension in the fetus. Nitroprusside is converted to cyanide, and cyanide accumulation and toxicity in the human fetus pose at least a theoretical risk. If this agent is used, it should be for only a short time. It should be discontinued if the required infusion rate exceeds 0.5 mg/kg/hr, if maternal metabolic acidosis ensues, or if resistance to the agent is apparent.

Nitroglycerin has not been associated with adverse fetal effects. It is metabolized to nitrites, which have produced methemoglobinemia

experimentally. This agent, however, is less predictable in its hypotensive effect than sodium nitroprusside. Fetal heart rate monitoring should be employed, and hypotension should be limited to the shortest period possible. Although it is preferable to avoid or limit the period of hypotension in the pregnant patient, successful neonatal outcome after induced hypotension with careful control has been observed.⁴²

Hypothermia is used occasionally to decrease cerebral metabolic requirements and blood flow. The usual goal is to achieve a temperature of approximately 30° C. This measure induces similar temperature changes in the fetus, and fetal bradycardia occurs. The heart rate increases again with rewarming. Hyperventilation is commonly used during neuroanesthesia, because the decrease in PCO₂ reduces cerebral blood flow.⁴³ The goal is to reach a PaCO₂ of approximately 20 to 25 mm Hg.^{44,45} This degree of respiratory alkalosis should not be a problem for the healthy fetus, because a PaCO₂ of 32 mm Hg is the norm for pregnant women. Fetal heart rate monitoring should alert the anesthesiologist to compromises in fetal oxygenation, and adjustments may be made accordingly.

Diuresis is often accomplished with osmotic agents or loop diuretics to shrink the brain intraoperatively and postoperatively.^{44,45} These agents can cause significant negative fluid shifts for the fetus. Diuretic agents should be given only as necessary and not strictly by protocol for the pregnant patient.

The objectives in managing a patient for labor and delivery who has not undergone surgical repair are to avoid hypertension and to avoid elevations in intracranial pressure. The Valsalva maneuver should be avoided, because the sudden pressure changes at the end of the maneuver can produce a gradient that favors rupture of the lesion. Epidural analgesia and anesthesia can most effectively provide conditions to meet these goals. It may be relatively contraindicated for patients who already have marked increases in intracranial pressure, inasmuch as an unintentional dural puncture can lead to herniation of the cerebellum.⁴³⁻⁴⁵ There is also a theoretical risk of further increasing intracranial pressure from the volume of fluid placed in the epidural space. This pressure increase is minimal and transient in the normal parturient when the volume administered is kept relatively small and the rate of injection slow.

Other commonly used forms of analgesia may be employed as long as maternal respiratory depression is avoided. Cesarean delivery anesthesia is best provided by the continuous epidural technique. Spinal anesthesia may be used if intracranial hypertension does not exist. If general anesthesia is required, the steps outlined previously for preventing the hypertensive response to laryngoscopy and intubation will be necessary. More information about these neurologic complications is provided in Chapter 52.

Respiratory Disorders

Significant alterations occur in the pulmonary system during pregnancy, which primarily serve to meet the increased oxygen consumption by the growing fetus. When pregnancy is complicated by a respiratory tract disorder such as asthma, cystic fibrosis, or tobacco-related respiratory complications, obstetric and anesthetic management during the peripartum period may become challenging. To understand the implications of anesthesia superimposed on a pregnant woman with respiratory disease, the physician should be well acquainted with the physiologic alterations in the respiratory tract during pregnancy. These changes and the various respiratory disorders in pregnancy are reviewed in Chapter 45.

Asthma

Asthma is the most common respiratory problem encountered in women of childbearing age. The disease is characterized by bronchial constriction, bronchial secretions, and bronchial edema. Therapy commonly includes theophylline preparations, inhaled β -adrenoceptor agonists, anticholinergic agents, corticosteroids, and occasionally, cromolyn sodium. Magnesium sulfate has also been effective in alleviating acute symptoms.⁴⁶ The effect of pregnancy on the condition of the asthmatic has been controversial, but it does appear that with proper management and prompt attention to acute episodes, most patients fare well.⁴⁶⁻⁴⁸ Maintenance of the patient's medications and hydration are of major importance during labor and delivery.

Analgesia and anesthesia for labor and delivery of the asthmatic patient can alleviate anxiety and hyperventilation. Hyperventilation can precipitate an attack and lead to increased fluid losses and dehydration. Narcotic analgesia administered in a judicious fashion may be used, but narcotics are bronchoconstrictors and should be avoided if the patient is actively wheezing or in respiratory distress. Epidural analgesia with local anesthetics or opioids, or both, is extremely beneficial because pain can be relieved while respiratory depression is avoided.^{49,50} If the patient is severely asthmatic, it is essential to avoid a high and dense level of anesthesia because accessory muscles of respiration can be impaired. A high thoracic level can completely block sympathetic pathways, and the unopposed parasympathetic tone can lead to bronchoconstriction. Low spinal anesthesia or a pudendal block is a reasonable choice for vaginal delivery if epidural analgesia is not used.

Regional anesthesia is preferred because the insertion of an endotracheal tube at the light levels of anesthesia traditionally favored for obstetrics frequently results in bronchospasm.^{50,51} Even though pulmonary mechanics are reasonably well maintained under spinal, combined spinal-epidural, or epidural anesthesia to the fourth thoracic dermatome, the patient should receive an inhaled β -agonist before the procedure and bring her inhaler with her to the operating room because bronchospasm may occur.⁵⁰⁻⁵² Appropriate attention to hydration and maintenance of blood pressure are required, and supplemental oxygen is recommended.

General anesthesia for cesarean delivery in the asthmatic patient poses additional risk. Careful attention to detail is necessary to avoid life-threatening bronchospasm, and general anesthesia should be used only if regional anesthesia is contraindicated.^{49,50} Preoperative preparation should include adequate hydration, intravenous aminophylline, treatment with a β_2 -agonist inhaler, antacid therapy, and sufficient time for preoxygenation (≥ 3 minutes). A rapid-sequence induction may then be undertaken. The induction agent of choice is ketamine because it is a bronchodilator and does not release histamine.^{49,51} Propofol decreases the response to airway manipulation and may prove to be a reasonable alternative. Thiopental administered in the commonly used doses for cesarean delivery produces a plane of anesthesia that is too light to prevent bronchospasm. Larger doses are an alternative to ketamine and may be employed with the small risk that the newborn will be depressed from the anesthetic in the immediate post-delivery period.

The patient with active wheezing requiring a general anesthetic for cesarean delivery may require a slower induction. Anesthesia is induced intravenously, a muscle relaxant is administered, cricoid pressure is applied and maintained, and the patient is ventilated by mask with a volatile anesthetic agent to promote bronchodilation. When a deep plane of anesthesia is reached, the patient is intubated. This technique exposes the patient to a greater risk of regurgitation and aspiration of

gastric contents and should be employed only when there are no other reasonable options.^{49,51}

After anesthesia is induced and the patient has been intubated successfully, maintenance includes the administration of a volatile agent in a humidified gas mixture because all gases used (e.g., isoflurane, sevoflurane, desflurane) produce direct bronchial muscle relaxation.⁵³ If intraoperative wheezing occurs, a β_2 -agonist may be aerosolized through the endotracheal tube. Although the effect is synergistic with the halogenated agents, two potential problems must be considered. First, administration of some halogenated agents (primarily halothane, which is very infrequently used) in the presence of therapeutic or higher levels of aminophylline has been associated with serious ventricular arrhythmias and cardiac arrest.⁵⁴ Isoflurane, sevoflurane, or desflurane is a safer alternative. Second, the volatile agents tend to relax uterine musculature at concentrations that are effective as bronchodilators, and the possibility of enhanced uterine bleeding exists. This effect can usually be counteracted by the administration of oxytocin. The use of prostaglandins to control hemorrhage is not recommended because prostaglandin $F_{2\alpha}$ is a bronchoconstrictor. After the infant has been delivered, ventilation with bag and mask oxygen eliminates most of the volatile agent from the infant in a few minutes.

Muscle relaxation can be maintained with a nondepolarizing neuromuscular-blocking agent. Curare and atracurium are associated with histamine release in large doses, whereas vecuronium, rocuronium, and *cis*-atracurium are not. When a nondepolarizing agent is used, it usually must be reversed at the end of the procedure with an anticholinesterase drug such as neostigmine or edrophonium. This group of nondepolarizing drugs can produce bronchoconstriction and increased production of secretions. Consequently, a sufficient dose of an anticholinergic agent such as atropine or glycopyrrolate must be administered before use. The nonpregnant asthmatic patient is usually extubated in a deep plane of anesthesia to avoid the stimulus of the endotracheal tube, but the pregnant patient should be extubated while awake because of the risks of vomiting and aspiration. Intravenous lidocaine can prevent coughing and bronchoconstriction on emergence.^{49,51}

Postoperative care includes humidified oxygen, incentive spirometry, and the required pharmacologic agents. Epidural and intrathecal narcotics provide excellent postoperative analgesia with minimal sedation.

Cystic Fibrosis

The meticulous use of pulmonary toilet and aggressive antibiotic therapy has made it possible for many women with cystic fibrosis to survive well into their childbearing years.⁵⁵ The pulmonary complications of patients with cystic fibrosis provide significant anesthetic challenges. Thick, excessive mucus production results in obstruction of the small and medium-sized airways, with subsequent bronchitis and bronchiectasis. Pneumothorax, atelectasis, progressive hypoxemia, and cor pulmonale commonly occur with the disease.

Therapy consists of postural drainage and chest percussion (often on a daily basis), antibiotics for symptoms of infection, bronchodilators for wheezing, intermittent mucolytic therapy (*N*-acetylcysteine), vitamins, and pancreatic enzyme replacement. Preoperative evaluation should include pulmonary function studies, cardiac evaluation, and measurement of arterial blood gases. Successful completion of pregnancy with careful attention to medical management is well established.⁵⁵

Optimal analgesia during the first stage of labor is provided by continuous lumbar epidural or combined spinal-epidural anesthesia.^{49,51} Intrathecal opioids should be avoided because they have

occasionally been associated with severe respiratory depression, particularly if parenteral opioids have been administered.^{56,57} Management concerns are similar to those of the severe asthmatic patient. The state of hydration needs to be maintained because these patients often lose excessive amounts of fluid through sweating. Narcotics should be used in very small amounts because they suppress the cough reflex and produce respiratory depression. Nitrous oxide should probably be avoided because of the frequency of pneumothorax from ruptured bullae. Anesthesia for vaginal delivery may be provided with low spinal, combined-spinal, epidural, or pudendal nerve block.

Anesthesia for cesarean delivery carries with it the same management concerns as for the patient with severe asthma, and carefully titrated continuous epidural anesthesia is recommended. Although general anesthesia can be used safely for patients with cystic fibrosis, the risk of maternal hypoxemia during induction is greater than for asthmatic patients, and the possibility of pneumothorax exists during positive-pressure ventilation.^{49,51,58,59} Anticholinergics (i.e., drying agents) and narcotics are usually excluded from the regimen, and gases should be humidified. Patients with very advanced disease may require postoperative mechanical ventilation until they regain their full operative capabilities.

Morbid Obesity

Morbid obesity is defined as an accumulation of adipose tissue that causes the body mass index (BMI) to increase by 30% or more, as shown by the following equation:

$$\text{BMI} = \frac{\text{weight (kg)}}{[\text{height (m)}]^2}$$

In the equation, weight is in kilograms and height is in meters.

Morbid obesity is perhaps the most common nutritional disorder seen in pregnancy, and morbidly obese parturients have more pregnancy complication than normal-BMI pregnant patients.⁶⁰ Substantial change takes place over time in the respiratory system. A restrictive lung disease pattern develops, and pulmonary function testing reveals a decrease in expiratory reserve volume, vital capacity, inspiratory capacity, and total lung capacity. Compliance decreases, and the work of breathing increases. There is also a ventilation-perfusion imbalance, leading to hypoxemia, particularly in the supine or Trendelenburg position.

Pregnancy imposes changes in lung volumes similar to those resulting from obesity.^{60,61} Fortunately, these effects are not additive. An important study evaluating 12 obese pregnant women revealed that the usual pulmonary changes of pregnancy occurred, but they were not accentuated by the obesity. Hypoxemia existed but was not worsened by pregnancy.⁶²

Labor should be conducted in the sitting or semirecumbent position with left uterine displacement. Supplemental oxygen administration and pulse oximeter monitoring are advised. Epidural or combined spinal-epidural analgesia is recommended but may be technically difficult or impossible to perform because of obscured landmarks, difficult positioning, and excessive layers of adipose tissue.⁶¹ Other forms of analgesia, including intrathecal narcotics, intravenous narcotics, and inhalation of nitrous oxide plus oxygen, are all suitable. The anesthetic for vaginal delivery may be any of the commonly used forms; the patient should remain in a semi-sitting position, if possible, to prevent small airway closure.

Cesarean delivery anesthesia may be provided by the spinal, epidural, or combined spinal-epidural route.⁶³ Technical difficulties can be

encountered, and the dosage of drug needs to be reduced because spread in the subarachnoid and epidural spaces is enhanced with morbid obesity.^{61,63} Care must be taken to avoid a significant motor block, which can compromise ventilation and result in hypoxemia. The Trendelenburg position should be avoided because it shifts the weight of the abdominal viscera and the panniculus toward the chest and diaphragm, further compromising respiration.

Technically, general anesthesia poses several challenges.^{15,19,20} First, the airway must be secured. Endotracheal intubation can be extremely difficult as a result of excessive tissue and edema. Exceedingly large breasts can interfere with the insertion of a conventional laryngoscope. A careful assessment of the airway must be made, and if standard intubation appears to be extremely difficult, a fiberoptic intubation is recommended with the patient awake. If a rapid-sequence induction is attempted and the airway cannot be conventionally secured, an alternative means, such as a laryngeal mask airway, Combitube, or transtracheal jet ventilation, must be at hand because hypoxia and acidosis can develop at an extremely rapid rate.

After the airway is secured, mechanical ventilation is required, and the pressures generated need to be high to move the large body mass. Large tidal volumes help to prevent airway closure. Extubation should be performed only when the patient is fully awake and has regained her full strength.^{15,19,20} Postoperative analgesia, preferably by the epidural route, is extremely helpful in allowing for deep breathing exercises to avoid atelectasis and pneumonia.

Cardiac Disease

The pregnant patient with heart disease represents a unique challenge for the anesthesiologist.^{64,65} Determination of the appropriate analgesic and anesthetic modalities requires a thorough understanding of the parturient's pathophysiology, pharmacologic therapy, and how these factors interact with anesthetic care. Chapter 39 offers an in-depth discussion of the various cardiac disorders in pregnancy.

Over the past 25 years, greater awareness of the physiologic burden that pregnancy places on an already compromised cardiovascular system in this subset of pregnant women has led to better counseling before conception and to major advances in treatment. Formerly, rheumatic heart disease was the most common cardiac disorder in pregnancy, with mitral stenosis the single most prevalent resulting lesion. The incidence of rheumatic heart disease has decreased dramatically in the United States and Western Europe, but in many other regions of the world, it remains an important cause of maternal morbidity and mortality.⁶⁴⁻⁶⁶ Many more women with congenital heart defects are reaching childbearing age as a consequence of surgical correction. As more women delay childbearing to later reproductive years, ischemic cardiac disease may be expected to become increasingly prevalent.⁶⁴⁻⁶⁶

General Considerations

Pregnancy normally results in dramatic changes in the cardiovascular system, and these changes and the cardiac disorders in pregnancy are reviewed in Chapters 7 and 39. Four principal changes that present unique problems to the patient with cardiac disease have been well delineated and have special anesthetic implications.⁶⁷

First, there is a 50% increase in intravascular volume that usually peaks by the early-to-middle third trimester. This relative volume overload may be poorly tolerated in women whose cardiac output is limited by myocardial dysfunction from ischemic, intrinsic, or valvular lesions.

Second, there is a progressive decrease in SVR throughout pregnancy, so that mean arterial pressure is preserved at normal values despite a 30% to 40% increase in cardiac output. This can be important for patients at risk for right-to-left shunting and for patients with some types of valvular disease (e.g., aortic stenosis).

Third, the compromised cardiovascular system is further stressed by the marked fluctuations in cardiac output observed during labor. Pain and apprehension can precipitate an increase in cardiac output to as much as 45% to 50% above the levels seen in the late second stage of labor. Each uterine contraction serves as an autotransfusion to the central blood volume, resulting in an increase in cardiac output of 10% to 25%.^{64,65} The Valsalva maneuver results in wide swings in venous and arterial pressures, which have been associated with acute cardiac decompensation. The increases in cardiac output reach a maximum of 80% higher than antepartum levels immediately after delivery because of relief of inferior vena cava obstruction and a final autotransfusion of approximately 500 mL from uterine contraction.

The fourth consideration is the hypercoagulability associated with pregnancy and the possible need for appropriate anticoagulation, especially in patients at increased risk for arterial thrombosis and embolization (i.e., prosthetic heart valve or chronic atrial fibrillation). Therapeutic anticoagulation affects the options for anesthetic management, as well as the placement and location of invasive monitors, and increases the risk of postpartum hemorrhage.

Optimal anesthetic management requires a thorough assessment of the anatomic and functional capacity of the diseased heart, along with an analysis of how the described major physiologic changes are likely to affect the specific limitations imposed by the intrinsic disease. To determine the most appropriate anesthetic regimen, the anesthesiologist must consider the following:

- Patient's tolerance to pain during labor or surgery
- Impact of uterine contraction-induced autotransfusion
- Postpartum changes induced by relief of vena caval obstruction
- Potential for postpartum hemorrhage
- Use of uterine oxytocic agents

The most basic principles of obstetric anesthesia management must always apply^{64,65}:

- Provisions for maintenance of uteroplacental perfusion by avoidance of aortocaval compression
- Minimizing sympathetic blockade coupled with intravascular volume maintenance
- Standard-of-care monitoring of parturient and fetus
- Provision for aspiration prophylaxis

Analgesia during the first stage of labor is focused on reducing the pain-related rises in catecholamine levels and avoiding aortocaval compression. Intravenous fluid management should be carefully monitored to avoid a lack of or an excess of fluids. Arterial, central venous, and pulmonary artery monitoring may be required to manage the patient optimally. Although such lines are generally reserved for symptomatic women, patients who have critical aortic stenosis, coarctation of the aorta, aortic aneurysm, right-to-left shunts, or primary pulmonary hypertension may benefit from invasive monitoring, even if they have minimal symptoms. Chapters 39 and 57 provide more detailed information.

Appropriate analgesia should be supplied. All of the available modalities have application for some patients. Continuous lumbar epidural analgesia with local anesthetics or narcotics, or both, is fre-

quently optimal. Limited sympathetic blockade can prove helpful for patients with mitral valve lesions because of the effects on preload and afterload. For a patient whose condition is so compromised that even the modest changes induced by segmental epidural analgesia are worrisome, the use of intrathecal narcotic analgesia by single injection or continuous catheter may be beneficial because all of the hemodynamic alterations of sympathetic blockade are avoided.⁶⁴⁻⁶⁶

After the patient with significant cardiac disease has entered the second stage of labor, it is prudent for her to avoid pushing. The lithotomy position may need to be avoided for patients with lesions such as mitral stenosis, inasmuch as this position results in an acute increase in central blood volume.

For second-stage management, analgesia for uterine contractions and anesthesia of the perineum are the objectives. Uterine contractions spontaneously bring the infant's head to a deliverable position, and delivery can then be assisted by the application of the vacuum extractor or forceps. A regional technique is optimal. Epidural analgesia or anesthesia may be continued. Attention must be paid to extension of the sympathetic blockade. If an epidural block is not used, a low spinal anesthetic may be appropriate. Pudendal nerve block, although it does not provide as complete an analgesia as an epidural, can be employed satisfactorily as an adjunct to regional anesthesia or can be used alone.⁶⁴⁻⁶⁶

It is thought that cesarean delivery should be reserved for obstetric indications only and that the presence of heart disease should not influence that decision. The overall stresses of labor and vaginal delivery, as measured by alterations in cardiac output, are approximately the same as with cesarean delivery. Some circumstances, however, may lead to the decision to perform an elective cesarean delivery. The choice of anesthesia depends on the lesion and its severity. Epidural anesthesia provides the least amount of alteration in hemodynamics during cesarean delivery, although general anesthesia can be equally as safe when the abrupt changes associated with laryngoscopy and intubation, as well as suction and extubation, are blunted by the appropriate choice of pharmacologic agents and anesthetic technique.

Anesthesia for Cardiac Surgery during Pregnancy

Cardiac surgery is avoided during pregnancy because of potential compromise to the fetus. The developing fetus may experience teratogenic effects from drugs administered during the course of anesthesia. This has been demonstrated in animals with a multitude of anesthetic adjuvants but has never been clearly documented in humans.⁶⁸⁻⁷⁰ Teratogenic changes can be induced by hypoxia during the procedure or by decreased uteroplacental perfusion. Premature labor is often associated with surgery during pregnancy, particularly abdominal procedures. If surgery is indicated during the course of pregnancy, it is usually performed during the second trimester whenever possible. This strategy avoids the period of organogenesis, and premature labor is said to be less likely. Many centers use tocolytic therapy as part of their routine for the surgical patient who is pregnant. Although this can be useful for patients without cardiovascular disease, most of these drugs have potent cardiovascular side effects and are less desirable for the patient with heart disease.^{64-66,70}

The pregnant patient with heart disease is often managed with medical therapy, which can include long periods of bed rest if necessary. If a surgical lesion is present, every attempt is made to delay the definitive procedure until after delivery of the fetus. Some patients decompensate so severely from the cardiovascular stress imposed by pregnancy that their chance of survival is very small unless surgical

correction is attempted. These patients usually suffer from rheumatic valvular disease, most often mitral stenosis.

The first cardiac operations performed during pregnancy in 1952 were closed mitral commissurotomies for severe congestive heart failure caused by mitral stenosis. A review of 514 cases by Ueland revealed a maternal mortality rate of 1.75% and a fetal loss rate of 8.6%.⁷¹ These results were quite favorable compared with a maternal mortality rate of 4.2% to 18.7% among pregnant patients with New York Heart Association (NYHA) class III and IV cardiac disease who were managed with medical therapy; the fetal loss rate for that group of patients was approximately 50%. The extremely good surgical survival figures in the cardiac surgery group probably reflect the fact that these patients are young with relatively healthy hearts that were overburdened by the circulatory changes of pregnancy and that the operations did not involve cardiopulmonary bypass. The use of cardiopulmonary bypass for open-heart procedures in the pregnant patient soon followed. The risks for the mother and fetus increase with this more complex procedure. A multi-institutional study of cardiopulmonary bypass in this subset of patients by Zitnik and colleagues⁷² revealed a 5% maternal mortality rate and a fetal loss rate of 33%. Current data indicate a maternal mortality rate of 0% to 2.9% and a fetal loss rate of 20%.⁷³ The high rate of fetal loss has been attributed to several factors that may affect fetal oxygen delivery during cardiopulmonary bypass, including nonpulsatile perfusion, inadequate perfusion pressure, embolic events to the uteroplacental circulation, disturbance of uteroplacental blood flow by cannulas, release of catecholamines and renin, and hypothermia.^{74,75} When cardiopulmonary bypass becomes mandatory, the shortest possible periods of mildly hypothermic or normothermic cardiopulmonary bypass are recommended, and a strategy of high-flow and high-pressure perfusion should be followed.⁷⁶ Some of these potential hazards can be avoided by the use of fetal monitoring during the operation.

Several reports of the benefit of fetal monitoring during cardiopulmonary bypass have appeared in the literature.⁷⁷⁻⁷⁹ In one instance, a fetal heart rate of 60 was restored to 100 by an increase in pump flow from 3100 to 3600 mL/min.⁷⁷ In addition to identifying potentially threatening events, all physicians have reported a sustained fetal bradycardia between 80 and 100 beats/min during hypothermic cardiopulmonary bypass, which resolves with the restoration of maternal temperature and normal circulation. One meta-analysis revealed that the fetal mortality rate was reduced to 0% when normothermic cardiopulmonary bypass was used.⁷³

Based on the available knowledge of the physiologic changes of pregnancy, the pharmacology of drugs employed during cardiopulmonary bypass, the physiology of extracorporeal circulation, and experiences reported, the following recommendations for cardiopulmonary bypass during pregnancy can be made. Although it is desirable to avoid surgery until after pregnancy, no pregnant patient should be denied a definitive operation because of gestation.^{64-66,70} Whenever possible, the period of organogenesis should be avoided and the second trimester favored. If cardiopulmonary bypass is required after 28 weeks' gestation, it has been suggested that cesarean delivery immediately before the cardiac surgery is a reasonable and safe procedure.^{64-66,70,74} Hemostasis must be meticulous in such cases, because full anticoagulation is necessary.^{80,81}

Every effort to ensure adequate fetal oxygenation and perfusion during the procedure should be exercised. Maternal inspired oxygen concentration should be maintained as high as possible, and arterial blood gases should be checked frequently. Maternal ventilation should be adjusted to avoid respiratory alkalosis, because this causes a shift in the oxyhemoglobin dissociation curve to the left, potentially decreas-

ing oxygen transport to the fetus. Aortocaval compression must be minimized by using a wedge to provide left uterine displacement if the patient is at 20 weeks' gestation or more. Calculation of pump flows should include a 30% to 50% increase above normal to compensate for the increase in cardiac output that occurs with pregnancy. Pomini and coworkers⁷³ recommend maintaining flows at 2.7 L/m²/min or greater. Perfusion pressures of 60 mm Hg or greater appear optimal for maintaining uteroplacental perfusion. Perfusion times should be kept to a minimum, and normothermic bypass should be used whenever possible. Electrolyte balance should be maintained, and the impact of vasopressors on the uteroplacental circulation should be considered before they are instituted. Electronic fetal monitoring should be used, and a member of the health care team experienced in its interpretation should be available. Monitoring of uterine activity can be desirable, because increased uterine activity has been associated with cardiopulmonary bypass.^{64-66,70}

Valvular Heart Disease

Rheumatic fever continues to be the predominant cause of valvular heart disease in pregnancy. Acquired or congenital valvular heart disease in a pregnant woman poses a clinical challenge to physicians involved in her antepartum and peripartum care.^{64-66,70} Complications during pregnancy include univentricular or biventricular failure, atrial dysrhythmias, systemic or pulmonary embolism, and infective endocarditis, with an overall incidence of complications estimated at 15% among all patients with valvular disease. In general, regurgitant lesions are well tolerated during pregnancy because the increased plasma volume and lowered SVR result in increased cardiac output. In contrast, stenotic valvular disease is poorly tolerated with advancing pregnancy because of the inability to increase cardiac output sufficiently to accommodate the augmented plasma volume; this situation leads to pulmonary venous congestion and possibly to frank pulmonary edema.⁶⁴

Mitral Stenosis

Mitral stenosis can occur as an isolated lesion or in conjunction with right-sided or aortic valvular disease. It accounts for nearly 90% of rheumatic heart disease in pregnancy, with 25% of patients first experiencing symptoms during pregnancy.⁶⁴ The principal pathophysiologic derangement is a decrease in mitral valve orifice, resulting in obstruction to left ventricular filling. This hemodynamic aberration leads to a relatively fixed cardiac output. Although the left atrium initially may overcome this obstruction, with progression of disease, left atrial volume and pressure ultimately increase and lead to a progressive and chronic elevation in pulmonary capillary wedge pressure and pulmonary venous pressure; pulmonary hypertension and right ventricular hypertrophy and failure can ensue.^{82,83} An anatomically moderate lesion can become functionally severe with the marked increase in cardiac output that accompanies normal pregnancy, labor, and delivery.

Anesthetic management is oriented toward the avoidance of tachycardia, because the time required for left ventricular diastolic filling is prolonged. Patients who are asymptomatic at term usually require increased vigilance but should not require invasive monitoring. Patients with marked symptoms are at significant risk in the peripartum period and should receive arterial and pulmonary artery catheter monitoring continuing through a minimum of 24 hours after delivery.^{64-66,70} An increase in central circulating blood volume can occur suddenly in the immediate postpartum period, and tolerance of this intravascular load may be poor, especially for patients with a fixed cardiac output.⁶⁴⁻⁶⁶

Vaginal delivery is best accomplished with segmental lumbar epidural analgesia to minimize hemodynamic changes. The combined spinal-epidural analgesia is an attractive alternative to the conventional epidural block.^{64,84,85} A sudden decrease in SVR may be poorly tolerated after the development of reflex tachycardia. Although other analgesic modalities may be employed, segmental epidural analgesia allows for careful titration to the desired result while minimizing undesirable changes. The addition of opioids, such as fentanyl or sufentanil, to the dilute local anesthetic mixture enhances the quality of analgesia but does not add to the sympathetic blockade. Opioids alone may be administered by the epidural or intrathecal route for the critically ill patient. Adequate segmental and perineal anesthesia reduces catecholamine-induced increases in heart rate and the urge to push, allowing fetal descent to be accomplished by uterine contractions and avoiding the deleterious effects of the Valsalva maneuver during the second stage of labor. When epidural anesthesia has not been used, a low spinal anesthetic may be administered to allow for a controlled second stage and delivery.

Caudal anesthesia is another reasonable option. Pudendal nerve block can provide adequate, although not ideal, pain relief for some patients.

Cesarean section should be reserved for obstetric indications. Anesthetic options for cesarean delivery must take into account the additional potential hazards of marked fluid shifts resulting from anesthetic technique, operative blood loss, and the mobilization of fluid in the postpartum period. Regional or general anesthesia may be used. Epidural anesthesia is preferred over spinal anesthesia because the former results in slower onset of blockade and therefore more controllable hemodynamic alterations. Prophylactic ephedrine and arbitrary intravascular volume loading are best avoided; instead, a careful titration of anesthetic level allows judicious and appropriate intravenous fluid administration, which should be guided by hemodynamic monitoring in the symptomatic patient. These patients may be prone to hypotension with epidural anesthesia because of a combination of venous pooling and prior β -adrenergic blockade and diuretic therapy.^{70,86} The usual vasopressor choice of ephedrine should be avoided, because it can result in tachycardia. Instead, judicious use of metaraminol or low-dose (20 to 40 μ g) phenylephrine assists in restoration of maternal blood pressure with little or no unwanted effect on uteroplacental perfusion.⁶⁴

Some patients with mitral stenosis may require general anesthesia. General anesthesia also can provide a very stable hemodynamic course if the sympathetic stimulation associated with laryngoscopy and intubation and with suction and extubation is minimized.⁸⁷ This can be accomplished with anesthetic agents or β -adrenergic blockade, or both. Induction of general anesthesia should be accomplished carefully, without drugs that commonly produce tachycardia. Depending on the severity of the disease, the need to blunt the hemodynamic response to endotracheal intubation may necessitate the use of a high-dose, narcotic-based technique. This strategy also avoids myocardial depression and the decreases in SVR that can occur with commonly employed short-acting barbiturates. Anesthesia is maintained with narcotics, muscle relaxants, nitrous oxide, and oxygen. Emergence must be controlled carefully to ensure return of protective reflexes and avoidance of tachycardia.

Aortic Stenosis

Congenital aortic defects are the usual causes of aortic stenosis in reproductive-age women. Rheumatic disease-related aortic stenosis rarely complicates pregnancy, primarily because the natural history of this lesion resulting from rheumatic heart disease typically requires 3 to 4

decades to achieve severity adequate to produce symptoms.^{88,89} Women with congenitally bicuspid aortic valves and patients with a history of bacterial endocarditis, however, can present in pregnancy with severe aortic stenosis. Unlike mitral stenosis, with aortic stenosis, symptoms of congestive heart failure, angina, and syncope develop relatively late in the course of the disease. The pathophysiology of severe aortic stenosis entails narrowing of the valve orifice to less than 1 cm², associated with a transvalvular gradient of 50 mm Hg, which results in significant increases in afterload to left ventricular ejection. The left ventricle appropriately and concentrically hypertrophies and becomes markedly less compliant, although contractility is usually well preserved. The transvalvular gradient increases progressively throughout pregnancy as a result of increasing blood volume and decreasing SVR.^{64,65}

Anesthetic management encompasses the following goals:

- Avoiding tachycardia and bradycardia
- Maintaining adequate preload so the left ventricle may generate an adequate cardiac output across the stenotic valve
- Maintaining hemodynamic parameters within a narrow therapeutic window

Patients with transvalvular gradients greater than 50 mm Hg and patients with symptomatic aortic stenosis warrant invasive monitoring with arterial and pulmonary artery catheters in the peripartum period.⁶⁴

Provision of labor analgesia with segmental epidural or combined spinal-epidural anesthesia remains a controversial issue because these patients may not be able to tolerate the decreases in preload and afterload due to sympathetic blockade.^{88,89} Easterling and associates⁹⁰ described a series of four patients with moderate to severe aortic stenosis who were managed successfully with epidural anesthesia without untoward sequelae; adequate time was allowed to titrate the level of block carefully and initiate appropriate compensatory actions to correct hemodynamic alterations associated with the anesthetic agent. Kuczkowski and Chow⁸⁹ described a case of a parturient with severe aortic stenosis who received uneventful combined spinal-epidural analgesia with levobupivacaine and fentanyl for the first stage of labor, but in the second stage of labor, cesarean section under general anesthesia was required for fetal indications (i.e., fetal distress). The investigators concluded that anesthetic management of a parturient with aortic stenosis must be based on individual assessment of cardiac function and reserve and anticipation of the impact of selected anesthetic technique (regional or general for vaginal or abdominal delivery) on cardiac performance.⁸⁹ Subarachnoid or epidural opioids, whether alone or in combination with an epidural segmental anesthetic, are other appropriate choices. Spinal opioids have no cardiovascular effects. In particular, myocardial contractility is unaltered, preload is preserved, and, most importantly, SVR is not diminished by this technique. Local anesthetics and opioids are believed to act synergistically, allowing for a decrease in concentration of both drugs when they are used together. Effective analgesia can prevent the tachycardia associated with labor pain.

For cesarean delivery, judiciously titrated epidural anesthesia or general endotracheal anesthesia may be used. General anesthesia can be accomplished with the same caution that applies for parturients with mitral stenosis; myocardial depression associated with halogenated volatile anesthetics should be avoided.^{64,65,91}

Mitral Insufficiency

Mitral valve insufficiency and regurgitation is the second most prevalent valvular lesion in pregnancy. Chronic left ventricular volume

overload and work are usually well tolerated, with symptoms developing relatively late in life after childbearing age; most patients with mitral regurgitation tolerate pregnancy well.^{64-66,70} Complications include an increased risk of atrial fibrillation during pregnancy, bacterial endocarditis requiring antibiotic prophylaxis, systemic embolization, and pulmonary congestion during pregnancy.⁸⁷

Congenital mitral valve prolapse is much more common during pregnancy than mitral regurgitation, and it can be present in 10% to 17% of pregnancies. It is a well-tolerated and generally benign form of mitral regurgitation, and therapeutic interventions are rarely necessary.⁶⁴⁻⁶⁶

The pathophysiology of regurgitation through an incompetent mitral valve results in chronic volume overload of the left ventricle and dilatation. If left ventricular compromise is sufficiently long-standing and severe, the increase in plasma volume with pregnancy progression can result in pulmonary venous congestion. In contrast, the decreasing SVR associated with pregnancy may improve forward flow across the aortic valve at the expense of regurgitant flow. Increases in SVR, which occur with labor pain, uterine contractions, or surgical stimulation, can result in an increase in the proportion of regurgitant blood flow, perhaps leading to acute left ventricular failure.⁹²

Anesthetic management of labor and delivery can be provided safely with any of the available techniques, including segmental lumbar epidural anesthesia or combined spinal-epidural anesthesia.^{64,85} Adequate analgesia and anesthesia minimize the peripheral vasoconstriction, attenuating the increase in left ventricular afterload associated with labor pain and thereby augmenting the forward flow of blood. Sympathetic blockade also decreases SVR and is beneficial in this regard; the caveat is that venous capacitance will increase, and the physician must be prepared to augment preload cautiously with intravenous fluid infusion to maintain left ventricular filling volume.

Asymptomatic patients at term are unlikely to require invasive monitoring. Continuous electrocardiographic (ECG) monitoring is a reasonable addition to basic standards of peripartum monitoring. In symptomatic patients, invasive monitoring with arterial and pulmonary arterial catheter should be used.

Aortic Insufficiency

Aortic insufficiency can be congenital or acquired. If congenital, it is commonly associated with other lesions; if acquired, it may result from rheumatic heart disease or endocarditis in association with aortic root dissection. Symptoms after rheumatic fever usually develop during the fourth or fifth decade of life, and most women in whom this is the dominant lesion have uneventful pregnancies.^{64-66,70}

The basic pathophysiology is chronic volume overloading of the left ventricle resulting in hypertrophy and dilation associated with increased compliance. Because of hypertrophy, myocardial oxygen requirements are higher than normal, but perfusion pressure (and oxygen supply) can be decreased by a reduction in diastolic pressure and an increased left ventricular end-diastolic pressure.⁶⁴⁻⁶⁶

Anesthetic considerations focus on the following goals:

- Minimizing pain and therefore catecholamine-induced increases in SVR
- Avoiding bradycardia, which increases time for regurgitant flow
- Avoiding myocardial depressants, which can exacerbate failure

Because the anesthetic concerns are similar to those for patients with mitral regurgitation, epidural anesthesia for labor and delivery is desirable to prevent increases in peripheral vasoconstriction. Epidural

anesthesia is also appropriate as a surgical anesthetic agent, as is general anesthesia with judicious avoidance of direct myocardial depressants. Invasive monitoring is a requirement in any patient with symptoms of congestive heart failure.^{64-66,70}

The parturient who has undergone mitral or aortic valve replacement faces several potential problems, such as thromboembolism, valvular outflow obstruction, endocarditis, and hemolysis.^{93,94} These patients have received anticoagulation, usually with coumarin derivatives, to prevent the thrombotic problems mentioned. Heparin is usually substituted for coumarin anticoagulants during pregnancy to avoid potential congenital anomalies.⁶⁴ Full anticoagulation is a direct contraindication to the use of regional anesthesia because of the risk of causing epidural or spinal hematoma. The use of low-molecular-weight heparin (e.g., enoxaparin) has been associated with spinal epidural hematoma when regional anesthesia was used or attempted in Europe and in the United States,^{95,96} probably because of its longer half-life than unfractionated heparin. It is therefore recommended that regional anesthesia not be administered unless the drug has been discontinued for at least 12 to 24 hours, depending on the dosage. One alternative is to continue heparinization throughout labor and delivery and use systemic analgesia for labor and general anesthesia for delivery. Another option with unfractionated heparin is to discontinue heparin therapy just before labor and delivery, normalize the coagulation results, use regional anesthesia, and restart heparin 12 hours later. This may not be practical in an obstetric setting. The choice of strategies depends on the severity of the patient's hemodynamic derangement and the optimal analgesic management.^{64,65}

Congenital Heart Disease

Congenital heart disease is becoming the most common cardiac problem encountered in pregnant patients. Patients are increasingly likely to survive to childbearing age with the advent of palliative surgery or total correction of their defects. Many of these patients can be expected to have an uneventful pregnancy and delivery.^{64,65}

Left-to-Right Shunts

VENTRICULAR SEPTAL DEFECT

Ventricular septal defect (VSD) occurs in 7% of adults with congenital heart disease. Patients with uncorrected lesions in the absence of pulmonary hypertension fare well during pregnancy. In the small percentage of patients with large VSDs and coexisting pulmonary hypertension, maternal mortality rates range from 7% to 40%. Severe right ventricular failure with shunt reversal (i.e., Eisenmenger syndrome) is the major ensuing complication. During pregnancy, elevation of plasma volume, cardiac output, and heart rate can increase left-to-right shunt and can further worsen the degree of pulmonary hypertension.^{64,65,70}

The major goals in peripartum management include awareness that marked increases in peripheral vascular resistance and heart rate may be poorly tolerated, with ventricular failure a distinct possibility. Conversely, acute increases in pulmonary vascular resistance (PVR) and right ventricular compromise can lead to shunt reversal and hypoxia.

Optimal anesthesia for labor and vaginal delivery is achieved with segmental epidural or combined spinal-epidural anesthesia consisting of local anesthetics, opioids, or their combination to permit control of painful stimuli, minimizing changes in heart rate and SVR. Anesthesia for cesarean delivery can be accomplished with slow titration of an epidural or combined spinal-epidural anesthetic agent to allow time for correction of pressure changes or with a general anesthetic agent that combines opioid and inhalation technique to depress the adre-

nergic response to endotracheal intubation and minimize myocardial depression.^{64,65}

ATRIAL SEPTAL DEFECT

Atrial septal defect is one of the most common congenital cardiac lesions in women of childbearing age, and pregnancy is generally well tolerated even when pulmonary blood flow is increased. However, the risk of left ventricular failure is increased during pregnancy. Increases in atrial volume result in biatrial enlargement, and supraventricular dysrhythmias are likely.

Pregnancy-associated increases in plasma volume and cardiac output accentuate the left-to-right shunt, right ventricular volume work, and pulmonary blood flow, with the possible development of pulmonary hypertension and left and right ventricular failure. Peripartum management centers on avoiding vascular resistance changes that can increase the degree of shunt. Increases in SVR or decreases in PVR may not be well tolerated.^{64,65,87}

Although all of the common methods of providing labor analgesia are useful, lumbar epidural analgesia for labor, vaginal delivery, or cesarean delivery attenuates the hazards of increased SVR. General anesthesia for cesarean delivery is also well tolerated, provided that increases in SVR are avoided and sinus rhythm is maintained.

PATENT DUCTUS ARTERIOSUS

Patent ductus arteriosus (PDA) accounts for 15% of all cases of congenital heart disease, and most patients with a large PDA (>1 cm) receive early surgical intervention. Patients with a small PDA typically have normal pregnancies, but for those pregnant women with superimposed pulmonary hypertension, the maternal mortality rate can reach 5% to 6% because of ventricular failure. The progressive decrease in SVR development throughout pregnancy can be associated with shunt reversal and peripheral cyanosis.^{64,87}

Anesthetic considerations include avoidance of increases in SVR and hypervolemia. Conversely, acute decreases in SVR may result in reversal of shunt in patients with preexisting pulmonary hypertension and right ventricular compromise. All modalities may be used, depending on the severity of the disease. Continuous lumbar epidural analgesia for labor and delivery diminishes the increase in SVR associated with pain. Epidural or general anesthesia is appropriate for cesarean delivery if increases in SVR associated with endotracheal intubation and surgical stimulation are addressed adequately.

Right-to-Left Shunts

Eisenmenger syndrome consists of pulmonary hypertension, a right-to-left intracardiac shunt resulting from pulmonary hypertension superimposed on a previously left-to-right shunt, and arterial hypoxemia.^{97,98} Pregnancy is not well tolerated by patients with this condition. The maternal mortality rate is estimated at 30% to 50%. This entity is responsible for approximately 50% of the maternal mortality rate among parturients with congenital heart disease.⁶⁴

Anesthetic considerations center on avoidance of any decrease in SVR and therefore on avoidance of hypotension or myocardial depression. Hypotension from any cause, including conduction block or hemorrhage, can progress to insufficient right ventricular pressures to perfuse the hypertensive pulmonary arterial bed and can result in sudden death.

Analgesia for vaginal delivery can be accomplished with systemic narcotics, intrathecal narcotics, or cautious application of a segmental epidural if SVR is maintained. During the first stage of labor, epidural or intrathecal opioid administration can be a useful adjunct, and its sole administration has been recommended as the safest approach.⁶⁴⁻⁶⁶

If an epidural block is employed, epinephrine should be omitted from the test dose because peripheral β -adrenergic effects can decrease SVR.

For second-stage analgesia and anesthesia, a caudal epidural block may be preferable to the lumbar route because dense perineal analgesia can be provided without extensive sympathetic blockade. Cesarean delivery can be safely accomplished with the use of general anesthesia, although regional anesthesia for elective cesarean delivery has been reported.⁹⁹⁻¹⁰²

Regardless of the anesthetic technique employed, the postpartum period is probably the most likely time for life-threatening complications of hypoxemia, cardiac dysrhythmias, and thromboembolic events to occur; most maternal deaths occur in the first postpartum week.^{64-66,102,103} Martin and colleagues¹⁰² conducted an extensive literature search that identified 57 articles describing 103 anesthetics administered to patients with Eisenmenger syndrome.¹⁰² The overall perioperative mortality rate was 14%; patients receiving regional anesthesia had a mortality rate of 5%, whereas those receiving general anesthesia had a mortality rate of 18%. This trend favored the use of regional anesthesia but was not statistically significant. A better predictor of outcome was the nature of the surgery and presumably the surgical disease. Patients requiring major surgery had mortality rate of 24%, whereas those requiring minor surgery had mortality rate of 5%. Patients in labor receiving regional anesthesia had a mortality rate of 24%, and most of these deaths occurred several hours after delivery.¹⁰² The study authors concluded that most deaths probably occurred as a result of the surgical procedure and disease, not anesthesia.¹⁰²

The use of invasive monitoring is highly recommended in the management of these patients in the peripartum period. Pulmonary artery catheters and serial arterial blood gas determinations allow early detection of changes in cardiac output, pulmonary artery pressures, and shunt fraction. Serial measurements of cardiac output and especially of SVR are useful in this regard. The technical difficulties in passage of a pulmonary artery catheter and obtaining wedge pressures are well documented, and a central venous catheter may have to suffice.¹⁰⁴

TETRALOGY OF FALLOT

Tetralogy of Fallot comprises 15% of all congenital heart disease and is the most common etiologic factor in right-to-left shunt in women of childbearing age. Improvements in early diagnosis and treatment of patients with tetralogy of Fallot have led to an increase in the number of women who survive to reproductive age.^{64-66,106} Particularly poor prognostic signs include a history of syncope, polycythemia (hematocrit <60), decreased arterial oxygen saturation (<80%), right ventricular hypertension, and congestive heart failure.^{64,105} Increased right-to-left shunt can accompany pregnancy-induced decreases in SVR. The stress of labor can increase PVR and increase the degree of shunt. Most complications occur in the postpartum period when SVR is lowest, exacerbating the right-to-left shunting of blood and worsening the degree of arterial hypoxemia.¹⁰⁶

Anesthetic considerations must focus on minimizing the hemodynamic changes that would exacerbate the degree of shunt. Strict avoidance of decreased SVR, decreased venous return, and myocardial depression are essential. Analgesia for labor and vaginal delivery in these patients is most safely provided by systemic medication, inhalational nitrous oxide analgesia, or pudendal block. Intrathecal opioids can prove optimal in some circumstances. Regional anesthetic techniques should be used with extreme caution because the decrease in SVR can result in increased shunt. Historically, general anesthesia has been regarded as the safer (than regional) option for abdominal deliv-

ery in pregnant women with uncorrected tetralogy of Fallot.¹⁰⁵ However, in many cases of tetralogy of Fallot, corrective heart surgery results in nearly complete or complete repair and nearly normal or normal cardiovascular function. If the extent of surgical repair (i.e., correction) cannot be fully established in the peripartum period, the obstetric and anesthetic management of these parturient can become challenging and complex. Anesthesia for cesarean delivery should be provided by general anesthesia in patients with uncorrected lesions. Invasive monitoring with arterial and pulmonary artery catheters to evaluate cardiac filling pressures and SVR is warranted in patients with uncorrected tetralogy or only palliative correction.

PRIMARY PULMONARY HYPERTENSION

Primary pulmonary hypertension predominantly affects women of childbearing age and is associated with a maternal mortality rate greater than 50%. Most deaths occur during labor and the puerperium.^{64-66,70,87,106,107} Signs and symptoms depend on severity of the disease and are caused by a fixed low cardiac output, the degree of pulmonary hypertension, and the degree of right ventricular compromise. Pulmonary hypertension is a major component of Eisenmenger syndrome.^{97,98}

Anesthetic considerations focus on the following goals:

- Evaluating the severity of the disease and its responsiveness to therapy
- Maintaining hemodynamic stability
- Administering the appropriate analgesia and anesthesia for labor and delivery

In selecting an analgesic or anesthetic regimen, the physician must consider primarily the prevention of increases in PVR from under-ventilation, pharmacologic agents, pulmonary hyperinflation, and stress. Decreases in right ventricular volume from intravascular volume depletion, venodilation, or aortocaval compression are poorly tolerated. Significant decreases in SVR from sympathetic blockade from regional anesthesia or volatile anesthetic agents can produce severe decompensation because the cardiovascular system may be unable to compensate for the decline in afterload.⁶⁴⁻⁶⁶ Right ventricular contractility may be marginal, and the addition of negative inotropic anesthetic agents can lead to marked depression in cardiac function. The parturient should be monitored with an ECG, pulse oximetry, radial artery catheter, and a pulmonary artery catheter throughout labor and the postpartum period. The use of a pulmonary artery catheter allows early detection of changes in PVR or right ventricular function and serves as a guide to fluid and pharmacologic therapy.⁸⁷

Labor and vaginal delivery can best be managed by the judicious use of systemic narcotic analgesics and pudendal nerve block. Epidural analgesia with local anesthesia may be provided only if the block is slowly titrated in a limited dermatomal fashion from T10 to L1 to avoid extensive sympathetic blockade. Intrathecal or epidural opioids also provide effective first-stage analgesia. Vaginal delivery can be managed by the addition of a caudal catheter or pudendal block.

Regional anesthesia is best avoided for cesarean delivery, and a slow induction with high-dose narcotics or an inhalation agent is recommended.¹⁰⁸ This practice is necessary to avoid marked increases in PVR with laryngoscopy. Cricoid pressure must be maintained throughout the induction to prevent the aspiration of gastric contents. Ventilation must be adequate, but pulmonary hyperinflation must be avoided. Uterine stimulants should be omitted because they can be associated with significant elevations in PVR.⁶⁴⁻⁶⁶

Coronary Artery Disease

Coronary artery disease is uncommon in women of childbearing age, with a reported incidence of 1 case in 10,000 pregnancies.⁶⁴ In one study, it was determined that only 13% of gravidas who had a myocardial infarction had a known history of coronary artery disease; the overall maternal mortality rate was 37%, increasing to 45% if the infarction occurred in the third trimester.¹⁰⁹

The pathophysiology and clinical manifestations of coronary artery disease in pregnant women are identical to those in nonpregnant patients. The hemodynamic demands that pregnancy places on the myocardium stress the coronary circulation.¹¹⁰ General management guidelines include efforts to reduce the cardiac workload with measures such as bed rest, nitrate therapy for preload reduction, and conduction anesthesia during delivery. Cardiac medications, such as β -blockers and nitrates, should be continued throughout the pregnancy, labor, delivery, and puerperium.^{111,112} Effort must be directed toward optimizing myocardial oxygen supply; supplemental oxygen should be provided, anemia treated, and respiratory depression caused by sedation meticulously avoided.

Although reasonable pain relief can be achieved with systemic narcotic analgesia, the early institution of continuous regional anesthesia (e.g., epidural or combined spinal-epidural anesthesia) for labor and delivery is recommended to minimize the pain and stress that have the potential to precipitate ischemia and angina.⁶⁴⁻⁶⁶ Beneficial effects associated with regional anesthesia may also include decreased preload and afterload so that myocardial work is diminished. Marked and sudden decreases in afterload must be avoided because coronary artery perfusion depends on diastolic pressure. Significant decreases in SVR can precipitate reflex tachycardia, which may increase cardiac workload sufficiently to produce ischemia. Epidural anesthesia effectively attenuates the progressive increase in central venous pressure and cardiac output that occurs during labor in the unanesthetized parturient. Multiple-lead ECG monitoring should be instituted early in labor so that ischemia can be detected and treated promptly.⁸⁷

When establishing an epidural blockade, epinephrine should be omitted from the test dose to avoid potential tachycardia, and the block should be established by administration of slower-onset local anesthetic agents, such as bupivacaine, ropivacaine, or levobupivacaine.¹¹³ Supplementation of a dilute local anesthetic solution with an epidural opioid has been advocated.^{114,115} Fetal descent during the second stage of labor should be by force of uterine contraction, with avoidance of the Valsalva maneuver, according to the patient's baseline ejection fraction and analysis of the hemodynamic response to contractions. When epidural analgesia for first-stage labor is not employed, a low spinal anesthetic (i.e., saddle block) provides excellent conditions for an assisted delivery with minimal hemodynamic trespass.

Elective cesarean delivery can be performed safely with a slowly titrated level of epidural anesthesia, allowing judicious intravenous fluid infusion to maintain pulmonary capillary wedge pressure and blood pressure.¹¹⁶ Spinal anesthesia is much less desirable, because the rapid onset of sympathetic block has great potential for hypotension and reflex tachycardia. When administering general anesthesia for cesarean delivery, the anesthesiologist considers the importance of minimizing the cardiovascular response to the stress of endotracheal intubation and surgery. In the absence of congestive heart failure, an inhalation technique is recommended.⁶⁴

Myocardial infarction (especially in the third trimester) occurring less than 6 weeks earlier, congestive heart failure, or unstable or crescendo angina warrants invasive monitoring with arterial and pulmonary artery catheters.¹¹⁷ Monitoring should be continued for a

minimum of 24 hours into the postpartum period to assess increases in pulmonary capillary wedge pressure as intravascular volume increases after delivery and as anesthesia subsides.

Hypertrophic Obstructive Cardiomyopathy

Hypertrophic obstructive cardiomyopathy (HOCM), also called asymmetrical septal hypertrophy (ASH) or idiopathic hypertrophic subaortic stenosis (IHSS), is a disease without a defined cause, but at least one third of the subjects have a familial history, and it appears to be inherited as an autosomal dominant trait.¹¹⁸⁻¹²¹ The primary features of this cardiomyopathy include marked hypertrophy of the left ventricle and interventricular septum and obstruction of the left ventricular outflow tract during systole by the hypertrophied muscle. The anterior leaflet of the mitral valve can be displaced by the hypertrophied muscle and contribute to the obstruction in some patients.

The disease commonly manifests during the second to fourth decades of life. Common symptoms include angina pectoris, dizziness, and exertional dyspnea.^{64-66,118-121} Physical findings include signs of left ventricular hypertrophy, a systolic ejection murmur, and a third heart sound. The ECG pattern indicates left ventricular hypertrophy and, in many cases, evidence of Wolff-Parkinson-White syndrome and abnormal Q waves. There is wide variability in the findings and the symptoms of the disease.¹¹⁸⁻¹²¹

The hemodynamic limitations of HOCM are produced as the ventricle contracts. The hypertrophied walls narrow the outflow region during systole. The determinants of the degree of obstruction are the volume of the left ventricle at systole, the force of left ventricular contraction, and the degree of left ventricular distention during systolic contraction. The patient therefore requires a high preload to maintain a full left ventricle, a reduced contractile force to minimize outflow tract narrowing, and a high SVR to maintain distention of the left ventricle during systole.

Therapy primarily focuses on the administration of β -adrenergic blocking agents to reduce myocardial contractility and heart rate. Some patients also receive calcium channel blocking drugs. Patients with HOCM do not tolerate hypovolemia, decreased SVR, or increases in myocardial contractility very well.¹¹⁸⁻¹²¹ The cardiovascular and hemodynamic changes of pregnancy have a variable effect on patients with HOCM, depending on the severity and the nature of the disorder. The increase in blood volume associated with pregnancy should yield a beneficial effect because it increases preload. The usually observed increase in heart rate and stroke volume during pregnancy can have a negative effect, and the decrease in SVR, which begins during the second trimester, may also negatively affect cardiac performance. Although the potential for left ventricular failure and cardiac arrhythmias during pregnancy exists, the outcome of patients with HOCM has been reasonably good.⁶⁴⁻⁶⁶

There are several therapeutic objectives during parturition:

- Minimizing pain-associated increases in catecholamine levels
- Maintaining preload by adequate intravenous fluid administration
- Avoiding a Valsalva maneuver, which decreases preload abruptly

Invasive monitoring with an arterial line and a pulmonary artery catheter can yield the information necessary to provide precise management. Recommendations for analgesia during the first stage of

labor have been to employ systemic narcotics, inhaled analgesics, or paracervical block. Regional analgesia has been considered a substantial risk because of the potential for venodilation (i.e., decreased preload) and arterial dilation resulting in decreased SVR. Decreased SVR can be avoided if careful incremental titration of continuous lumbar epidural analgesia is carried out. A limited segmental level of analgesia from T10 to L2 provides adequate analgesia with minimal sympathetic blockade, preserving preload. Dilute solutions of a local anesthetic agent with the addition of a narcotic, such as fentanyl or sufentanil, provide optimal analgesia.⁶⁴⁻⁶⁶ Intrathecal narcotics may be used, eliminating the risk of sympathetic blockade but adding the potential side effects of respiratory depression, pruritus, and nausea, all of which are easy to treat.

A combined spinal and epidural analgesic approach has been used successfully for a patient with HOCM.¹²² Vaginal delivery can be accomplished with pudendal block, carefully extended epidural analgesia, and combined spinal-epidural or low spinal anesthesia (i.e., saddle block).^{64-66,123} The saddle block involves the spinal segments from L2 to S5 and avoids most sympathetic nerve elements. Regional anesthesia is effective at blocking the uncontrollable urge to bear down. If hypotension necessitating a vasopressor does occur, the use of ephedrine is relatively contraindicated because it causes tachycardia and increased myocardial contractility. Metaraminol or a pure vasoconstricting drug, such as phenylephrine (20 to 40 μg), should be employed in the lowest effective doses to minimize its effect on the uterine arteries.

Anesthesia for cesarean delivery offers additional challenges. Left uterine displacement must be maintained and volume requirements carefully assessed in view of the increased blood loss. Invasive monitoring is needed. Regional anesthesia is usually avoided for the aforementioned reasons, and the level of anesthesia required is likely to produce extensive sympathetic blockade with undesirable consequences.^{64,65,87} Nonetheless, a carefully titrated epidural anesthetic with ongoing compensation for the induced hemodynamic changes can prove acceptable. General anesthesia is preferred by many, although the ideal technique has not been established and experience is limited. Although the use of volatile anesthetic agents is advantageous because they reduce myocardial contractility, they also decrease uterine contractility and SVR. Modest doses should have a minimal effect on both.

As with the preeclamptic patient, the stimulating effects of laryngoscopy and intubation on patients with HOCM need to be blunted pharmacologically. Oxytocin must be administered cautiously because it tends to decrease SVR and results in tachycardia when administered rapidly. The parturient with HOCM requires careful attention by means of appropriate monitoring and immediate availability of the necessary vasopressors, β -blockers, and intravenous volume expanders.

Marfan Syndrome

Marfan syndrome is an autosomal dominant disorder characterized by connective tissue abnormalities of the cardiovascular, skeletal, and ocular systems. The principal cardiovascular involvement is weakness of the aortic media, which can result in progressive aortic dilatation or acute dissection.⁹¹ Dilatation can begin as early as the first year of life and typically occurs first in the coronary sinuses. Profound aortic regurgitation can predate clinical evidence of aortic dissection, and dissection may not be heralded by the classic chest pain with radiation to the back that usually accompanies aortic dissection from other causes. These patients also can experience coronary artery

involvement, pulmonary artery dilatation, redundant chordae tendinae, or an increased incidence of aortic coarctation.

Anesthetic management options for labor and delivery or cesarean delivery has been only rarely reported. In one case report of two patients with Marfan syndrome and evidence of aortic dissection, epidural anesthesia was provided successfully for cesarean delivery with invasive monitoring by means of a pulmonary artery catheter and an arterial line.¹²⁴ In another report, Brar¹²⁵ described a case of a Stanford type B aortic dissection (i.e., originating distal to the left subclavian artery and extending to the aortic bifurcation and proximal left iliac artery) in a primigravid woman at term who had Marfan syndrome. The dissection was managed conservatively. Cesarean section was performed under epidural anesthesia with aggressive control of hypertension. Postoperatively, there was no extension of the dissection and no aneurysm formation.¹²⁵ In the asymptomatic patient without cardiovascular manifestations and a normal echocardiographic examination, segmental epidural anesthesia for labor and vaginal delivery without invasive hemodynamic monitoring are appropriate and inherently safe if the severity of associated scoliosis does not preclude the success of this technique. Adequate analgesia provided by an epidural block is distinctly advantageous in decreasing pain and catecholamine output, diminishing the stress on the aortic wall. Anesthesia for cesarean delivery may be provided by regional or general technique.

General anesthesia for cesarean delivery in the presence of cardiovascular complications must be tailored to minimize the hemodynamic response to endotracheal intubation and surgical stimuli.⁹¹ Prophylactic β -adrenergic blockade and inhalational agents that produce decreased myocardial contractility and slow the force of cardiac ejection have been advocated.⁹¹ Control of blood pressure alone with vasodilators may only increase left ventricular ejection velocity and, unless combined with β -adrenergic blockade, may not prevent dissection. The potential for temporomandibular joint laxity and dislocation on endotracheal intubation also exists, although difficult intubation has not been reported.

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome is a rare, genetically transmitted connective tissue disorder that is not specific to pregnancy. Because of the multi-organ involvement and varied presentations of this disease, no uniform or routine anesthetic recommendations can be made.¹²⁶ The features of Ehlers-Danlos syndrome that have the greatest impact on the management of anesthesia include fragile, poorly healing skin; excessive bleeding; spontaneous pneumothorax; easy joint dislocation; valvular prolapse; and spontaneous dissections or ruptures of major vessels.

Some of the problems in Ehlers-Danlos syndrome may have implications for the administration of regional anesthesia.¹²⁶ Although bruising, bleeding, and hematomas are common, no coagulation disorder has been consistently associated with Ehlers-Danlos syndrome. Nevertheless, bleeding can complicate arterial, peripheral, or central line and neuraxial needle placement. If general anesthesia is selected for these parturients, the airway must be managed gently in view of the possible presence of spine involvement, periodontal disease, propensity for gingival bleeding, and oropharyngeal tissue fragility.^{127,128} Cardiac function must be evaluated preoperatively, and anesthetic implications must be considered. Intraoperatively, low airway pressures are needed because of the increased risk of pneumothorax. If possible, spontaneous ventilation is recommended. Elaborate padding of pressure points is indicated.

Spinal Abnormalities

Kyphoscoliosis occurs in approximately 0.4% to 1% of the population in the United States and is associated with obstetric and anesthetic concerns during pregnancy and delivery.⁹¹ Specific obstetric concerns relate to concomitant disease and the risk of dystocia in labor. Lesions involving the upper spine are commonly associated with disordered cardiorespiratory function. The natural history of an untreated severe curve is progression of deformity over time, resulting in early death from cardiorespiratory failure.

Anesthetic management for labor and vaginal delivery must be designed to minimize respiratory depression from systemic opioids or respiratory embarrassment from excessive intercostal muscle paralysis during high levels of regional anesthesia in patients with preexisting pulmonary dysfunction.¹²⁹ It is equally important to emphasize the need for adequate analgesia to minimize catecholamine-induced increases in cardiac output that can precipitate high-output, right-sided heart failure. A closely monitored segmental epidural analgesic technique can serve all of these purposes and avoid systemic opioid-induced respiratory depression.

Although an epidural analgesic is optimal for the aforementioned reasons, it can be difficult to achieve in the kyphoscoliotic obstetric patient. Distortion of the spinal column and of the epidural space can prevent proper placement of an epidural catheter and uniform distribution of the local anesthetic solution, resulting in an incomplete block. Subarachnoid catheter placement and segmental block have been reported for use in labor and vaginal delivery when epidural anesthesia had been unsuccessful.⁹¹

Continuous epidural and subarachnoid approaches have been employed to provide surgical anesthesia for cesarean delivery. Both techniques offer the distinct advantage of slow titration of anesthetic level, which allows time for assessment of adequacy of respiratory function and for compensatory hemodynamic mechanisms to become operative. Another significant factor favoring regional anesthesia is that it provides superior analgesia after cesarean delivery in the patient with scoliosis and respiratory impairment.

General anesthesia for cesarean delivery is indicated when severe scoliosis and cardiorespiratory impairment (i.e., cor pulmonale) are apparent at presentation, because respiratory embarrassment is likely to develop in these patients if a high regional anesthetic block is administered. These patients also warrant invasive monitoring of central venous pressure and serial arterial blood gas measurements.

Previous Spinal Surgery

Administration of lumbar epidural analgesia in a parturient who has had previous spinal surgery presents a unique challenge to the anesthesiologist. The difficulties include an inability to identify the epidural space, multiple attempts before catheter insertion, vascular trauma, and subdural local anesthetic injection to accidental dural puncture. In the past, previous spinal surgery was thought by some to represent a relative contraindication to regional anesthesia.¹³⁰⁻¹³⁴ A potential problem is obliteration of the epidural space from adhesions, which can limit spread of local anesthetics and increase the risk of dural puncture. Insertion of an epidural needle in the fused area can be relatively contraindicated or impossible to perform because of the presence of bone graft material and scar tissue, degenerative changes that occur in the spine after fusion, persistent back pain, and the risk of introducing infection in the area of foreign bodies.¹³⁰ These patients

may express considerable anxiety and reluctance regarding catheter insertion in their backs.

Patients who have undergone earlier spinal surgery should be seen in antepartum consultation by the anesthesiologist, and the options for analgesia and anesthesia for labor and delivery should be discussed in detail. Epidural anesthesia may be offered if the patient accepts the higher incidence of complications and failure rate. Alterations in dosage with larger-than-usual doses of local anesthesia required have been described, and, with adjustments and vigilance, this technique has been used successfully.¹³²

Achondroplastic Dwarfism

Although achondroplastic dwarfism is a rare complication of pregnancy, the patient may have a number of anatomic and physiologic abnormalities that contribute to problems with the administration of anesthesia.⁹¹ The airway in a patient with achondroplasia typically has narrowed nasal passages and pharyngeal and maxillary hypoplasia. The base of the skull is shortened (because of early fusion of constituent bones) and angulated, yielding limited extension and making endotracheal intubation potentially difficult. However, easy-mask general anesthetic ventilation has been described.¹³⁵ Kyphoscoliosis is a common associated clinical finding in dwarfs, and respiratory problems caused by decreased functional residual capacity because of scoliosis and advancing enlargement of the uterus throughout pregnancy may be encountered.⁹¹ Obstructive sleep apnea has become recognized as an insidious cause of morbidity in patients with achondroplasia, and it is more common than central apnea because of cervicomedullary cord compromise. Acquired pulmonary hypertension leading to cor pulmonale can occur in women with achondroplasia, with contributions by restrictive lung disease associated with scoliosis, chronic upper airway obstruction, and sleep apnea.

Abnormalities of the spinal cord can result from severe kyphosis and scoliosis or from odontoid hypoplasia with cervical instability, leading to spinal cord and nerve root compression.⁹¹ The vertebral bodies are abnormally shallow, with underdeveloped vertebral arches causing narrowing of the subarachnoid and epidural space. Adults with the condition have hypoplastic intervertebral disks that can prolapse easily into a congenitally stenotic canal and produce neural compression. All of these factors can make regional anesthesia difficult or impossible to achieve, with unpredictable spread of local anesthetic solutions and increased risk of unintentional dural puncture.

Cesarean delivery is inevitable for these women because the maternal pelvis is invariably small and contracted, resulting in cephalopelvic disproportion. In this setting, the anesthesiologist must fully understand the previously described problems to facilitate the safe delivery of anesthesia and select methods of minimizing the risk of maternal aspiration and avoiding fetal depression.

Pregnancy in achondroplasia compounds many of the outlined problems and presents a unique challenge to the obstetrician and anesthesiologist. General endotracheal anesthesia has traditionally been considered the technique of choice in women with achondroplasia, even though case reports have detailed difficult endotracheal intubation.⁹¹ In those instances, extension of the neck was difficult or impossible. These patients warrant early discussion of the probability of intubation while awake after a thorough examination of the airway and review of any available cervical radiographs.

Technically challenging problems are also associated with regional anesthesia because of the skeletal abnormalities encountered. Epidural anesthesia has been administered successfully.¹³⁶⁻¹³⁸ A relative contraindication to regional anesthesia has been a concern that neurologic

sequelae can be attributed to the anesthetic agent. Patients who have received successful epidural anesthesia have not experienced preoperative or postoperative neurologic dysfunction. Epidural anesthesia is theoretically preferable to spinal anesthesia because it lends itself to titration of the level of block. A smaller dose of anesthesia than usual may be required because of maternal short stature and kyphoscoliosis. The dangers of intraoperative hypotension and high or total spinal block are greater for spinal than for epidural anesthesia.

Substance Abuse

Substance abuse has crossed social, economic, and geographic borders, and throughout the world, it remains one of the major problems facing society. The prevalence of substance abuse in young adults (including women) has increased markedly over the past 20 years. Almost 90% of drug-abusing women are of childbearing age.¹³⁹⁻¹⁴⁴ Substance abuse is “self-administration of various drugs that deviates from medically or socially accepted use, which if prolonged, can lead to the development of physical and psychological dependence.”¹⁴⁵ Most often, abuse of an illicit substance is first suspected or diagnosed during medical management of another condition, such as hepatitis, human immunodeficiency virus (HIV) infection, or pregnancy.¹³⁹⁻¹⁵⁰ Illicit substances most commonly abused in pregnancy include cocaine, amphetamines, opioids, ethanol, tobacco, marijuana, caffeine, and toluene-based solvents. Polysubstance abuse is common.^{139-144,146-157} Regardless of the drugs ingested and the clinical manifestations, it is always difficult to predict the exact anesthetic implications in chemically dependent patients. Most patients with a history of drug abuse deny it when interviewed preoperatively by anesthesiologists or obstetricians.¹⁵⁸⁻¹⁶⁰

Anesthesiologists become involved in the care of drug-abusing patients in emergency situations, such as fetal distress, placental abruption, or uterine rupture, or in more controlled situations, such as a request for labor analgesia. Of the drugs abused, cocaine has the most profound implications for the obstetric anesthesiologist. Regional and general anesthesia in the cocaine-abusing parturient can be associated with serious complications.^{139,144,148,150,152,158} When regional anesthesia is selected, combative behavior, altered pain perception, cocaine-induced thrombocytopenia, and epinephrine-resistant hypotension may be encountered. Low doses of phenylephrine titrated to the effect usually restore blood pressure to normal. Pronounced abnormalities in endorphin levels and changes in mu and kappa opioid receptor densities resulting from cocaine addiction can result in perception of pain despite adequate spinal or epidural anesthesia sensory levels.¹³⁹

Hypertension, cardiac arrhythmias, and myocardial ischemia may be encountered under general anesthesia. Propranolol is contraindicated in cocaine-intoxicated patients because of the potential for unopposed α -adrenergic stimulation following β -blockade.¹⁶¹ Although esmolol may provide effective control of tachycardia and hypertension, β -blockade has also been shown to enhance cocaine-induced coronary vasoconstriction. The short elimination half-life of esmolol can offer some advantages if the drug administration is deemed necessary.

The administration of hydralazine has become a standard drug therapy for the treatment of hypertension in cocaine-addicted parturients. The action of this drug includes vasodilation and a decrease in SVR, leading to reflex tachycardia, which may not always be desirable in the patient who is already tachycardic from cocaine intake. Labetalol, a combined, nonselective β - and α -adrenergic blocker, rapidly restores blood pressure without affecting heart rate or uterine blood

flow and has been recommended by many in treating cocaine toxicity. Some authorities have suggested, however, that labetalol should not be used to treat cocaine-induced hypertension because labetalol's antagonism of β -adrenergic receptors is greater than its effect on α -adrenergic receptors.¹³⁹ The use of calcium channel blockers in drug-abusing parturients remains unclear. Many other drugs, such as nitroglycerin and nitroprusside, have been recommended, although the best drug intervention remains to be established.

All potent volatile anesthetic agents can produce cardiac arrhythmias and increased SVR in cocaine-intoxicated parturients. Halothane has been found to sensitize the myocardium to the effects of catecholamines and therefore should be avoided. When ketamine is used in cocaine-abusing patients, caution is indicated, because it can stimulate the central nervous system and potentiate the cardiac effects of cocaine by further increasing catecholamine levels.^{143,159} Nitroglycerin is safe and effective in the treatment of anginal chest pain resulting from acute cocaine ingestion.

Chapter 57

Intensive Care Monitoring of the Critically Ill Pregnant Patient

Stephanie Rae Martin, DO, and Michael Raymond Foley, MD

Less than 1% of pregnant women will become critically ill and require admission to an intensive care unit (ICU).¹⁻⁸ Between 47% and 93% of ICU admissions result from an obstetric complication, primarily hemorrhage and hypertensive disorders. Other common causes include respiratory failure and sepsis. Common non-obstetric indications for ICU admission include maternal cardiac disease, trauma, anesthetic complications, cerebrovascular accidents, and drug overdose. In many series, most obstetric ICU admissions occur in the immediate postpartum period and are most likely caused by complications of acute hemorrhage.^{1,4-6,9}

An intimate understanding of the physiologic changes of pregnancy is essential in managing critically ill patients. This chapter addresses basic critical care monitoring in obstetrics and discusses conditions in which more intensive management of the pregnant patient may be indicated.

Maternal Mortality

Epidemiology

Maternal mortality is defined as the number of maternal deaths (direct and indirect) per 100,000 live births. Direct obstetric deaths result primarily from thromboembolic events, hemorrhage, hypertensive disorders of pregnancy, and infectious complications. Indirect obstetric deaths arise from preexisting medical conditions, including diabetes, systemic lupus erythematosus, pulmonary disease, and cardiac disease aggravated by the physiologic changes of pregnancy. Figure 57-1 shows specific causes of pregnancy-related mortality for three time periods as reported by the Centers for Disease Control and Prevention.¹⁰⁻¹²

Maternal mortality rates are periodically surveyed by various local, state, and national agencies. Because these data are primarily collected from death certificates, some have suggested that the numbers underestimate the mortality rate by as much as 20% to 50%.¹³ Variations in the definition of maternal death, medicolegal concerns, and physicians untrained in the proper completion of death certificates further confuse these investigations. To address these concerns, the Division of Reproductive Health at the Centers for Disease Control and Prevention, in collaboration with the American College of Obstetricians and Gynecologists (ACOG) and state health departments, began in 1987 to systematically collect these data in the Pregnancy-Related Mortality Surveillance System.

Mortality rates have declined precipitously in the United States over the past century, but a slight increase has been observed in more recent years, as shown in Figure 57-2.¹¹ Some of this increase has been attributed to better ascertainment of data collected prospectively and to the use of multiple source documents. Although this trend is exhibited for all races, wide discrepancies still exist between white and non-white populations, even when controlling for age and use of prenatal care (Fig. 57-3).¹² The reasons for this discrepancy remain unclear. Geographic differences in maternal mortality rates are also apparent and are likely influenced by racial disparities. States with higher percentages of births to African-American women are also those with the highest maternal mortality rates. The data on pregnancy-related mortality in the United States between 1990 and 1997 indicate a rate of 11.8 deaths per 100,000 pregnant women (8.1 deaths per 100,000 whites, 30.0 deaths per 100,000 African Americans).¹² Advancing maternal age and lack of education are also associated with an increased risk for death in pregnancy.¹² Potential explanations for this increased risk include a higher incidence of underlying or undiagnosed chronic disease.

Prediction of Maternal Mortality

Predicting the risk of mortality for pregnant patients remains a challenge. The overall maternal mortality rate for critically ill gravidas admitted to an ICU ranges from 0% to 20%, with most series reporting maternal mortality rates of less than 5% for all obstetric ICU admissions.^{1,3-5,8} Several scoring systems are routinely employed in critical care settings in an attempt to objectively describe the severity of the critical illness and accurately predict mortality risks. The Acute Physiologic and Chronic Health Evaluation (APACHE) scoring system,^{14,15} Simplified Acute Physiologic Score (SAPS),¹⁶ and Mortality Prediction Model (MPM)¹⁷ are three widely used methods that track a variety of variables in nonpregnant patients.

Several authors have evaluated the applicability of the scoring systems in critically ill pregnant patients.¹⁸⁻²⁰ In a study of obstetric ICU patients, the APACHE III score did not accurately predict maternal mortality.¹⁸ In the largest series, 93 gravidas were compared with 96 nonpregnant women. The overall mortality rate in the obstetric population was 10.8%. The APACHE II, SAPS II, and MPM II scoring systems each performed well in predicting mortality (14.7%, 7.8%, and 9.1%, respectively).¹⁹ The predicted mortality rate was significantly higher among obstetric patients compared with non-obstetric

FIGURE 57-1 Causes of maternal mortality for three time periods. Obstetric deaths are caused by thromboembolic events, hemorrhage, hypertension, infections, and preexisting medical conditions, such as diabetes, systemic lupus erythematosus, pulmonary disease, and cardiac disease aggravated by the physiologic changes of pregnancy. CVA, cerebrovascular accident; HTN, hypertension. (From Berg CJ, Chang J, Callaghan WM, et al: Pregnancy-related mortality in the United States, 1991-1997. *Obstet Gynecol* 101:289-296, 2003.)

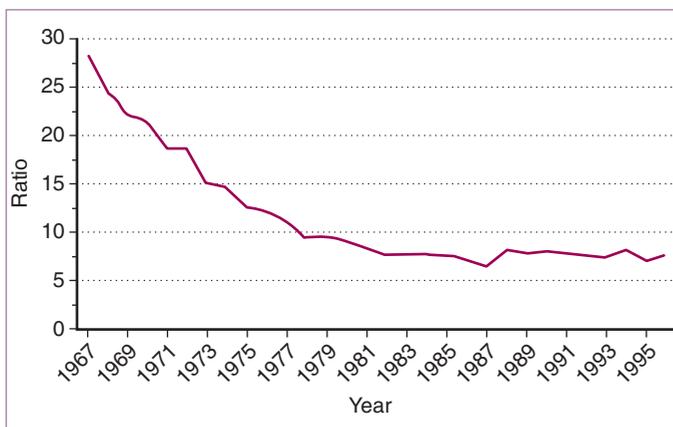

FIGURE 57-2 Maternal mortality ratios in the United States by year for 1967 to 1996. Ratios are the number of maternal deaths per 100,000 live births. The term *ratio* is used instead of rate because the numerator includes some maternal deaths that were not related to live births and therefore were not included in the denominator. (From Centers for Disease Control and Prevention: Maternal Mortality—United States, 1982-1996. *MMWR Morb Mortal Wkly Rep* 47:705-707, 1998.)

patients for each of the three scoring tools, despite no difference in actual mortality between the two groups (10.8 versus 10.4%).

None of the scoring systems includes adjustments for normal obstetric physiologic changes such as decreased blood pressure and increased respiratory rate. Laboratory abnormalities such as elevated liver function test results and low platelet counts, which are common in obstetric disorders such as HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*), are not included in the assessments and may limit their potential applicability. In summary, although the available critical care mortality scoring systems can possibly be applied

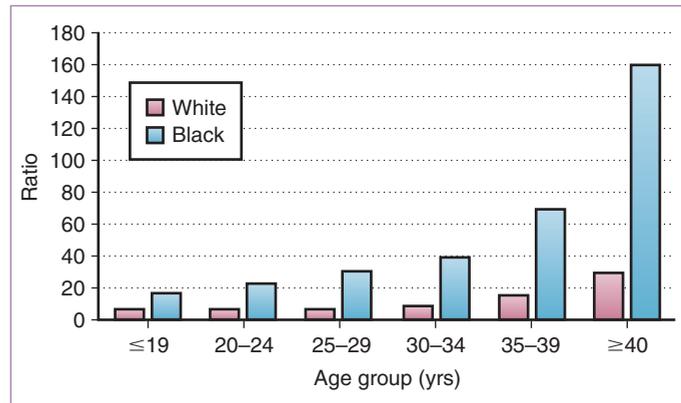

FIGURE 57-3 Pregnancy-related mortality ratios by age and race in the United States for 1991 to 1999. The mortality ratios are the number of deaths per 100,000 live births.

to the obstetric population, they have the potential to overestimate the mortality risk for critically ill gravidas.

Invasive Central Hemodynamic Monitoring

Background and Insertion Technique

Placement of a central venous catheter may be indicated to provide central venous access for fluid replacement, medication administration, or hemodynamic measurements. Since its introduction in the early 1970s,²¹ invasive hemodynamic monitoring with a pulmonary artery catheter (PAC) has become quite common in critically ill patients. The most commonly available Swan-Ganz catheters are multilumen devices that enable direct monitoring of central venous pressure (CVP, right ventricular preload), pulmonary capillary wedge pressure (PCWP, left ventricular preload), cardiac output (CO), systemic vascular resistance (SVR, left ventricular afterload), pulmonary artery pressures, and mixed venous oxygen saturation. CO and mixed venous oxygen saturation can be measured in the conventional manner by thermodilution and direct distal port aspiration, respectively, or by newer fiberoptic technology that allows continuous monitoring of CO and mixed venous oxygen saturation.

PACs (i.e., Swan-Ganz catheters) are typically inserted percutaneously through an introducer sheath and in a sterile manner through the left subclavian or right internal jugular veins and advanced into the right heart. The right internal jugular vein is usually preferred because it offers the shortest and most direct entry into the right heart. Access through the femoral vein offers the advantage of compressibility in a patient with a coagulopathy, but it is most distant from the right heart and may require fluoroscopic guidance. As the catheter is advanced, characteristic oscilloscopic pressure waveforms are used to establish the catheter's location within the heart. A 1.5-mL balloon is positioned close to the tip of the catheter. Inflation of the balloon allows the catheter to be carried through the heart by flowing blood.

After the inflated balloon reaches the pulmonary artery, it travels distally until it wedges in a smaller-caliber artery and occludes blood flow. This results in a nonpulsatile waveform from which the PCWP is measured. When the balloon is deflated, return of an identifiable

pulmonary artery systolic and diastolic pressure tracing should occur. A portable chest radiograph is indicated after placement of a PAC to verify appropriate catheter positioning and exclude pneumothorax.

Indications for Pulmonary Artery Catheterization

The most common indications for PAC placement in the obstetric population include the following²²:

- Hypovolemic shock unresponsive to initial volume resuscitation attempts
- Septic shock with refractory hypotension or oliguria
- Severe preeclampsia with refractory oliguria or pulmonary edema
- Ineffective intravenous antihypertensive therapy
- Adult respiratory distress syndrome (ARDS)
- Intraoperative or intrapartum cardiac failure
- Severe mitral or aortic valvular stenosis
- New York Heart Association (NYHA) class III or IV heart disease in labor
- Anaphylactoid syndrome of pregnancy (i.e., amniotic fluid embolism)

Although use of the PAC in nonpregnant critically ill patients is widespread, until recently, randomized trials demonstrating a clear benefit of PAC-directed care were lacking. Several small studies suggested a decrease in mortality when PACs are used to direct therapies,²³⁻²⁵ while others reported an increase in mortality associated with the use of PACs²⁶⁻²⁹ or no benefit.³⁰⁻³² The large Canadian Critical Care Clinical Trials Group study prospectively randomized 1994 high-risk surgical patients to receive a PAC to direct therapy or standard therapy and reported no survival benefit when therapy was directed by a PAC (7.8% versus 7.7% for controls).³³ A British trial randomized more than 1000 critically ill patients to management with or without a PAC and failed to demonstrate a survival benefit (68.4% versus 65.7% for controls).³⁴ The Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE trial) also demonstrated no difference in mortality or length of stay for 433 patients with congestive heart failure randomized to PAC or no catheter.³⁵

A meta-analysis of 13 trials published since 1985 included 5051 patients randomized to a PAC or to no PAC to guide management. No difference was identified in mortality or length of hospital stay. Conversely, the use of a PAC was significantly associated with more frequent use of inotropes and vasodilators.³⁶ In summary, although placement of PACs remain widespread, the available data do not support the routine use of PACs for all critically ill patients. Data addressing the role of PACs in pregnant critically ill patients are lacking.

Complications of Central Venous Catheters

Common complications associated with initial venous access, advancement, and maintenance of a PAC are listed in Table 57-1.³⁷ Some complications, such as pulmonary infarction and pulmonary artery rupture, are specific to placement of a PAC and do not occur with central venous access alone. Minimal available data address specific complication rates associated with PAC use in pregnant women. Initial

TABLE 57-1 POTENTIAL PULMONARY ARTERY CATHETER COMPLICATIONS

At Insertion	After Placement
Pneumothorax	Pulmonary infarction
Thrombosis	Pulmonary artery rupture
Arterial puncture	Infection
Air embolization	Balloon rupture
Catheter knotting	Endocardial or valvular damage
Cardiac arrhythmias (transient, sustained)	

complication rates decline as operator experience increases, and only properly trained personnel should insert catheters for invasive hemodynamic monitoring.³⁸ Several studies have also demonstrated that ultrasound-guided placement results in fewer failed attempts at placement, fewer complications such as hematoma or arterial puncture, and less time for placement.³⁹

Complications encountered at initial insertion include arterial puncture, pneumothorax, and air embolism. Pneumothorax risks are highest with a subclavian approach. Transient cardiac arrhythmias are commonly encountered during placement and advancement of the PAC. The majority consist of premature ventricular contractions or nonsustained ventricular tachycardia, and they resolve with withdrawal or advancement of the catheter. The overall incidence of transient minor arrhythmias during advancement of a PAC exceeds 20% in most studies.³⁷ Significant arrhythmias such as sustained ventricular tachycardia or fibrillation are less common, occurring in less than 4% of patients in most series, and they are more likely to be encountered in patients with cardiac ischemia.³⁷

Infections related to central venous catheters are common and may involve a superficial skin infection, colonization, or a more serious bacteremia. Skin flora, particularly *Staphylococcus* species, are most commonly involved. Positive cultures from the tip of a PAC are common and are considered evidence of colonization. However, for bacteremia or sepsis to be diagnosed, the patient must also have positive blood cultures with the same organism and clinical evidence of systemic infection, such as fever or hypotension.⁴⁰ The risk of bacteremia is approximately 0.5% per catheter day, and the risk increases with each day the catheter remains indwelling. Bacteremia resulting from central venous catheters accounts for 87% of bloodstream infections in critically ill patients.⁴¹ Infectious complications can be minimized by adherence to strict sterile technique, placement in the subclavian site, use of antimicrobial-coated catheters, avoiding antibiotic ointments that can increase fungal colonization, avoiding empiric catheter changes, and removing the catheter as soon as possible.⁴²

Venous thrombosis risk can be minimized by placement at the subclavian site and by limiting the duration of catheter placement. Pulmonary infarction may occur as a result of direct occlusion of a pulmonary artery branch caused by drifting of the catheter or thromboembolic events. Catheter knotting can be avoided during placement if the operator remains aware of the centimeter markings on the advancing catheter. The right ventricle usually is reached when the catheter has been inserted 25 to 30 cm from the jugular vein site. Few patients require more than 50 cm of catheter to reach the pulmonary artery. Inflated catheter balloons should be checked before insertion to reduce the risk of air leakage and balloon rupture. Overinflation of the balloon with air (>1.5 mL) should be avoided. A pressure-release balloon has been described that limits overinflation and thereby minimizes pulmonary

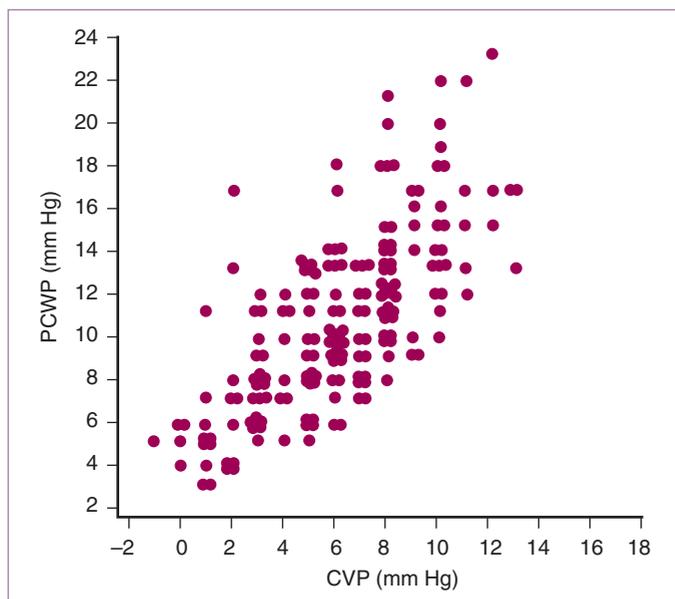

FIGURE 57-4 Relationship of central venous pressure (CVP) to pulmonary capillary wedge pressure (PCWP) in severe pregnancy-induced hypertension. If an accurate assessment of left ventricular preload is deemed important in the management of the patient's cardiovascular complications, insertion of a pulmonary artery catheter may be indicated. (From Cotton DB, Gonik B, Dorman K, et al: Cardiovascular alterations in severe pregnancy-induced hypertension: Relationship of central venous pressure to pulmonary capillary wedge pressure. *Am J Obstet Gynecol* 151:762, 1985.)

vessel injury. Pulmonary artery rupture is a rare but often fatal complication that occurs more commonly in patients with pulmonary artery hypertension or who are anticoagulated. Valvular damage can occur from chronic catheter irritation or during insertion when the catheter balloon is not deflated before retrograde movement.

CVP monitoring alone should not be considered equivalent to PAC monitoring. Preeclampsia and its complications, such as oliguria and pulmonary edema, may prompt central venous access. However, several investigators have described poor correlation between the central venous catheter and PCWP in gravidas with pregnancy-induced hypertension (Fig. 57-4).^{43,44} If an accurate assessment of left ventricular preload is deemed important in the management of the patient's cardiovascular complications, insertion of a PAC may be indicated. Whether this holds true for pregnant women with critically ill disease states other than pregnancy-induced hypertension remains unknown.

Hemodynamic Considerations

With a PAC, the following hemodynamic variables can be directly measured in the patient:

- Heart rate (beats/min)
- CVP (mm Hg)
- Pulmonary artery systolic and pulmonary artery diastolic pressures (mm Hg)
- PCWP (mm Hg)
- CO (L/min)
- Mixed venous oxygen saturation (%)

By use of a sphygmomanometer or by peripheral artery catheterization, direct measurements of systemic arterial pressures can also be

TABLE 57-2 FORMULAS FOR CALCULATING HEMODYNAMIC VARIABLES

CaO₂, arterial oxygen concentration; **CcO₂**, end capillary O₂ content; **CO**, cardiac output; **CvO₂**, venous oxygen concentration; **DO₂**, oxygen delivery; **Hb**, hemoglobin; **MAP**, mean arterial pressure; **O₂**, oxygen; **PaO₂**, arterial partial pressure of oxygen; **PAP**, pulmonary artery pressure; **PCWP**, pulmonary capillary wedge pressure; **PvO₂**, venous partial pressure of oxygen; **PVR**, pulmonary vascular resistance; **Qs/Qt**, shunt fraction; **RAP**, right atrial pressure; **SaO₂**, arterial oxygen saturation; **SvO₂**, venous oxygen saturation; **SVR**, systemic vascular resistance; **VO₂**, oxygen consumption.

obtained. Table 57-2 lists formulas for calculating selected hemodynamic variables.

Hemodynamic variables often are expressed in an “indexed” fashion (i.e., cardiac index). To do this, the original nonindexed CO value must be divided by body surface area. Because standard body surface area calculations have never been established specifically for pregnancy, this traditional way of expressing hemodynamic data is somewhat controversial in obstetrics. Those who argue for its use point out that indexing allows direct comparison of hemodynamic parameters for pregnant women of different sizes, a critical issue when interpreting these values.

Mean hemodynamic measurements for pregnant and nonpregnant patients are presented in Table 57-3. They are paired data from 10 healthy subjects, taken between 36 and 38 weeks' gestation and between 11 and 13 weeks after delivery.⁴⁵ Using the noninvasive technique of M-mode echocardiography, other investigators have demonstrated that many of these physiologic alterations in hemodynamics begin in the early phases of pregnancy.⁴⁶ Position changes late in pregnancy significantly influenced central hemodynamic stability. The standing position increased pulse by 50%, left ventricular stroke work index by 21%, and pulmonary vascular resistance by 54%.⁴⁷ Compared with the nonpregnant state, the pregnant state seemed to result in a buffering of orthostatic-related hemodynamic changes. The investigators speculated that the increased intravascular volume during pregnancy accounted for this stabilizing effect.

Hemodynamics of Specific Conditions during Pregnancy

Mitral Valve Stenosis

Mitral stenosis is the most common rheumatic valvular lesion encountered in pregnancy (see Chapter 39). When the valve area falls below 1.5 cm², filling of the left ventricle during diastole is severely limited, resulting in a fixed CO. Prevention of tachycardia and maintenance of adequate left ventricular preload is essential in these patients. As the heart rate increases, less time is allowed for the left atrium to adequately empty and fill the left ventricle during diastole. The left atrium may become overdistended, resulting in dysrhythmias (primarily atrial

TABLE 57-3 NORMAL CENTRAL HEMODYNAMIC PARAMETERS IN HEALTHY NONPREGNANT AND PREGNANT PATIENTS

Hemodynamic Parameter	Nonpregnant Values	Pregnant Values
Cardiac output (L/min)	4.3 ± 0.9	6.2 ± 1.0
Heart rate (beats/min)	71 ± 10	83 ± 10
Systemic vascular resistance (dyne × cm × sec ⁻⁵)	1530 ± 520	1210 ± 266
Pulmonary vascular resistance (dyne × cm × sec ⁻⁵)	119 ± 47	78 ± 22
Colloid oncotic pressure (mm Hg)	20.8 ± 1.0	18.0 ± 1.5
Colloid oncotic pressure – pulmonary capillary wedge pressure (mm Hg)	14.5 ± 2.5	10.5 ± 2.7
Mean arterial pressure (mm Hg)	86.4 ± 7.5	90.3 ± 5.8
Pulmonary capillary wedge pressure (mm Hg)	6.3 ± 2.1	7.5 ± 1.8
Central venous pressure (mm Hg)	3.7 ± 2.6	3.6 ± 2.5
Left ventricular stroke work index (g × m × m ⁻²)	41 ± 8	48 ± 6

fibrillation, which increases the risk of thromboembolic complications) or pulmonary edema. Adequate preload, however, is essential to maintain left ventricular filling pressure. Alternatively, if preload is excessive, pulmonary edema and atrial dysrhythmias may result. Medical management of these patients involves activity restriction, treatment of dysrhythmias, β -blockers to control heart rate, and careful diuretic use. The goal of diuretic therapy is to treat pulmonary edema, with care not to overly reduce left ventricular preload. Adequate analgesia and anesthesia during labor and delivery also reduce excessive cardiac demands associated with pain and anxiety.

The other important hemodynamic consideration for patients with mitral valve stenosis relates to the potential for misinterpretation of the invasive monitoring data. Because of the stenotic mitral valve, PCWP readings do not accurately reflect left ventricular diastolic pressure. In some instances, very high PCWP values are recorded (and are needed to maintain an adequate CO). Overt pulmonary edema is usually not associated with these high readings. During attempts at maintaining a relatively constricted intravascular volume, the CO should be concomitantly monitored and maintained. For each individual patient, optimal PCWP and CO values (i.e., values that maintain blood pressure and tissue perfusion) should be determined.

Aortic Stenosis

The major problem encountered with aortic stenosis is the patient's potential inability to maintain CO because of severe obstruction or in the setting of decreasing left ventricular preload (see Chapter 39). Unlike mitral valve stenosis, aortic valve stenosis requires that attempts be made to maintain the patient in a relatively hypervolemic state, although the fixed CO may lead to pulmonary edema. The time surrounding labor and delivery is particularly risky for these patients. To maintain an adequate CO, adequate venous return to the heart is crucial. Decreased venous return can result from excess blood loss, hypotension, and ganglionic blockade from a regional anesthetic or even vena caval occlusion in the supine position. Pulmonary artery catheterization may be indicated in patients with significant aortic stenosis to accurately estimate intravascular volume and guide fluid replacement.

Pulmonary Hypertension

Pulmonary artery hypertension may arise as a primary lesion or result from an underlying cardiac abnormality (see Chapter 39). Primary pulmonary hypertension is characterized by an unexplained elevation in pulmonary artery pressures (>25 to 30 mm Hg). Prognosis is grim

for patients with primary pulmonary hypertension; mean survival is 2.8 years from the diagnosis. Maternal mortality rates for patients with pulmonary hypertension have been as high as 50%.⁴⁸⁻⁵⁰ These patients are at increased risk for complications from placement of a PAC. Pulmonary hypertension may also result from unrepaired congenital intracardiac shunts such as a ventricular septal defect, atrial septal defect, or patent ductus arteriosus, which lead to chronic overperfusion of the pulmonary vasculature. Over time, pulmonary arterial pressures may become significant enough to reverse the direction of flow across the shunt. This reversal of shunt flow to a right-to-left pattern defines Eisenmenger syndrome. The estimated maternal mortality rate for Eisenmenger syndrome is between 30% and 40%.^{50,51} In a review of 73 patients with Eisenmenger syndrome, the overall mortality rate was 36%, which has been essentially unchanged during the past 2 decades.⁵⁰

The underlying problem in patients with this condition is obstruction to right ventricular outflow caused by a fixed and elevated pulmonary vascular resistance. This can ultimately lead to right-to-left shunting of deoxygenated blood with resultant hypoxemia. Reductions in blood return to the heart can decrease right ventricular preload so that the pulmonary vasculature is further hypoperfused. The resultant hypoxemia has been associated with sudden death. Intrapartum management requires maintenance of a relatively hypervolemic state, and any interventions that may lead to significant reduction in preload or decrease in SVR should be avoided. Placement of a PAC may be quite challenging in these patients, and many experts believe the risks of placement may outweigh any potential benefit.

Anaphylactoid Syndrome of Pregnancy

Anaphylactoid syndrome of pregnancy (i.e., amniotic fluid embolus) is a rare but devastating complication of pregnancy characterized by acute onset of hypoxia, hypotension or cardiac arrest, and coagulopathy occurring during labor, during delivery, or within 30 minutes after delivery.^{52,53} This same constellation of findings may have other causes, such as hemorrhage, uterine rupture, or sepsis, and each should be excluded before assigning a diagnosis of amniotic fluid embolism. The combination of sudden cardiovascular and respiratory collapse with a coagulopathy is similar to that observed in patients with anaphylactic or septic shock. In each of these settings, a foreign substance (e.g., endotoxin) is introduced into the circulation. This initiates a cascade of events resulting in activation and release of mediators such as histamines, thromboxane, and prostaglandins, which lead to disseminated intravascular coagulation (DIC), hypotension, and hypoxia. The

inciting factor is presumed to be present in amniotic fluid that is introduced into the maternal circulation, but the precise factor that initiates the sequence have not been identified. It is a commonly held misconception that the presence of fetal debris in the pulmonary circulation is diagnostic of an amniotic fluid embolus. Fetal debris can be found in the pulmonary circulation in most normal laboring patients, and it is identified only in 78% of patients who meet the criteria for the diagnosis of amniotic fluid embolism.^{52,53}

Management of amniotic fluid embolism is entirely supportive. Replacement of blood and clotting factors, adequate hydration and blood pressure support, ventilatory support, and invasive cardiac monitoring in addition to resuscitation efforts usually are required for these patients. The data suggest mortality rates approach 61% or higher. Most patients do not survive the initial course and die within 5 days. For those who survive, neurologic impairment is common.⁵²

Hypertensive Disorders of Pregnancy

Most clinical hemodynamic monitoring studies in obstetrics have enrolled patients with hypertensive disorders of pregnancy (see Chapter 35). From a purely clinical perspective, clear indications for this invasive technology have not been established. Arguments for its use center on reports demonstrating a broad spectrum of hemodynamic findings in this group of patients. For patients identified to be relatively hypovolemic, optimizing intravascular volume status should improve uteroplacental perfusion, reduce SVR, and blunt hypotensive complications associated with conduction anesthesia and antihypertensive therapy. Oliguria (particularly if unresponsive to fluid therapy) and refractory pulmonary edema, both recognized complications of severe preeclampsia, may also be better defined and managed with invasive monitoring.

Vasospasm is a central feature of preeclampsia. In one series of 51 untreated preeclamptic patients, an elevated SVR value was identified with invasive monitoring.⁵⁴ Preeclampsia likely represents an overall vasoconstrictive condition that is frequently influenced by underlying disease processes such as chronic hypertension, duration and severity of illness, and various therapeutic modalities.

Using ventricular function curves that correlate PCWP (i.e., left ventricular preload) with left ventricular stroke work index (i.e., myocardial contractility), investigators found that most preeclamptic and eclamptic patients fall into a relatively hyperdynamic range.⁵⁵ The values shown in Figure 57-5 are superimposed on ventricular function graphs derived from nonpregnant subjects. The preeclamptic patient probably has at least a normal and probably a somewhat hyperdynamic functioning heart during pregnancy. As expected, this cardiac function, as estimated by CO, appears to be inversely related to SVR.

Some investigators have recommended that patients with pregnancy-induced hypertension be classified by different hemodynamic subsets so that management protocols can be tailored to individual needs. Clark and associates⁵⁶ first reported the use of this approach for dealing with the oliguric preeclamptic patient. They found that these patients had low PCWP values (i.e., hypovolemic) and elevated SVR (i.e., severe vasoconstriction) or were volume replete with normal to elevated vascular resistances. A third group had markedly elevated PCWP and SVR readings with depressed cardiac function.⁵⁶ Management of these groups of oliguric patients varies. In the first subset, patients respond favorably to volume expansion therapy. The next two groups of patients are best managed with vasodilators and aggressive afterload reduction therapy.

Another important issue in the management of oliguric patients with preeclampsia is the use of standard urinary diagnostic indices, such as urine-to-plasma ratios of osmolality, urea nitrogen, and creati-

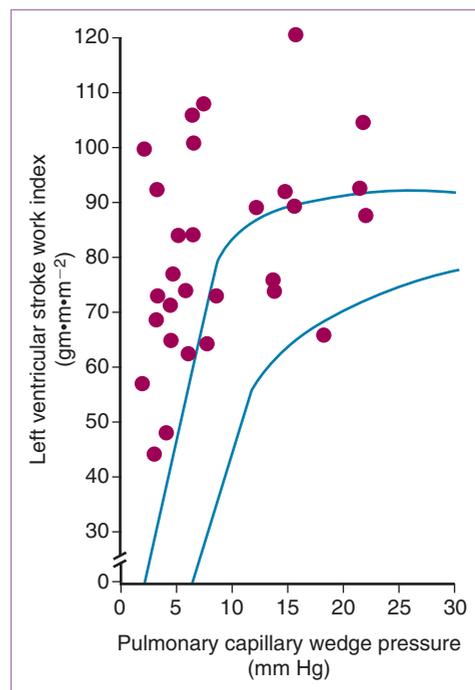

FIGURE 57-5 Ventricular function in pregnancy-induced hypertensive patients. On plots of ventricular function curves that correlate pulmonary capillary wedge pressure with left ventricular stroke work index, most preeclamptic and eclamptic patients fall into a relatively hyperdynamic range. (Combined data from Benedetti TK, Cotton DB, Read JC, et al: Hemodynamic observations in severe pre-eclampsia with a flow-directed pulmonary artery catheter. *Am J Obstet Gynecol* 136:465, 1980; Hankins GDV, Wendel GP, Cunningham FG, et al: Longitudinal evaluation of hemodynamic changes in eclampsia. *Am J Obstet Gynecol* 15:506, 1984; Phelan JP, Yurth DA: Severe preeclampsia. I. Peripartum hemodynamic observations. *Am J Obstet Gynecol* 144:17, 1982; and Rafferty TD, Berkowitz RL: Hemodynamics in patients with severe toxemia during labor and delivery. *Am J Obstet Gynecol* 138:263, 1980.)

nine or fractional excretion of sodium. Although these urinary parameters are routinely used in non-obstetric patients to differentiate prerenal and renal causes of oliguria, they have proved to be unreliable in patients with preeclampsia. In preeclampsia complicated by oliguria, urinary diagnostic indices may suggest a prerenal cause despite normal intravascular volume, demonstrated by invasive pressure measurement determinations. From a physiologic standpoint, it is postulated that the kidney misinterprets local renal artery vasospasm to indicate a volume-depleted state.

Septic Shock

Septic shock refers to the systemic inflammatory response syndrome associated with infection, persistent hypotension, and major organ dysfunction despite initial fluid resuscitation.⁵⁷ Although the hemodynamic effects of septic shock have been well described in the non-obstetric literature, limited information is available for obstetric patients. One study described the hemodynamic profiles of 10 obstetric patients at various gestational ages, who were identified to have septic shock and required invasive monitoring. In this small series, SVR and myocardial function were depressed but improved with therapy.⁵⁸ Mabie and coworkers⁵⁹ described similar findings in a more recent series of 18 obstetric patients with septic shock. The main hemody-

dynamic characteristics of those who succumbed to septic shock included lower blood pressure, stroke volume, and left ventricular stroke work index than survivors.⁵⁹ Sepsis and septic shock are addressed in more detail later in this chapter.

Noninvasive Hemodynamic Assessment

The PAC is the gold standard for measurement of hemodynamic status in the critically ill patient. However, according to available data, use of the PAC to guide therapy does not favorably affect survival and carries substantial risks.

Transesophageal echocardiography (TEE) has emerged as a noninvasive tool for the bedside assessment of the hemodynamic status of nonpregnant, critically ill adults. In an anesthetized patient, a small transducer is introduced into the esophagus and real-time data collected. TEE can accurately measure left ventricular preload, left ventricular filling pressure, CO, left ventricular ejection fraction, and severe right ventricular dysfunction.⁶⁰⁻⁶² TEE is often used in hypotensive patients to determine the cause of the hypotension, such as inadequate filling or depressed contractility (Table 57-4). TEE can detect other abnormalities, including left ventricular obstruction, structural abnormalities, proximal pulmonary emboli, and valvular disease. It is also useful in evaluating the left atrium and mitral valve because of the proximity of these structures to the transducer, and it appears to be superior in evaluating congenital cardiac defects.

Only a few small series have compared data derived from a PAC with two-dimensional transthoracic and Doppler echocardiography in obstetric patients. In one report of 12 patients requiring PAC for preeclampsia management, CO measured by Doppler echocardiography correlated well with CO assessed by thermodilution using a PAC.⁶³ Another study of 16 obstetric patients found good correlation between thermodilution assessment of CO and Doppler echocardiography.⁶⁴ In a study of 11 critically ill obstetric patients, Belfort and colleagues⁶⁵ demonstrated no difference between Doppler echocardiographic and PAC-derived estimation of stroke volume, CO, cardiac index, left ventricular filling pressure, pulmonary artery systolic pressure, and right atrial pressure.⁶⁵ The data from these reports are encouraging, but echocardiographic estimation of pulmonary artery pressure was significantly overestimated in 32% of obstetric patients with suspected pulmonary artery hypertension.⁶⁶ The technique appears to be well-tolerated, but further study is warranted.

TABLE 57-4 ORIGIN OF HYPOTENSION

End-Diastolic Cross-Sectional Area	Ejection Fraction	Cause
Decreased	>0.8	Hypovolemia
Increased	<0.2	Left ventricular failure
Normal	>0.5	Low SVR or severe MR, AR, or VSD

AR, aortic regurgitation; MR, mitral regurgitation; SVR, systemic vascular resistance; VSD, ventricular septal defect.

From Cahalan MK: *Intraoperative Transesophageal Echocardiography: An Interactive Text and Atlas*. New York, Churchill Livingstone, 1996.

Respiratory Failure

Substantial anatomic and physiologic changes occur over the course of pregnancy that impact respiratory function (see Chapter 7). Minute ventilation increases in a normal pregnancy and is determined by respiratory rate and tidal volume. The 40% increase in tidal volume (i.e., amount of air exchanged during a cycle of inspiration and expiration) primarily drives the increase in minute ventilation. As a result, the levels of CO₂ decline, creating an alkalotic state. To accommodate for the decrease in CO₂, the kidneys excrete bicarbonate (HCO₃⁻). An arterial blood gas determination in a normal pregnant woman therefore reflects a slightly increased pH, decreased PCO₂, and decreased serum HCO₃⁻ (i.e., respiratory alkalosis with compensatory metabolic acidosis), as outlined in Table 57-5. As the pregnancy progresses, increasing abdominal girth leads to an upward displacement of the diaphragm, widening of the subcostal angle by 50%, and increased chest circumference. The end result is a decrease in the functional residual capacity by 20%. The functional residual capacity reflects the amount of air remaining in the alveoli at the completion of expiration. As the functional residual capacity decreases, the alveoli collapse, and gas exchange decreases.⁶⁷

Common causes for respiratory failure in pregnancy include pulmonary edema, asthma, infection, and pulmonary embolus.^{68,69} In a series of 43 gravidas requiring mechanical ventilation while undelivered, 86% delivered during the admission, and of these, 65% underwent cesarean section, with an associated mortality rate of 36% for those delivered by cesarean section. Overall maternal and perinatal mortality rates were high (14% and 11%, respectively).⁶⁸

Debate continues about whether delivery improves respiratory status in these patients. Tomlinson and coworkers⁷⁰ described their experience with 10 patients who delivered while mechanically ventilated. In all but one patient, the cause of respiratory failure was pneumonia.⁷⁰ The only demonstrable benefit after delivery was a 28% reduction in FIO₂ in the ensuing 24 hours. The investigators concluded that routine delivery of these patients was not recommended. This is the only study published that was designed specifically to address this question. However, data from other series support the conclusion that delivery does not uniformly result in significant maternal improvement. Mortality rates after delivery while requiring ventilatory support range from 14% to 58%, and cesarean section may further increase this risk.^{68,69,71}

TABLE 57-5 CHANGES IN ARTERIAL BLOOD GAS MEASUREMENTS IN PREGNANCY

Measurements	Pregnant Values	Nonpregnant Values
pH	7.4-7.46	7.38-7.42
PCO ₂ (mm Hg)	26-32	38-45
PO ₂ (mm Hg)	75-106	70-100
HCO ₃ ⁻ (mEq/L)	18-21	24-31
O ₂ saturation (%)	95-100	95-100

Modified from Dildy G, Clark SL, Phelan JP, et al: *Maternal-fetal blood gas physiology*. In *Critical Care Obstetrics*, 4th ed. New York, Blackwell, 2004.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is characterized by rapid onset of progressive respiratory distress. Evaluation reveals bilateral pulmonary infiltrates without evidence of cardiac failure or increased hydrostatic pressure (i.e., PCWP < 18 mm Hg). These patients require high concentrations of oxygen and frequently need intubation. ARDS is also defined by a diminished ratio of the partial pressure of oxygen to the fraction of inspired oxygen ($\text{PaO}_2/\text{FiO}_2 \leq 200$). If the ratio falls between 200 and 300, acute lung injury is present that is not severe enough to be called ARDS.

In pregnant women, infections with varicella or herpes simplex virus, severe preeclampsia, eclampsia, and hemorrhage most commonly precipitate respiratory failure.^{68,72} Septic patients are at particular risk for developing acute pulmonary injury and ARDS as a consequence of pulmonary vascular damage that facilitates the leakage of intravascular fluid into the pulmonary interstitial spaces. Mortality rates are quite high, and patients who survive often have pulmonary function compromised by fibrosis and scarring of pulmonary tissue.

The treatment of ARDS focuses on identifying and treating underlying causes such as infection and then providing respiratory, hemodynamic, and nutritional support to facilitate lung healing. Respiratory support may precipitate additional lung injury, and efforts to maintain adequate oxygen delivery should also minimize lung trauma in an effort to facilitate healing of the lungs.

Management of respiratory failure in nonpregnant, critically ill patients has historically used a goal of maintaining a tidal volume of 10 to 15 mL/kg. In ARDS, high tidal volumes may lead to alveolar overdistention or repeated recruitment and collapse of alveoli, predisposing to alveolar damage and release of inflammatory mediators that worsen pulmonary damage. In 2000, the ARDSNet published results of 861 patients with ARDS randomized to traditional tidal volumes (12 mL/kg) or to a low tidal volume of 6 mL/kg.⁷³ The traditional tidal volume group also maintained a goal of 50 cm of H₂O or less, compared with lower peak pressures of 30 cm of H₂O in the low tidal volume group. Low tidal volumes and lower peak pressures were associated with lower mortality rates (31% versus 40%) and shorter periods of intubation compared with conventional tidal volumes and peak pressure goals. Increased tidal volume and other normal changes in pulmonary physiology may affect the utility of this approach in pregnant women.

Prone Ventilation

Mechanical ventilation in the prone position has improved oxygenation in up to 80% of patients with ARDS and acute lung injury. Approximately 50% of patients maintain improved oxygenation after they return to the supine position.⁷⁴ Mechanical ventilation in the prone position is believed to achieve several beneficial physiologic changes: improved aeration of well-perfused dorsal atelectatic lung areas, improved alveolar recruitment, relief of cardiac compression on the lung posteriorly, and improved mobilization of secretions.

Several randomized trials have compared supine with prone positioning in nonpregnant patients with ARDS and acute lung injury. In one randomized trial of 304 patients, prone positioning maintained for an average of 7 hours daily was not associated with a decrease in mortality, but significant improvement in oxygenation was observed in 70% of patients, with most of the benefit occurring in the first hour of prone positioning.⁷⁵ Another multicenter, randomized trial of 791 patients with hypoxemic respiratory failure with multiple causes, including ARDS, found similar results. In addition to improved oxygenation with prone positioning at least 6 hours daily, a decrease in

ventilator-associated pneumonia was observed. However, no difference in mortality was demonstrated by prone positioning.⁷⁶ Only one study has shown a mortality benefit with early and prolonged prone positioning of ARDS patients. The major difference in this study was the length of time patients were maintained prone—on average 17 hours daily for a mean of 10 days. The 136 patients were randomized within 48 hours of intubation.⁷⁷

Prone positioning can be accomplished manually or with a special bed designed to rotate the patient. Complications related to prone positioning include pressure sores, endotracheal tube displacement or obstruction, loss of venous access, vomiting, and edema. Data on prone ventilation in the pregnant patient are lacking. Anticipated problems include the gravid abdomen and difficulties in accomplishing fetal monitoring while prone.

Pulmonary Edema

Pregnant women are predisposed to developing pulmonary edema for various reasons, including increased plasma volume and CO in conjunction with decreased colloid oncotic pressure (COP), which occurs normally over the course of pregnancy. Alterations in the balance of hydrostatic and oncotic pressure between the pulmonary vessels and the interstitial spaces can lead to an egress of fluid from the vascular space into the interstitium and manifest clinically as pulmonary edema. Approximately 1 in 1000 pregnancies is complicated by pulmonary edema. In a review of almost 63,000 pregnancies, Sciscione and coworkers⁷⁸ reported pulmonary edema occurring most often during the antepartum period (47%), with 39% occurring in the postpartum period and the remaining 14% in the intrapartum period.⁷⁸ In this series, the two most common attributable causes of pulmonary edema were cardiac disease and tocolytic use (25.5% each). The remaining cases of pulmonary edema were caused by fluid overload (21.5%) and preeclampsia (18%). The management of patients with pulmonary edema is focused on establishing the diagnosis, determining the cause, and improving oxygenation.

Colloid Oncotic Pressure Abnormalities

Four forces affect fluid balance between vascular and interstitial spaces. The COP is the force exerted primarily by albumin and other proteins within the capillary, which holds fluid within the vascular space. The oncotic pressure within the interstitial space also works to hold fluid in the interstitium. Hydrostatic forces within the vessel and the interstitium exert the opposite effect.

COP decreases over the course of pregnancy, and by term, it approximates 22 mm Hg.⁷⁹ This is approximately 3 mm Hg lower than pre-pregnancy values as a result of the dilutional effect from plasma expansion. An isolated decrease in oncotic pressure, as may occur in pregnancy or in patients with nephrotic syndrome, is usually well compensated and does not lead to pulmonary edema unless complicated by additional factors such as increased intravascular pressure or pulmonary injury resulting in vascular permeability.⁸⁰ Excessive intravenous fluids, blood loss, decreasing COP after delivery, and the postpartum autotransfusion effect can place patients at further increased risk for pulmonary edema.

Hydrostatic or Cardiogenic Pulmonary Edema

Pulmonary edema due to primary cardiac issues with or without alterations in COP is referred to as *hydrostatic* or *cardiogenic pulmonary*

edema. CO is controlled through continuous adjustments in heart rate and stroke volume. At some point, the heart is no longer able to increase the CO in response to increasing preload because of intrinsic cardiac abnormalities or excessive fluid administration, resulting in overload. If left ventricular outflow is restricted, blood intended to empty into the left atrium remains in the pulmonary vasculature, which is reflected by the increased PCWP, left ventricular end-diastolic pressure, and pulmonary artery pressure. The net result is an increase in the pulmonary intravascular hydrostatic pressure. When this pressure exceeds the interstitial pressures, fluid is forced out of the pulmonary vasculature into the interstitial spaces, resulting in pulmonary edema.

A transthoracic or transesophageal echocardiogram can distinguish whether pulmonary edema is cardiogenic in origin. Evidence of poor ventricular systolic function is identified by a decreased ejection fraction, as seen in patients with a cardiomyopathy. Echocardiography may also identify valvular abnormalities that may lead to compromised cardiac function and predispose patients to pulmonary edema, such as aortic or mitral stenosis.

Pulmonary Edema in the Setting of Preeclampsia

Pulmonary edema develops in approximately 2.5% of patients with preeclampsia, most commonly in the postpartum period.^{43,81,82} The cause is not completely understood, but it likely results from a combination of problems. Impaired left ventricular function may be a result of chronic hypertension, particularly if it develops in the antepartum period. Substantially increased SVR may also impair left ventricular function and lead to pulmonary edema, especially in the setting of iatrogenic fluid overload. Preeclamptic patients often lose significant amounts of albumin through the urine and exhibit decreased albumin production, both of which can lower the COP. In preeclamptic patients, the COP can decrease to 18 mm Hg by term and drop further after delivery to 14 mm Hg.⁴³ Endothelial damage also leads to increased capillary permeability. Preeclamptic patients with pulmonary edema that fails to respond to oxygen, diuresis, and fluid restriction, especially when combined with oliguria, may require pulmonary artery catheterization to guide further therapy. In a series of 10 patients with severe preeclampsia who underwent placement of a PAC, the findings varied. Five patients demonstrated a decreased gradient between the COP and PCWP, but two patients had a cardiac explanation for the pulmonary edema, and three patients had increased pulmonary vascular permeability.⁸³

Tocolytic-Induced Pulmonary Edema

In the past, the use of parenteral β -agonists such as terbutaline and ritodrine was more common and became associated with the development of pulmonary edema.^{78,84} However, as the use of intravenous β -agonists for tocolysis has decreased, the incidence of pulmonary edema related to tocolytic use appears to have diminished. Magnesium does not appear to independently increase the risk of pulmonary edema.⁸⁵

Shock

Shock is the physiologic response to impaired tissue oxygenation. Oxygen deficiency at the cellular level may result from inadequate delivery of oxygen, such as in hypovolemic states, cardiac failure, and hemorrhage or from improper uptake or use of oxygen, as in septic

states and neurogenic shock. In obstetric patients, shock most commonly results from hemorrhage and sepsis. Regardless of the cause, therapy is directed at restoring tissue oxygenation by eliminating the originating cause, providing adequate volume replacement, and improving cardiac function and circulation. Difficulty in reversing this phenomenon explains the high mortality rates for patients with shock.

Sepsis and Septic Shock

Incidence and Mortality

Sepsis accounts for 9.3% of deaths occurring in the United States and complicates approximately 1 in 8000 deliveries.⁸⁶ Fortunately, only a small percentage of these deaths can be attributed to gynecologic or obstetric problems. Bacteremia is not uncommon in obstetric patients, but these patients appear to be less likely to progress to septic shock.^{59,87,88} An epidemiologic review of sepsis in the United States gathered discharge data on more than 10 million cases of sepsis over a 22-year period ending in 2000.⁸⁹ According to this study, the incidence of sepsis in the population is increasing at a rate of 8.7% annually. However, the percentage of pregnant women diagnosed with sepsis in that period decreased by 50%, from 0.6% to 0.3%. African Americans and men appear to be at higher risk for developing sepsis, but mortality rates did not appear to differ from those of whites and women, respectively.

Mortality rates overall have declined significantly to approximately 17%, but the marked increase in sepsis diagnosis in the population accounts for tripling of the rate of hospital death from sepsis. Between 1987 and 1997, infectious causes accounted for 13% of maternal deaths.^{10,11} Mortality rates associated with septic shock in pregnancy are uncertain and are derived primarily from older, small series of cases, but they generally appear to be much lower than for the nonpregnant population. Estimates range from 12% to 28% for obstetric septic patients^{58,59,87,90} to 40% to 80% for the nongravid population.⁹¹ Improved outcomes for pregnant patients have been attributed to a younger patient population, type of organisms, sites of infection more easily accessed and treated, and lower rates of coexistent diseases.

Definitions

The American College of Chest Physicians and the Society of Critical Care Medicine published consensus guidelines in 1991 that were designed to create consistency in the definitions used to describe septic conditions. Updated guidelines were published in 2003.⁵⁷ These definitions represent the understanding that these conditions exist along a continuum of increasing severity while sharing a common pathophysiology. This continuum begins after the body develops a systemic response to an infection and may progress to multiorgan dysfunction with hemodynamic instability and even death.

The later classification system questions the utility of the diagnosis of systemic inflammatory response syndrome (SIRS), suggesting that the criteria previously set forth are too sensitive and nonspecific. SIRS was defined as the clinical response to infection manifested by two or more of the following: temperature of 38° C or higher or 36° C or lower; pulse of 90 beats/min or higher; respiration rate of 20 breaths/min or higher or a PaCO₂ less than 32 mm/Hg; or a white blood cell count of 12,000 or more or 4000 or less or more than 10% immature neutrophils. When SIRS criteria are met and infection is confirmed or suspected, the patient is then considered to be septic. The latest guidelines expanded on this concept in the definitions (Table 57-6). These definitions do not take into account the physiologic changes of pregnancy and therefore may overdiagnose sepsis.

TABLE 57-6 DIAGNOSTIC CRITERIA OF SEPSIS SYNDROMES

Condition	Definition
Infection	Pathologic process caused by the invasion of normally sterile tissue or fluid or body cavity by pathogenic or potentially pathogenic microorganisms
Bacteremia	Presence of bacteria in the bloodstream
Sepsis	Systemic inflammation accompanied by infection
Severe sepsis	Sepsis complicated by major organ dysfunction
Septic shock	Persistent unexplained arterial hypotension in the setting of severe sepsis

Data from Levy MM, Fink MP, Marshall JC, et al: 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference. *Crit Care Med* 31:1250-1256, 2003.

Gram-positive organisms have surpassed gram-negative organisms as the most common cause of sepsis in the general population, unlike the situation for pregnant patients. Common organisms isolated from pregnant patients in septic shock include *Escherichia coli*, groups A and B streptococci, *Klebsiella* species, and *Staphylococcus aureus*.⁵⁹ The source of infection in pregnant women is typically the genitourinary tract and includes lower urinary tract infections, pyelonephritis, chorioamnionitis, endometritis, and rarely, septic abortion, necrotizing fasciitis, and toxic shock syndrome.^{58,59,87,88,92}

Pathophysiology of Sepsis

Sepsis is a complex phenomenon that originates with invasion of the host by an offending organism. After infection, macrophages are recruited, bind to the organism, and initiate a collection of responses resulting in the activation of the inflammatory and coagulation cascades. Initially, the sepsis response was postulated to be the result of an exaggerated inflammatory response. Initial pharmacologic approaches therefore targeted suppression of the inflammation process, including corticosteroids and agents to block cytokines such as tumor necrosis factor α (TNF- α) and interleukin 1 β (IL-1 β).⁹³ These approaches have been largely unsuccessful, a testament to the complexity of the sepsis syndromes. The roles of anti-inflammatory mediators and genetics in the sepsis cascade has been increasingly appreciated.⁹⁴ Activation of the inflammatory cascade after infection causes release of interleukins, tumor necrosis factors, interferons, prostaglandins, platelet-activation factor, oxygen free radicals, nitric oxide, complement, and fibrinolysins.⁹⁵

Hemostatic mechanisms are also affected in severe sepsis. Initiation of the clotting cascade results from macrophages and monocytes involved in production of inflammatory mediators. Endothelial damage also contributes to the procoagulant effect, causing platelet activation and suppression of protein C activity. These derangements in the hemostatic balance lead to clotting factor consumption, fibrin deposition, thrombin generation, and decreased platelet levels.⁹⁶ The resultant microthrombi are thought to negatively affect end-organ damage and contribute to the clinical features of severe sepsis and septic shock, such as oliguria, ARDS, and hepatic dysfunction. In severe cases, consumption of clotting factors is substantial enough to cause hemorrhagic complications from DIC. Figure 57-6 outlines the sepsis cascade.

Clinical Manifestations

Septic shock has been classified as three progressive clinical stages: warm shock, cold shock, and irreversible (secondary) shock, which are

summarized in Table 57-7. The initial phase is characterized by vasodilation, increased capillary permeability, and endothelial damage. Clinically, the patient may have evidence of infection or fever and may have positive blood cultures. Peripheral vasodilation causes flushing and warm extremities. It also leads to a decrease in blood pressure with diminished cardiac preload, which leads to a tachycardic response in an effort to maintain or increase the CO. Initial laboratory findings vary. An elevated white blood cell count may be followed by neutropenia. Hyperglycemia is typical as a result of altered adrenal responsiveness, insulin resistance, and increased levels of catecholamines and cortisol.

If uninterrupted, sepsis progresses and is characterized by intense vasoconstriction. This leads to poor perfusion, which is manifested by cool extremities and altered organ function as a result of inadequate oxygenation (i.e., cold shock). Oliguria is typical, as are respiratory failure and ARDS. The CO decreases as a result of inadequate venous return and increasing peripheral resistance. In the advanced stages of septic shock (i.e., secondary or irreversible shock), symptoms progress and reflect the global effects of inadequate tissue perfusion and oxygenation: hypotension, respiratory failure, renal failure, DIC, myocardial depression, electrolyte disturbances, obtundation, and metabolic acidosis.

Management

If the patient is at a viable gestational age and is undelivered with evidence of sepsis or septic shock, the fetal status should be monitored closely with continuous fetal heart rate monitoring and ultrasound evaluation to estimate fetal weight, assess amniotic fluid volume, and confirm gestational age. Uterine perfusion and oxygenation are adversely affected as the sepsis progresses. Contractions are often encountered, possibly as a result of decreased uterine perfusion and decreased oxygen delivery to the myometrium. Tocolysis should be undertaken with caution because the side effects of the medications (e.g., tachycardia, vasodilation) may impair physiologic adaptations to sepsis. If maternal status can be corrected and fetal status remains reassuring, delivery can be avoided. The decision about whether to proceed with delivery may be challenging, particularly if maternal status is deteriorating. The fetus may not tolerate labor because of poor uterine perfusion and maternal hypoxemia; conversely, the mother may be too unstable to safely undergo a surgical procedure. If the source of infection is the uterus, as in septic abortion or chorioamnionitis, evacuation of the uterus is necessary.

Sepsis management has several goals:

- Identification of the source of infection
- Institution of empiric antibiotic therapy
- Early, aggressive improvement in circulating volume
- Optimization of hemodynamic performance
- Maintenance of oxygenation
- Volume resuscitation

Aggressive fluid replacement to improve circulating intravascular volume is a mainstay of sepsis management and has improved CO, oxygen delivery, and survival. Studies have demonstrated a survival benefit for patients with septic shock managed with protocol-driven, early, aggressive volume resuscitation. Early goal-directed therapy (EGDT) involves tailoring treatments and resuscitative efforts to achieve specified endpoints, which include normal mixed venous oxygen saturation, arterial lactate concentration, base deficit, and pH in an effort to reduce end-organ dysfunction and ultimately reduce mortality.

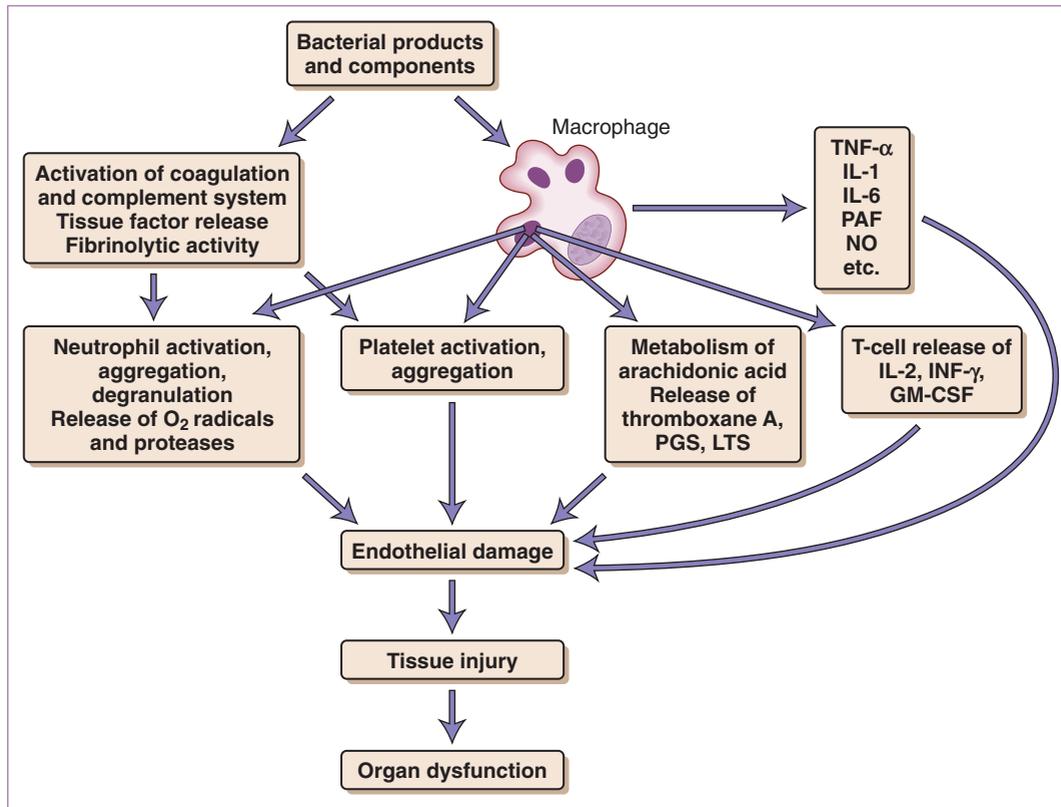

FIGURE 57-6 The sepsis cascade. Hemostatic mechanisms are affected in patients with severe sepsis, and derangements in the hemostatic balance lead to clotting factor consumption, fibrin deposition, thrombin generation, decreased platelets, tissue injury, and organ dysfunction. GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; LTS, leukotrienes; NO, nitric oxide; PAF, platelet-activating factor; PGS, prostaglandin synthesis; TNF- α , tumor necrosis factor α . TABLE 57-7 STAGES OF SHOCK

Warm (Early) Shock	Cold (Late) Shock	Secondary (Irreversible) Shock
Flushing	Cyanosis	Renal failure
Warm extremities	Cool extremities	Disseminated intravascular coagulopathy
Rapid capillary refill	Delayed capillary refill	Myocardial failure
Decreased mental status	Increased vascular resistance	Refractory hypotension
Hypotension	Decreased cardiac output	Obtundation
Increased cardiac output	Respiratory failure or adult respiratory distress syndrome	
Tachycardia	Oliguria	
Tachypnea		

In 2001, Rivers and colleagues⁹⁷ published the results of a prospective, randomized trial of EGDT compared with standard therapy for patients in septic shock in a single institution. Therapy for patients in the EGDT group was initiated in the emergency room setting before transfer to the intensive care unit and included placement of central venous catheters with the ability to measure continuous venous oxygen saturation (ScvO₂). An elevated ScvO₂ value reflects inadequate perfusion and uptake of oxygen in the tissues. Red blood cell transfusions were administered to maintain the hematocrit at 30% or higher, and inotropic agents were added if the ScvO₂ level was inadequately corrected (<70%). The protocol called for a 500-mL crystalloid bolus every 30 minutes until the CVP reached 8 to

12 mm Hg. The volume of fluid administered to both groups of patients was similar in the first 72 hours (>13 L), but the EGDT group received more volume in the initial 6 hours of therapy (5 versus 3.5 L). This aggressive approach decreased the mortality rate by 16% (30.5% versus 46.5%).

Clinicians have questioned whether modification of this protocol, particularly elimination of continuous venous oxygen saturation (ScvO₂), could produce similar results. In 2006, Lin and coworkers⁹⁸ randomized patients to EGDT without measurement of ScvO₂ and confirmed survival benefit. Patients randomized to receive modified EGDT were significantly less likely to die (71.6% versus 53.7%), spent fewer days in the hospital, were intubated for a shorter time, and were

at less risk for developing sepsis-associated central nervous system and renal dysfunction compared with controls.

Because of the encouraging survival and morbidity data, EGDT is being widely adopted in the management of severe sepsis, but it remains to be confirmed whether this approach will produce similarly improved outcomes in a pregnant population. The precise goals to appropriately guide therapy in a pregnant population also must be defined.

Optimization of Hemodynamic Performance

In addition to replacing intravascular volume to improve perfusion and cardiac preload, early pharmacologic interventions to improve vascular tone, cardiac contractility, and cardiac preload confer a considerable survival advantage.^{97,98} If the patient fails to respond appropriately to aggressive fluid resuscitation efforts, vasopressors are indicated to improve vascular tone, resulting in improved cardiac return and CO, peripheral perfusion, and oxygen delivery. In the initial publication on EGDT, the requirement for vasopressors was significantly diminished by early, aggressive fluid resuscitation (37% versus 51%), but there was no difference in the requirement for inotropic agents between the two groups (9% versus 15%).⁹⁷ In this study, vasopressors were initiated to maintain mean arterial pressure above 65 mm Hg. Use of a similar protocol minimized the delay in initiation of vasopressors and reduce mortality.⁹⁸

Dopamine hydrochloride is the most commonly employed first-line vasopressor in the intensive care setting. Dopamine's α - and β -adrenergic effects are dose dependent. Low doses (<10 $\mu\text{g}/\text{kg}/\text{min}$) improve myocardial contractility, CO, and renal perfusion without negatively affecting myocardial oxygen consumption. As the dose increases (>20 $\text{mg}/\text{kg}/\text{min}$), α -adrenergic effects predominate, resulting in increasing SVR in addition to increased CO. In a viable gestation requiring vasopressor support, fetal monitoring is essential because dopamine has decreased uterine perfusion in an animal model.⁹⁹ Dobutamine is similar to dopamine, but it has primarily β_1 -adrenergic effects. Dobutamine therefore improves CO with minimal impact on heart rate or vascular resistance. In the EGDT protocol, dobutamine was used to improve oxygen consumption in patients who failed to respond to fluid resuscitation, dopamine infusion to improve mean arterial pressure, and red cell transfusion to correct anemia.⁹⁷ Table 57-8 lists other commonly used vasopressor agents for the management of severe sepsis and septic shock.

Source Control and Antimicrobial Therapy

Prompt identification of the probable source of infection is essential to initiate appropriate antimicrobial therapy and improve outcomes for septic patients. In an obstetric population, common sources of

infection are the uterus and genitourinary tract, and gram-negative bacteria constitute the primary organisms. In the non-obstetric population, gram-positive organisms represent most of the organisms isolated in septic patients, followed closely by gram-negative bacteria.⁸⁹ Cultures should be collected from blood and any suspected site, including the uterus if necessary, for identification of the organism and determination of antibiotic sensitivities. Empiric antimicrobial therapy targeted at the suspected organism should not be delayed pending culture results.¹⁰⁰⁻¹⁰³

In an obstetric and postpartum population, antibiotic coverage usually consists of β -lactam antibiotics (i.e., penicillins, cephalosporins, carbapenems, and monobactams) with or without an aminoglycoside (see Chapter 38). Monotherapy with a carbapenem or third- or fourth-generation cephalosporin is as effective as a β -lactam antibiotic in combination with an aminoglycoside in non-neutropenic patients with severe sepsis.¹⁰⁴ In undelivered patients, tetracycline derivatives and quinolones should be avoided. When culture results become available, antibiotic therapy can be adjusted if necessary.

After appropriate antibiotic therapy has been initiated and the process of stabilization of the patient has begun, attention should be directed to source control. This entails removal of indwelling lines and catheters, with replacement if necessary. Indications for more aggressive surgical approaches are less clearly defined. Generally, more invasive surgical approaches are not emergent and can be accomplished after the condition of the patient has stabilized.¹⁰⁵ Exceptions are infections involving clostridia and group A streptococci, such as necrotizing fasciitis. In this scenario, delay in excision of affected tissues can have a dramatic negative effect on the patient's condition.¹⁰⁶ Evaluation of the abdomen by ultrasound or computed tomography (CT) can assist in identification of an intra-abdominal abscess. When drainage of an intra-abdominal abscess is necessary, the percutaneous approach is preferable. In obstetric conditions, evacuation of the uterus by suction curettage in septic abortion or delivery of the neonate in viable gestations should occur after initiation of antibiotics and stabilization of the patient. Postpartum hysterectomy may be necessary if the patient fails to respond to antibiotics and the uterus is the suspected source.

Adjunctive Therapies in Sepsis Management

INSULIN THERAPY

In the critically ill population, hyperglycemia is a common phenomenon attributable to insulin resistance and escalations in glucagon, cortisol, and catecholamine levels, which promote glycogenolysis and gluconeogenesis.¹⁰⁷ In 2001, Van den Berghe and colleagues¹⁰⁸ published a large, prospective, randomized trial that demonstrated that tight glycemic control (blood glucose level of 80 to 110 mg/dL) in critically ill patients decreased overall mortality by 34%. Septic patients exhibited an even more impressive 76% reduction in mortality as a result of aggressive euglycemia with insulin therapy.¹⁰⁸ Other significant benefits of tight glycemic control included fewer ventilator days, less time in the ICU, decrease risk for developing septicemia, and a reduced need for dialysis.

Pregnant women demonstrate insulin resistance and to have higher circulating insulin levels than their nonpregnant counterparts. They are also predisposed to developing fasting hypoglycemia because of higher levels of insulin and continuous delivery of glucose to the fetus. However, the impact of aggressive euglycemia in the critically ill pregnant patient remains to be studied.

CORTICOSTEROIDS

Empiric administration of corticosteroids in high doses does not improve survival of unselected septic patients and may worsen out-

TABLE 57-8 INOTROPIC DRUGS FOR MANAGEMENT OF SHOCK

Agent	Dose	Hemodynamic Effect
Dopamine		
Low dose	<10 $\mu\text{g}/\text{kg}/\text{min}$	\uparrow CO, vasodilation of renal arteries
High dose	10-20 $\mu\text{g}/\text{kg}/\text{min}$	\uparrow CO, \uparrow SVR
Dobutamine	2.5-15 $\mu\text{g}/\text{kg}/\text{min}$	\uparrow CO, \downarrow SVR or \uparrow SVR
Phenylephrine	40-180 $\mu\text{g}/\text{min}$	\uparrow SVR
Norepinephrine	2-12 $\mu\text{g}/\text{min}$	\uparrow CO, \uparrow SVR
Isoproterenol	0.5-5 $\mu\text{g}/\text{min}$	\downarrow CO, \uparrow SVR

CO, cardiac output; SVR, systemic vascular resistance; \uparrow , increase; \downarrow , decrease.

comes because of secondary infection.^{109,110} However, as the pathophysiology of sepsis has become more clearly understood, the contribution of relative adrenal insufficiency in critically ill patients and the potential benefit of lower-dose, selective corticosteroid replacement have reemerged.

Stresses such as pain, fever, hypovolemia, or severe illness normally stimulate marked increases in cortisol levels. In the patient with septic shock, the adrenal gland may not respond to adrenocorticotropic hormone (ACTH) stimulus appropriately and fail to mount adequate corticosteroid production. In the setting of septic shock, however, the levels of cortisol may be increased overall, but the magnitude of increase after ACTH administration may be blunted. This phenomenon is described as relative adrenal insufficiency.^{111,112} This group of patients is being evaluated for potential benefit from lower doses of corticosteroids. A randomized trial conducted by Annane and colleagues¹¹³ demonstrated a survival benefit (mortality rate of 37% versus 47% for controls) for patients with septic shock treated with low-dose hydrocortisone and fludrocortisone. Patients who had documented blunted adrenal responsiveness also benefited from a reduced need for vasopressor support. All of these patients had elevated baseline cortisol levels. A 2004 meta-analysis of 16 trials that included more than 2000 patients suggested similar benefit from lower-dose steroid replacement in patients with severe sepsis and septic shock.¹¹⁴ Steroids did not appear to confer a mortality benefit when all data were included. However, inclusion of only studies utilizing low-dose (300 mg of hydrocortisone or an equivalent), longer-duration (5 to 11 days) therapy did demonstrate a decrease in overall mortality rates. The investigators recommended initiation of low-dose glucocorticoid replacement in septic patients with blunted adrenal responsiveness confirmed by an ACTH stimulation test.

The degree of adrenal suppression in pregnant or postpartum septic shock patients and the effect of low-dose steroids on outcomes in this population are unknown. If the patient remains undelivered, care should be taken in the choice of corticosteroids. Betamethasone and dexamethasone cross the placenta and have improved neonatal outcomes for premature infants. However, both can negatively impact neonatal outcomes when administered in large doses.¹¹⁵

ACTIVATED PROTEIN C THERAPY FOR SEVERE SEPSIS

One of the pathophysiologic mechanisms thought to contribute to morbidity and mortality in sepsis patients is inappropriate activation of the coagulation system. As a result, many trials have been performed involving various antithrombotic agents, including antithrombin III and tissue factor-pathway inhibitor, without successfully identifying a treatment to reduce mortality among septic shock patients.¹¹⁶ In contrast, activated protein C (APC, drotrecogin alfa) has been approved by the U.S. Food and Drug Administration (FDA) for use in severely septic patients at high risk for death as evidenced by an APACHE II score greater than 25.

Patients with severe sepsis have an acquired deficiency of protein C and are limited in their ability to convert protein C to its active form. These low protein C levels have been associated with poorer outcomes for severe sepsis patients.^{117,118} APC is believed to mediate the effects of severe sepsis in several ways. APC stimulates fibrinolysis and inactivates factors Va and VIIIa, resulting in inhibition of thrombin formation.^{94,119} Decreased thrombin formation then leads to decreased inflammation by inhibiting platelet activation, neutrophil recruitment, and mast cell degranulation. Two trials have evaluated APC's effect on mortality in patients with severe sepsis. In the Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS)

trial, a multicenter, randomized trial, APC administration to patients in septic shock decreased the 28-day mortality rate from 30.8% in the placebo group to 24.7% ($P = .005$) in the study group. This represents a 6.1% absolute reduction in overall mortality due to septic shock and a 13% reduction in the groups with the highest predicted mortality based on APACHE II scores.¹²⁰ A subsequent single-arm trial (EXTENDED Evaluation of Recombinant Human Activated Protein C [ENHANCE] trial) using APC in severe sepsis patients demonstrated a mortality rate (25.3%) similar to that seen in the PROWESS trial (24.7%). Patients who received the therapy in the first 24 hours after diagnosis of major organ dysfunction had the lowest mortality rate (22.9%).¹²¹

The most significant complication resulting from the use of APC is hemorrhage. In the PROWESS trial, 3.5% of patients receiving APC suffered a significant hemorrhagic event such as intracranial hemorrhage or need for transfusion, compared with a 2% incidence in the control group. The risk of bleeding appears to be greatest during the infusion period, because APC has a very short half-life. Because of this risk, APC is not indicated for all patients with septic shock, and its use should be limited to patients with greatest risk of mortality (i.e., APACHE II scores ≥ 25 and one major organ dysfunction). APC is contraindicated if the risk of bleeding is increased (i.e., active internal bleeding, hemorrhagic stroke in the preceding 3 months, intracranial or intraspinal surgery, severe head trauma in the preceding 2 months, trauma, or epidural catheter). The role of APC in managing obstetric patients has not been established. Significant changes in the coagulation cascade occur, including elevated factor VIII levels. The impact of these changes on the responsiveness to APC is unknown; however, pregnancy is not a contraindication to its use.

Hemorrhagic Shock

Incidence and Etiology

Obstetric hemorrhage is the leading cause of maternal death after an intrauterine gestation. The overall incidence of maternal death from hemorrhage is 1.4 per 100,000 live births. When ectopic gestations are excluded, placental abruption is the most common cause of death (18.5%).¹²² The cause of hemorrhage varies by pregnancy outcome; maternal deaths after a live birth are most likely associated with postpartum hemorrhage. Stillbirths are most likely to be associated with death from placental abruption, and undelivered pregnancies occur most often with lacerations or uterine ruptures.¹²² A significant increase in risk of death from hemorrhage is seen in nonwhite women and with advancing age. In an analysis of maternal morbidity and mortality, hemorrhage accounted for 39% of near-miss morbidities. The investigators estimated that 46% of these near-miss events were preventable and were related to communication issues, policies and procedures, failure to identify high-risk status, failure to transfer to a higher level of care, or inappropriate care. The presence of a significant disease state, such as preeclampsia, was also a contributor.¹²³

Causes of obstetric hemorrhage associated with an intrauterine gestation include placental abruption or previa, uterine rupture, surgical lacerations, invasive placentation, uterine inversion, and postpartum hemorrhage, usually caused by atony or retained products of conception. The source of hemorrhage can usually be determined by assessment of the patient. Concealed hemorrhage (e.g., abruption, liver capsule rupture in HELLP syndrome) is also possible and should be considered in a patient with evidence of shock and no obvious source of hemorrhage.

Obstetric hemorrhage has been arbitrarily defined as an estimated blood loss of more than 500 mL in a vaginal delivery and greater than

TABLE 57-9 CLINICAL STAGING OF HEMORRHAGIC SHOCK BY VOLUME OF BLOOD LOSS

Severity of Shock	Findings	Blood Loss (%)	Volume (mL)*
None	None	Up to 20	Up to 900
Mild	Tachycardia (<100 beats/min) Mild hypotension Peripheral vasoconstriction	20-25	1200-1500
Moderate	Tachycardia (100-120 beats/min) Hypotension (80-100 mm Hg) Restlessness Oliguria	30-35	1800-2100
Severe	Tachycardia (>120 beats/min) Hypotension (<60 mm Hg) Altered consciousness Anuria	>35	>2400

*Based on an average blood volume of 6000 mL at 30 weeks' gestation.

1000 mL for cesarean section.¹²⁴ Other definitions describe a decrease in the hematocrit by 10% or the need for transfusion.¹²⁵ However, estimates of blood loss are inaccurate and can vary widely. The true incidence of obstetric hemorrhagic shock is unknown.

Clinical Staging of Hemorrhage

Because of the normal blood volume expansion in pregnancy, clinical evidence of hypovolemia becomes evident much later than expected. Relatively minor symptoms such as orthostatic hypotension and tachycardia typically do not appear until at least 20% to 25% of the blood volume is lost. Table 57-9 outlines the clinical staging of hemorrhagic shock, depending on severity.

Management

The goal of management of hemorrhagic shock is to identify and control the bleeding source while restoring circulating blood volume and clotting factors. Baseline laboratory evaluation is recommended on recognition of the hemorrhage and should include a complete blood cell count, blood type and crossmatch, fibrinogen level, prothrombin time (international normalized ratio), and activated partial thromboplastin time. A basic metabolic panel is potentially useful to assess renal function and electrolyte disturbances. These laboratory tests should be repeated at regular intervals until the situation is resolved. The Lee-White whole-blood clotting time test can be used as a crude method to assess for the presence of DIC. Whole blood is collected in an unheparinized tube and observed. A stable clot should form between 5 and 15 minutes.

VOLUME REPLACEMENT THERAPY

Adequate and timely replacement of circulating volume is essential in the management of hemorrhagic shock. This is accomplished by administering crystalloid solutions such as normal saline or colloids such as albumin or blood products. Controversy exists about the most appropriate combination of fluids to replace circulating volume. Crystalloid solutions appear to be as effective as colloid solutions in most settings.¹²⁶ The Advanced Trauma Life Support (ATLS) course has proposed widely accepted standards for management of the trauma patient. For the patient in hemorrhagic shock, initial resuscitation with 2 L of crystalloid solution is followed by packed red cell transfusions.¹²⁷ The degree of volume resuscitation is also a matter of debate. Historically, aggressive, early fluid resuscitation was thought to result in improved outcomes. However, later data suggest that excessive fluid

TABLE 57-10 COLLOID INFUSIONS

Colloid	Dose (mL)	Crystalloid Volume Expansion Equivalent	Estimated Duration of Effect (hr)
Albumin			
5% solution	500-700	Similar to crystalloid	24
25% solution	100-200	3.5 times crystalloid	24
Hetastarch	500-1000	Similar to crystalloid	24-36
Dextran (70)	500	1050 mL over 2 hours	24

resuscitation may destabilize clot formation and stability, worsen hypothermia, and contribute to hemodilution without providing the expected benefit for survival. Some physicians recommend resuscitation to allow for *permissive hypotension* (i.e., systolic blood pressure >80 mm Hg).¹²⁷

COLLOID SOLUTIONS

Colloid solutions are intravenous fluids containing particles larger than 10,000 daltons. Packed red cells are considered a colloid, but this discussion focuses on additional colloid products. The major advantage provided by a colloid solution is the significant increase in plasma volume compared with a crystalloid solution. Colloid solutions increase intravascular COP and draw fluid into the intravascular space. In achieving this effect, extravascular volume can become depleted, and fluid resuscitation should include adequate administration of crystalloids. The degree of plasma expansion depends on the availability of extravascular fluid. In certain clinical settings such as sepsis, surgical trauma, or preeclampsia, vascular permeability is altered, and colloid solutions can escape into extravascular spaces, particularly the lungs, and lead to pulmonary edema. Available colloid solutions include albumin, dextran, and hetastarch. Table 57-10 compares the effects of these agents.

Albumin solutions are available in concentrations of 5% or 25%. A 25-g infusion of albumin temporarily increases intravascular volume by roughly 450 mL over 60 minutes as a result of its considerable oncotic activity. Albumin is cleared rapidly from the circulation, particularly in patients with shock or sepsis.

Dextran solution contains large glucose polymers with mean molecular weights of 40,000 daltons (dextran 40) or 70,000 daltons

(dextran 70). Dextran 40 is rarely used for the purposes of volume expansion. A 500-mL infusion of 6% dextran 70 should rapidly expand intravascular volume by more than 1000 mL. Adverse effects of dextran administration include increased bleeding risk and allergic reaction. Anaphylactic reactions affect 1 in 3300 patients receiving dextran. In higher doses (>20 mL/kg/24 hr), dextran may negatively affect platelet function and clotting factor activation, and it may interfere with fibrin function. It also may interfere with laboratory cross-matching of blood. Dextran should be used cautiously in patients with hypovolemia due to hemorrhage who may already have a coagulopathy and require further cross-matching of blood.

Hydroxymethyl starch (i.e., hetastarch) is a synthetic molecule available in a 6% solution in normal saline (Hespan) or lactated electrolyte solution (Hextend). Like the other available colloid solutions of albumin and dextran, hetastarch also induces intravascular volume expansion by increasing oncotic pressure. The effects of hetastarch can persist for 24 to 36 hours. As with dextran, hetastarch may negatively affect the clotting system. Hetastarch can prolong prothrombin and partial thromboplastin times, decrease platelet counts, and reduce clot tensile strength, and it should be used with caution in patients who may have a coagulopathy. Hextend is a newer hetastarch formulation with smaller-molecular-weight particles in addition to electrolytes and lactate similar to plasma levels. It may have less effect on the coagulation profile compared with other colloids and therefore offer a theoretical advantage in the setting of hemorrhage.¹²⁸

BLOOD COMPONENT THERAPY

Blood product replacement is the cornerstone of successful management of hemorrhagic shock. The variety of blood product components available for transfusion is summarized in Table 57-11, along with anticipated effects. Whole blood has not been separated into the various components and therefore offers a theoretical advantage because it contains clotting factors and platelets in addition to red blood cells. The major limitation to the use of whole blood is the inability to store the product beyond 24 hours. After 24 hours of extravascular storage, platelets and granulocytes are completely lost and 2,3-diphosphoglycerate is depleted, significantly compromising the oxygen carrying capacity of the red blood cells. Prolonged storage results in depletion of clotting factors and increasing levels of potassium and ammonia. For these reasons, whole blood is typically separated into its individual components and stored for later use; it is essentially unavailable in the United States. Individual components can then be administered to address specific derangements according to clinical indications. The routine

administration of clotting factors after every 4 to 6 units of packed red blood cells has not been demonstrated to improve outcomes.¹²⁹

A single unit of packed red cells has a hematocrit of approximately 80% and can increase the hemoglobin level by 1 g/dL in a 70-kg individual. Removal of white blood cells from the unit of blood (i.e., leukocyte-poor blood) decreases the risk of febrile transfusion reactions. Patients with evidence of acute hemorrhage (>30% blood volume loss), hemoglobin level between 6 and 10 g/dL with evidence of tachycardia and hypotension, or hemoglobin concentration less than 6 g/dL should be considered candidates for transfusion.^{130,131}

Dilutional thrombocytopenia can occur as a result of massive transfusion in a hemorrhaging patient. After replacement of one blood volume, 35% to 40% of a patient’s platelets usually remain, and platelet replacement is recommended in the setting of bleeding and significant thrombocytopenia. Platelet counts equilibrate within 10 minutes and can be assessed immediately after completion of the transfusion.

Fresh-frozen plasma (FFP) is plasma that is extracted from whole blood within 6 hours of collection and frozen. A single unit of FFP contains 700 mg of fibrinogen in addition to factors II, V, VII, IX, X, and XI. It is indicated for the replacement of multiple clotting factors in patients with acute hemorrhage and evidence of DIC. The goal is to correct clotting factor deficiencies and to achieve a post-transfusion serum fibrinogen level of approximately 100 mg/dL.

Cryoprecipitate is obtained from FFP and contains factor VIII (80 to 120 units), fibrinogen (200 mg), von Willebrand factor, and factor XIII. One unit of cryoprecipitate and one unit of FFP have similar effects on the fibrinogen level (increase of 10 to 15 mg/dL). However, because of its smaller volume, cryoprecipitate more efficiently raises the fibrinogen level compared with FFP.

COMPLICATIONS OF TRANSFUSION

Complications resulting from blood component transfusion vary from infections to immunologic responses. Table 57-12 outlines the frequency of various transfusion-related complications.

Minor transfusion reactions are relatively common occurrences and are not caused by hemolysis. Common clinical findings include low-grade fever, urticaria, or hives, and they result from exposure to incompatible platelet or white blood cell antigens. The use of leukocyte-poor packed red cells minimizes these types of reactions. Nonhemolytic reactions do not require discontinuation of the transfusion. Symptoms can be managed with antipyretic agents and antihistamines, as needed.

TABLE 57-11 BLOOD COMPONENTS

Component	Contents	Indications	Volume	Shelf Life	Expected Effect
Packed RBCs	Red cells, some plasma, few WBCs	Correct anemia	300 mL	21 days	Increase HCT 3%/unit, Hgb 1 g/unit
Leukocyte-poor blood	RBCs, some plasma, few WBCs	Correct anemia, reduce febrile reactions	250 mL	21-24 days	Increase HCT 3%/unit, Hgb 1 g/unit
Platelets	Platelets, some plasma, RBCs, few WBCs	Bleeding due to thrombocytopenia	50 mL	Up to 5 days	Increase total platelet count 7500 µL/unit
Fresh-frozen plasma	Plasma, clotting factors V, XI, XII	Treatment of coagulation disorders	250 mL	2 hours thawed, 12 months frozen	Increase total fibrinogen 10-15%/unit
Cryoprecipitate	Fibrinogen, factors V, VIII, XIII, von Willebrand factor	Hemophilia A, von Willebrand disease, fibrinogen deficiency	40 mL	4-6 hours thawed	Increase total fibrinogen 10-15 mg/dL per unit

HCT, hematocrit; Hgb, hemoglobin; RBCs, red blood cells; WBCs, white blood cells.

TABLE 57-12 TRANSFUSION-RELATED RISKS

Disease or Disorder	Risk
Hepatitis B	1/137,000
Hepatitis C	<1/1,000,000
Human immunodeficiency virus type 1 (HIV-1)	<1/1,900,000
Bacterial contamination	1/38,565
Acute hemolytic reaction	1/250,000-1/1,000,000
Delayed hemolytic reaction	1/1,000
Transfusion-related acute lung injury	1/5,000

Adapted from Goodnough LT, Brecher ME, Kanter MH, et al: *Transfusion medicine. Part 1. Blood transfusion. N Engl J Med* 340:438-447, 1999; and the American Association of Blood Banks 2002. Available at www.aabb.org.

Severe reactions after transfusion are usually the result of a hemolytic reaction to the administration of an incompatible unit of blood. Historically, administration of ABO-incompatible blood was thought to occur at a rate of 1 in 600,000 units, but a later report suggests it occurs with much greater frequency (1 in 25,000 units). Administrative error is the culprit in most of these events, underscoring the need for accurate accounting of transfused units, particularly in an emergent situation.¹³² Cardiovascular decompensation with DIC, fever, and renal failure usually develop rapidly after initiation of an incompatible transfusion. Treatment entails immediate discontinuation of the transfusion and supportive care.

ADDITIONAL SUPPORTIVE MEASURES

Red Blood Cell-Saving Devices. In patients anticipated to be at risk for excessive intraoperative blood loss, such as suspected placenta accreta, use of an autologous transfusion device (Cell Saver) should be considered.^{124,133} Theoretical risks of inducing amniotic fluid embolism have caused some concern regarding the use of intraoperative cell salvage during cesarean section. However, several reports have validated its safety in this arena.¹³⁴⁻¹³⁷ After delivery of the fetus and clearing the operating field of amniotic fluid, the suction device is changed, and blood is collected into the Cell Saver. In approximately 3 minutes, a unit of blood with a hematocrit of 50% is generated. In one study comparing patients who received blood salvage and autotransfusion during cesarean section with those receiving allogeneic blood transfusions, no differences in the rates of infection, coagulation abnormalities, or respiratory problems could be identified.¹³⁵ This technology may be particularly valuable for patients who have the potential for severe blood loss or who have religious preferences mandating the avoidance of transfused blood products.

Acute Normovolemic Hemodilution. Acute normovolemic hemodilution offers an additional option for patients at significant risk for intraoperative hemorrhage. The principle behind this approach is to dilute the patient's circulating volume so that when bleeding occurs, it has a lower hematocrit. This is accomplished by collecting blood from the patient preoperatively and placing it into special storage bags that can be obtained from the blood bank. Simultaneously, the patient is given crystalloid solution in a 3:1 ratio, resulting in a dilutional effect and a decrease in the maternal hematocrit. Intraoperatively, after achieving control of the blood loss, or at the discretion of the surgeon, the patient's blood is then reinfused, resulting in an increase in the hematocrit.

Potential advantages include preservation of clotting factors, a decreased likelihood of allogeneic transfusion, and therefore a

decreased risk of infectious morbidity, alloimmunization, and immunologic complications. Adverse fetal effects have not been described during this process.^{138,139} Acute normovolemic hemodilution is a time-consuming process and is not appropriate for an acutely hemorrhaging patient. Suggested criteria for acute normovolemic hemodilution include an increased likelihood of transfusion; preoperative hemoglobin level of 12 g/dL or higher; absence of clinically significant coronary, pulmonary, renal, or liver disease; absence of severe hypertension; and absence of infection and risk of bacteremia.¹⁴⁰

Other Measures. Supplemental oxygenation and elevation of the lower extremities are recommended for patients with hemorrhage. The use of antishock (MAST) trousers has fallen out of favor after publication of a randomized trial that failed to demonstrate survival benefit.¹⁴¹

Massive transfusion and blood loss place the patient at significant risk for concomitant abnormalities that can compromise successful resuscitation. Maintenance of the airway and ventilation cannot be ignored. Management of the hemorrhaging patient should include regular assessment for coagulation abnormalities and recurrent bleeding, correction of electrolyte abnormalities, particularly calcium and potassium, and maintenance of temperature above 35°C. After control of bleeding is achieved, resuscitation is considered complete if the following goals are met¹⁴²:

- Normal or hyperdynamic vital signs
- Hematocrit higher than 20% (transfusion threshold determined by the patient's age)
- Normal serum electrolyte levels
- Normal coagulation function, with a platelet count of at least 50,000
- Restoration of adequate microvascular perfusion, as indicated by a pH of 7.40 with a normal base deficit, normalized serum lactate level, normal mixed venous oxygenation, normal or high CO, and normal urine output.

DEFINITIVE THERAPY FOR HEMOSTASIS

Control of obstetric hemorrhage must take into consideration the apparent cause of the hemorrhage. For example, the most likely cause of postpartum hemorrhage is uterine atony, which would be expected to respond to uterine massage and uterotonic agents as first-line therapy. Hemorrhage due to placenta accreta or previa requires surgical intervention. Recombinant factor VIIa (rFVIIa, NovoSeven) is approved for the management of bleeding in hemophiliacs, but its role is emerging as an off-label adjunctive therapy for the control of catastrophic, coagulopathic bleeding. Recombinant factor VIIa functions by activating factor X, thereby enhancing thrombin production and formation of a stable clot. It is not intended as first-line therapy for control of hemorrhage, and most physicians recommend use of rFVIIa only after other attempts to control hemorrhage have failed. This includes any necessary surgical approach, appropriate replacement of blood products, and correction of severe acidosis, hypothermia, and hypocalcemia.^{143,144} rFVIIa has been employed for the control of obstetric hemorrhage.¹⁴⁵⁻¹⁴⁸ Table 57-13 outlines pharmacologic agents useful in controlling hemorrhage from an atonic uterus.

Hemorrhage after a vaginal delivery should prompt a thorough evaluation for and repair of cervical or vaginal lacerations, particularly if an instrumented delivery was performed. If uterine atony fails to respond to uterine massage and uterotonic agents, evaluation for potential retained placental fragments should be performed. Ultrasound may be of assistance in this assessment process, particularly if uterine curettage is necessary. Intrauterine pressure packs to control

TABLE 57-13 PHARMACOLOGIC AGENTS USEFUL FOR CONTROLLING UTERINE ATONY

Agent	Dose	Considerations/Side Effects
Oxytocin (Pitocin)	10-40 units/L IV 10 units IM	IV bolus may cause PVCs and hypotension
Methylergonovine (Methergine)	0.2 mg IM every 2-4 hours, maximum of 5 doses	Increased SVR, increased MAP, increased CVP Side effects include pulmonary edema, seizures, intracranial hemorrhage, retinal detachment, and coronary vasospasm. Avoid in patients with hypertension
Prostaglandin 15-methyl F _{2α} (Hemabate)	0.25 mg IM every 15-90 minutes, maximum dose of 2 mg	Diarrhea Bronchoconstriction Increased CO, increased heart rate, and increased right heart pressure Increased PVR Decreased SVR Decreased coronary artery perfusion Avoid in patients with asthma
Dinoprostone (prostaglandin E ₂)	20 mg per rectum or vagina every 2 hours	Diarrhea, nausea, vomiting Tachypnea, pyrexia, tachycardia Decreased SVR Decreased MAP Increased CO
Misoprostol (Cytotec, prostaglandin E ₁)	800-1000 µg per rectum	Diarrhea, vomiting Abdominal pain Headache
Recombinant factor VIIa (NovoSeven)	200 µg/kg initial dose; may repeat with 100 µg/kg at 1 and 3 hours after the first dose	Indicated with persistent bleeding despite adequate first-line therapies May increase risk for thromboembolic events

CVP, central venous pressure; CO, cardiac output; IM, intramuscular; IV, intravenous; MAP, mean arterial pressure; PVC, premature ventricular contraction; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

life-threatening postpartum hemorrhage have been successful according to some reports.^{149,150} However, the technique used to place the packing is integral to its success and can be challenging. Other physicians have attempted to provide packing by modifying various inflatable devices such as Foley catheters or Sengstaken-Blakemore tubes.^{151,152} The SOS Bakri tamponade balloon has been introduced specifically to provide intrauterine compression in the management of postpartum hemorrhage.¹⁵³ The SOS Bakri tamponade balloon has been placed vaginally and at cesarean section.

Surgery to Control Obstetric Hemorrhage. If uterine hemorrhage after vaginal delivery fails to respond to the previously described measures, exploratory laparotomy should be performed. If the bleeding is encountered at cesarean section, the same techniques for control of hemorrhage may be applied. The B-Lynch uterine body compression suture has been performed successfully to control hemorrhage due to unresponsive uterine atony, and it is demonstrated in Figure 57-7.^{154,155} The B-Lynch suture has been performed in conjunction with placement of an SOS Bakri balloon to achieve hemostasis.¹⁵⁶

Suture ligation of the ascending uterine arteries (i.e., O'Leary suture) is another option and is technically straightforward to perform in most scenarios. O'Leary and O'Leary^{157,158} reported the successful use of this technique (Fig. 57-8) in controlling postpartum and postcesarean bleeding. The uterine artery can be visualized and accessed anteriorly or posteriorly. The uterine arteries are readily accessible with uterine manipulation, and minimal or no vessel dissection is necessary for uterine artery ligation. Hypogastric artery ligation is more technically challenging, requiring dissection of the retroperitoneal space through the broad ligament. Bilateral ligation usually is necessary to achieve adequate reduction in pulse pressure. The surgeon must be familiar with pelvic vascular anatomy to avoid ureteral injury or inadvertent ligation of the common or exterior iliac artery, which will

obstruct blood flow to the lower extremity. If possible, ligation of the vessel should occur below the branch of the superior gluteal artery, as demonstrated in Figure 57-9. Because of the technical challenges and questionable efficacy of the procedure (hemorrhage controlled in approximately 40% of cases), hypogastric artery ligation is not commonly performed.¹⁵⁹

The incidence of emergent peripartum hysterectomy for obstetric hemorrhage is less than 0.8%.¹⁶⁰⁻¹⁶⁴ Cesarean delivery, prior cesarean delivery, and multiple gestation are significant risk factors.^{164,165} Other indications for peripartum hysterectomy include uterine rupture, extension of the uterine incision, infection, and myomas. A study reported peripartum hysterectomy data from a national database between 1998 and 2003 and included more than 18,000 hysterectomies. Although some case series have suggested that invasive placentation appears to be supplanting uterine atony as the leading indication for peripartum hysterectomy, other data suggest they may be equally common.^{160,161,164,166} Complications from emergency peripartum hysterectomy include excessive blood loss and the need for blood product replacement, fever, wound infection, ureteral injury, thromboembolic events, cardiac arrest, and death.^{160,162,163,166} Supracervical and total hysterectomy have been described for the management of obstetric hemorrhage, although data are lacking to determine whether one approach is superior to the other.

Pelvic Artery Embolization. Interventional radiologists have become proficient in arteriography for a variety of diagnostic and therapeutic approaches. It is no surprise then that selective pelvic artery embolization for the management of obstetric hemorrhage is gaining in experience. Many case series have described its effectiveness in this scenario, with success rates exceeding 90%.¹⁶⁷⁻¹⁷⁰ In addition to avoiding the added morbidity of surgical exploration, it preserves future fertility.^{170,171}

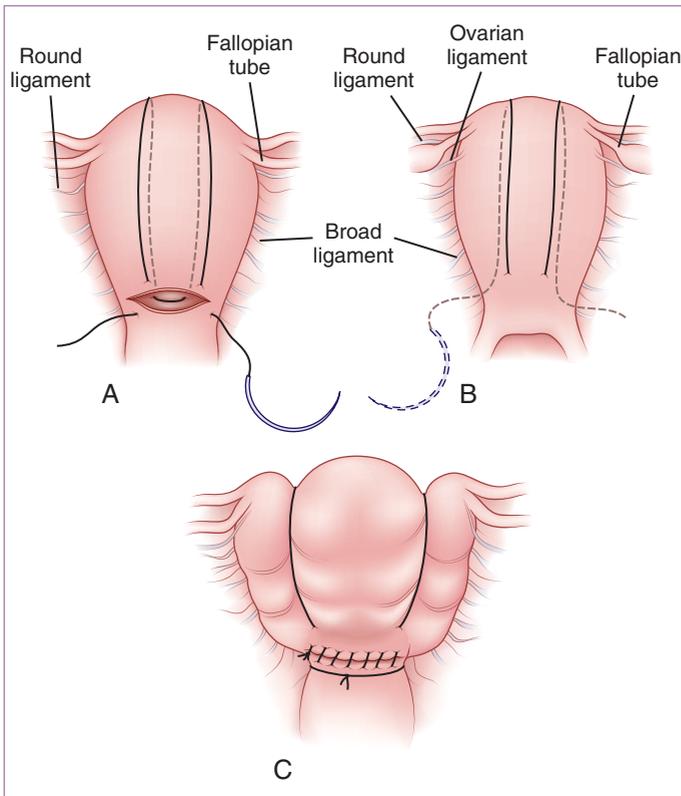

FIGURE 57-7 B-Lynch surgical technique. **A**, Anterior view of the B-Lynch stitch placement. **B**, Posterior view of the B-Lynch stitch placement. **C**, Anterior view of the completed procedure. (From B-Lynch C, Coker A, Lawal AH, et al: The B-Lynch surgical technique for the control of massive postpartum haemorrhage: An alternative to hysterectomy? Five cases reported. *BJOG* 104:372, 1997. Reprinted with permission.)

The procedure is performed in the interventional radiology suite. The femoral artery is accessed and diagnostic arteriography performed with fluoroscopic imaging to localize the target arteries for embolization. A variety of options are available for arterial occlusion, including an absorbable gelatin sponge (Gelfoam) or another type of particulate material.

Potential adverse results from the procedure include ischemia or tissue necrosis, infection, nephrotoxicity due to contrast medium, and bleeding at the access site or failure of the embolization. Failure of this approach does not preclude a subsequent surgical attempt at hemorrhage control. Conversely, after hypogastric artery ligation is performed, successful arteriographic embolization is much more difficult to achieve.

Trauma in Pregnancy

Trauma is a leading cause of non-obstetric deaths in the United States, and it is estimated to complicate 6% to 7% of all pregnancies.¹⁷² About 4000 fetuses are lost annually due to complications from trauma in pregnancy.¹⁷³ Most incidents are considered minor, and less than 0.4% of patients require hospitalization. Of those requiring admission, 24% proceed to delivery during the hospitalization.^{174,175} Motor vehicle accidents and falls account for most traumatic events affecting

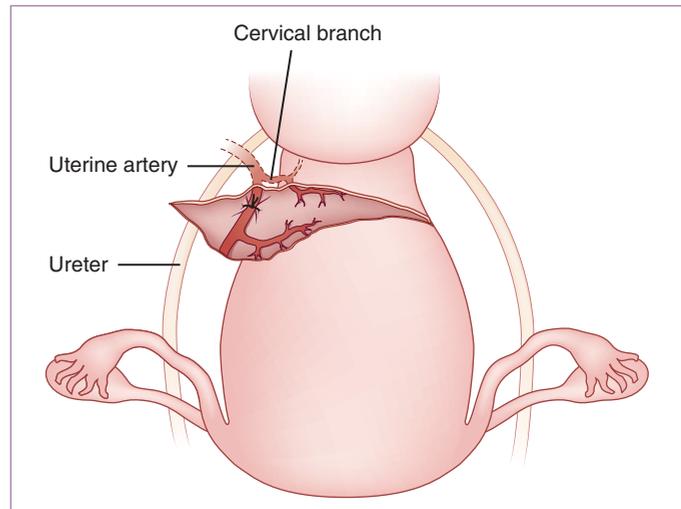

FIGURE 57-8 Anterior approach to the uterine artery ligation technique for postpartum obstetric hemorrhage.

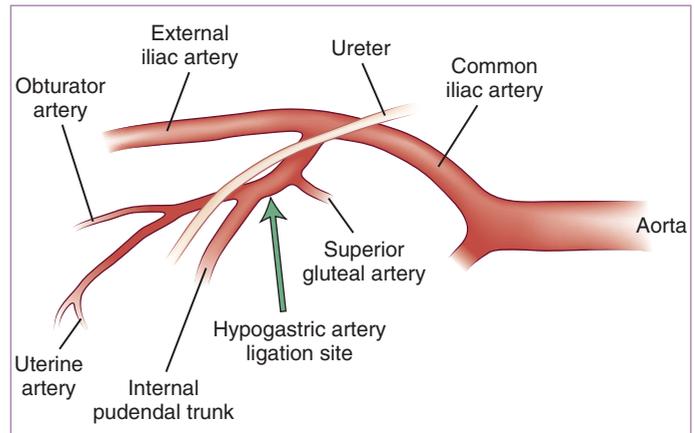

FIGURE 57-9 Localization of the hypogastric artery along the right pelvic side wall.

pregnant women, followed by domestic violence, assault, and suicide attempts.^{172,176-178} Domestic violence escalates during pregnancy and is estimated to affect as many as 20% of pregnant patients.¹⁷⁹ A high index of suspicion for domestic violence is warranted for any pregnant woman presenting for evaluation after a traumatic event.

Blunt Abdominal Trauma

The gravid uterus is particularly vulnerable to blunt trauma from motor vehicle accidents, assaults, and falls. When a pregnant woman is injured severely, it most likely involved a motor vehicle accident. Three-point restraint seatbelts are safe for use by pregnant women, they significantly decrease the risk of serious maternal injury and fetal loss, and they are recommended by ACOG.¹⁸⁰⁻¹⁸³ Proper use of seatbelts appears to be a significant predictor of maternal and fetal outcomes.^{181,184} Approximately one third of pregnant women do not wear seat belts because of discomfort, inconvenience, or fears about hurting the fetus. Prenatal education regarding seat belt use significantly improves proper seat belt use.¹⁷³ The addition of airbags does not appear to be problematic for pregnant patients and may further reduce risk of injury.¹⁸²

Placental abruption is a particularly serious complication after blunt trauma and motor vehicle accidents, because it may lead to premature labor and delivery, concealed hemorrhage, consumptive coagulopathy, fetomaternal hemorrhage, fetal distress, and death. Detection of an abruption in the patient without vaginal bleeding presents a challenge. Abruption occurs in approximately 7% of patients after trauma, but the severity of the injury does not appear to correlate with the presence of an abruption or to predict outcome. Most placental abruptions occur in patients after relatively minor trauma without evidence of serious injury.^{172,178,185-187} Unfortunately, a negative ultrasound result does not reliably exclude the possibility of a placental abruption. At best, the sensitivity of ultrasound to detect abruption is 25%.¹⁸⁸ However, the sonographic identification of an abruption correlates with a higher likelihood of adverse outcome.^{188,189}

The Injury Severity Score (ISS) is often used to quantify the risk of adverse outcomes for nonpregnant patients.¹⁹⁰ Unfortunately, the ISS does not translate well to the pregnant population and has not been shown to reliably predict outcomes in this group. El-Kady and colleagues¹⁷⁴ published a large, population-based study of more than 10,000 trauma evaluations in pregnant women.¹⁷⁴ Patients were divided into those delivering during the admission for trauma and those discharged to deliver at a later date. Falls were most common among women requiring delivery, followed by motor vehicle accidents. The likelihood of abruption, uterine rupture, maternal death, and adverse neonatal outcomes, including fetal and neonatal death, was significantly higher for the group that delivered during the trauma admission. Those women discharged undelivered after trauma had improved maternal outcomes compared with the delivered patients, but they remained at increased risk for preterm delivery, abruption, and the need for blood products compared with uninjured controls. These risks could not accurately be predicted by the ISS. Adverse fetal and neonatal outcomes were not increased after discharge. In contrast, for the group of patients who delivered during the trauma admission, a high ISS (>10) was associated with the highest risk for adverse outcomes. However, a lower ISS score (<10) was still associated with a significant increase in serious adverse events, including abruption, uterine rupture, and maternal or fetal death. The Revised Trauma Score (RTS), which includes the Glasgow Coma Scale, also appears to be limited in its ability to accurately predict pregnancy outcome after trauma.¹⁹¹

External monitoring of the fetal heart rate and contraction monitoring are recommended after blunt trauma in a viable gestation. Pearlman and associates¹⁷⁸ performed a prospective study monitoring patients for a minimum of 4 hours after blunt trauma. Eighty-eight percent of the patients had no visible trauma; 2.4% were critically injured. Most patients had contractions, and 70% required admission beyond the initial 4-hour observation period. Of these, 19% went on to deliver, with one fetal death. The abruption incidence in this subgroup was 9.4%. No adverse events occurred in the group of patients for whom contractions did not occur more frequently than every 15 minutes. However, all women suffering an adverse perinatal outcome had contractions every 2 to 5 minutes at some point during the initial 4-hour observation period. The severity of injury did not predict abruption or adverse outcomes.¹⁷⁸ Other investigators have since validated the concept that less than one contraction every 15 minutes is not associated with adverse outcomes after blunt trauma in pregnant patients.^{172,185,192} A minimum of 4 hours of fetal heart rate and contraction monitoring is recommended after blunt trauma in pregnant women, regardless of injury severity. Beyond the initial observation period, the recommended duration for monitoring is not clear, particularly for patients with evidence of contractions. Most physicians

$$\text{Fetal red blood cells} = \frac{\text{MBV} \times \text{maternal Hct} \times \% \text{ fetal cells (KB)}}{\text{Newborn Hct}}$$

If KB result is 0.9% : 0.9% of maternal blood volume (MBV) is fetal origin.

MBV is assumed to be 5000 mL for an average-size woman at term. Maternal hematocrit (Hct) should be measured; assume approximately 35%.

Normal Hct for term newborn infant can be assumed to be 50%, if the patient is undelivered.

$$\text{Fetal red blood cells} = \frac{5000 \times 0.35 \times 0.009}{0.5} = 31.5 \text{ mL}$$

Therefore, the fetus has hemorrhaged 31.5 mL of red cells into the maternal circulation. At term, the neonatal blood volume is 125 mL/kg. If the Hct is assumed to be approximately 50% at term, the actual amount of blood lost is 63 mL. In a term infant assumed to weigh 3500 g, the blood volume is approximately 438 mL, and the fetus has lost 7% of its blood volume.

FIGURE 57-10 Calculation of the volume of fetomaternal hemorrhage using the Kleihauer-Betke results.

recommend at least 24 hours because most serious complications occur shortly after the traumatic event.

Fetomaternal hemorrhage is another potential concern after blunt trauma in pregnancy. A Kleihauer-Betke test can provide an estimate of the amount of fetal blood within the maternal circulation, which is particularly important in determining if additional doses of RhGAM are necessary in Rh-negative women. The test is based on the detection of fetal hemoglobin. If the presence of fetal hemoglobin within maternal red cells, such as in a hemoglobinopathy, is detected, the result will be falsely elevated. Figure 57-10 describes how to interpret a Kleihauer-Betke result and calculate volume of fetomaternal hemorrhage. Spontaneous fetomaternal hemorrhage can occur throughout pregnancy in the absence of any identified precipitating event, but the volumes appear to be low.¹⁹³ Fetomaternal hemorrhage is thought to occur with greater frequency after blunt trauma, and Kleihauer-Betke testing is often recommended. However, the available data suggest that a positive Kleihauer-Betke result does not alter management. In four studies of 730 pregnant women who had Kleihauer-Betke testing performed after blunt trauma, 95 (13%) had evidence of fetomaternal hemorrhage.^{172,178,192,194} Of these, in only two cases (0.02%) did the result potentially alter management; one patient had significant hemorrhage requiring delivery as a result of fetal distress, and one underwent umbilical cord blood sampling but did not require transfusion or delivery. For the remainder, the result did not appear to affect management. In another study, no difference was found in the frequency of positive Kleihauer-Betke tests between normal controls and pregnant women being evaluated for trauma.¹⁹⁴

Because of the gravid uterus, patterns of traumatic injury are somewhat different in pregnant patients after blunt abdominal trauma, particularly motor vehicle accidents. Upper abdominal injury to the spleen and liver are more common, whereas bowel injuries occur less frequently.^{192,195} Traumatic uterine rupture has been reported, but it is rare with minor trauma.^{174,196} The risk increases with increasing severity of trauma and the size of the uterus. Most ruptures occur in the fundal or posterior regions. With traumatic rupture of the uterus, fetal mortality approaches 100%.

Pelvic fractures are typically related to trauma as a result of a motor vehicle accident. The presence of a pelvic fracture should raise concern

about significant bleeding risk and coexistent intra-abdominal trauma, such as splenic or hepatic laceration or urinary tract injury. Pelvic fracture is not a contraindication to vaginal delivery. The decision should be based on the stability of the fracture and presence of pelvic deformities. Fetal head injuries are also more common if a pelvic fracture is sustained.¹⁹⁷

Penetrating Abdominal Trauma

Gunshot and stab wounds are the most common penetrating injuries in pregnant women, usually as a result of assault or suicide attempt. The enlarged uterus increases the likelihood that the uterus and fetus will sustain injury, and the prognosis is generally less favorable for the fetus. Penetrating trauma to the lower abdomen carries a lower likelihood of maternal bowel injury. The impact of gunshot wounds is less predictable and varies according to the entry site and angle, size of uterus and distance from the gun. Visceral injuries occur in 19% of pregnant patients, compared with 82% in nonpregnant patients. Mortality rates are correspondingly lower in pregnant victims (3.9% versus 12.5%).¹⁹⁸ Stab wounds are more likely to involve the upper abdomen during pregnancy, and in these cases, bowel injury should be considered.^{198,199}

Evaluation of the patient after penetrating abdominal trauma should include an assessment of the likelihood of intra-abdominal bleeding. Ultrasound and CT are useful in this regard, and exploratory laparotomy is recommended if there is suspicion of bowel perforation or active hemorrhage. Diagnostic peritoneal lavage can help determine if bleeding is likely in hemodynamically stable patients with equivocal findings on abdominal ultrasound or CT. Lavage is performed by entering the abdomen through a small incision and infusing a saline wash. The presence of blood in the recovered lavage fluid supports the presence of intra-abdominal bleeding and warrants exploration. Tetanus toxoid prophylaxis should be used for the same indications as in the nonpregnant patient.

Trauma Management Issues

On initial presentation, the pregnant trauma patient should be evaluated similar to the nonpregnant patient. Assessment and stabilization of the airway, breathing, and circulation are the primary steps, followed by systematic evaluation for evidence of traumatic injuries. If the patient is pregnant, rapid confirmation of gestational age and assessment of fetal well-being are necessary. This evaluation can be performed simultaneous to any required maternal stabilization efforts.

Care should be taken to provide displacement of the gravid uterus off the aorta and vena cava. Compression of the great vessels occurs after the uterus reaches a size consistent with 20 weeks' gestation, and it decreases the CO. Displacement can be accomplished manually, by moving the patient to a lateral position, or by placing a wedge under the hip.

Evaluation of a pregnant trauma patient must take into consideration the physiologic changes of pregnancy that affect the clinical presentation. Pregnant women near term have expanded their circulating blood volume by 40% to 50%. As a result, significant intra-abdominal or intrauterine blood loss can occur with minimal change in maternal vital signs. Prognosis is worse if the patient develops hypotension and tachycardia.¹⁸⁷ In a viable gestation, a reassuring fetal heart rate tracing demonstrates adequate uterine perfusion and acts as a barometer of maternal status. As maternal cardiovascular status deteriorates, uterine perfusion suffers and manifests as contractions and fetal heart rate abnormalities. Fibrinogen levels decrease in the setting of hemorrhage

TABLE 57-14 ESTIMATES OF FETAL RADIATION EXPOSURE FROM COMMON RADIOLOGIC PROCEDURES IN A TRAUMA PATIENT

Radiologic Examination	Fetal Radiation Exposure (cGy)
Chest (posteroanterior, lateral)	<<0.1
Abdomen	0.15-0.26
Pelvis	0.2-0.35
Hip	0.13-0.2
Computed tomography of head	<<0.1
Computed tomography of abdomen	0.04
Computed tomography of pelvis	2.5

as a result of consumption. In pregnancy, fibrinogen levels are substantially elevated, and low and even normal-range fibrinogen should raise concern about the pregnant patient.

Delivery timing and route are dictated by maternal and fetal status and need to be individualized. If laparotomy is necessary, hysterotomy is not automatically indicated. If there is evidence of uterine injury, delivery may be necessary. Pregnancy should not preclude the use of diagnostic testing thought to be otherwise indicated for a pregnant trauma patient. No single diagnostic radiologic imaging study exists that can provide enough radiation exposure to adversely affect a developing fetus. Radiation exposure of less than 5 rads has not been associated with fetal abnormalities or pregnancy loss, and the radiation associated with abdominal and pelvic CT scans falls substantially below this threshold.²⁰⁰ Magnetic resonance imaging (MRI) does not produce ionizing radiation, and no adverse fetal effects have been reported from in utero exposure. However, because of theoretical concerns, ACOG states that the "National Radiological Protection Board arbitrarily advises against its use in the first trimester."²⁰⁰ Table 57-14 lists anticipated dose of radiation exposure to the fetus from examinations commonly required for a trauma patient.

Burns in Pregnancy

Background

According to the American Burn Association, 40,000 people require hospitalization because of burns each year. Of these, 60% are admitted to one of the 125 specialized burn centers in the United States. These centers admit 200 patients per year on average, compared with the average of three burn admissions to nonspecialized burn centers.^{201,202} Although current U.S. statistics are not available, burn injuries appear to be more common in developing countries, as evidenced by fewer case reports from the United States. In two larger series of burns in pregnancy collected in India and Iran, approximately 7% of burn victims were pregnant patients. Burns resulting from flames or scalds account for 78% of cases; the remainder resulted from hot object contact (8%) or electrical (4%), chemical (3%), or other (6%) causes.²⁰³

Classification

Burns are characterized by the depth and size of the involved area. Partial-thickness burns (formerly classified as first-degree and second-degree burns) involve superficial skin layers and are capable of re-

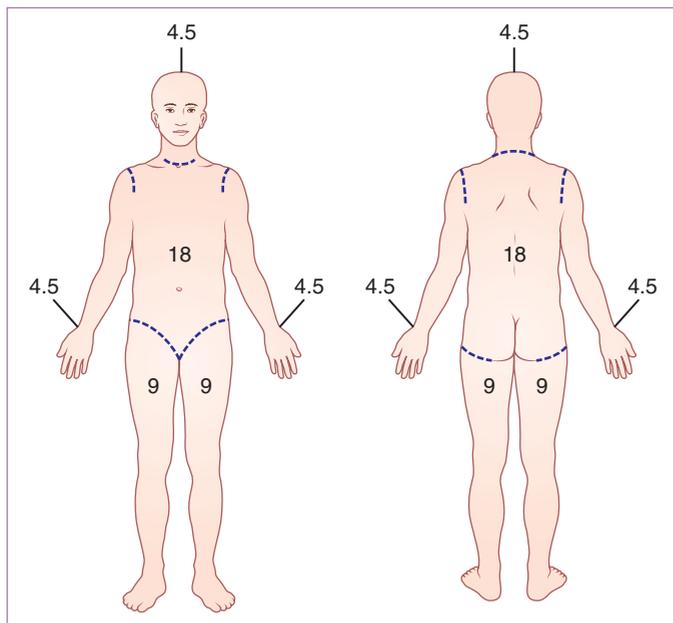

FIGURE 57-11 Body surface area diagram depicts the relative percentage of the total body surface area of defined anatomic areas in nonpregnant adults. (From Wolf SE, Hernon DN: Burns. In Townsend CM, Beauchamp RD, Evers BM, et al [eds]: Sabiston's Textbook of Surgery, 17th ed. Philadelphia, Elsevier Saunders, 2004.)

TABLE 57-15 CLASSIFICATION OF BURN SEVERITY	
Classification	Defined Body Surface Areas
Minor	<15% partial thickness <2% full thickness
Moderate	15-25% 2-10% full thickness
Major	>25% >10% full thickness Any burn involving the face, eyes, ears, feet, or perineum Inhalation injury or electrical injury

epithelialization. These burns are painful, blistering injuries that can be red, white, or pink. These wounds are usually managed with topical agents and dressings. If healing does not occur within 3 weeks, management converts to that for more serious burns. Full-thickness burns (formerly called third-degree burns) are the most severe, and epithelium does not regenerate. These burns are not blistering and are painless. They can be gray, white, or brown.

Early surgical excision of the eschar is the standard of management in the United States. Full-thickness wounds hold the greatest potential for scarring, contractures, and infection and should be referred to a burn center.^{204,205} The prognosis for pregnant and nonpregnant patients is directly related to the percentage of body surface area involved. Figure 57-11 shows one method of estimating the percentage of total body surface burned in nonpregnant adults. A modification for the pregnant patient has not been created, but the gravid abdomen should be taken into account when estimating body surface area involvement. The severity of the burn increases in proportion to the degree of involvement, as outlined in Table 57-15.

Outcomes

Severe burns are morbid events with significant short-term and long-term consequences. The pregnancy does not appear to negatively affect the outcome after a burn, but the burn has the potential to significantly affect the pregnancy outcome. Maternal and fetal survival depends most on the severity of the burn itself.^{201,202,206} In one of the largest series of burns in pregnancy, Maghsoudi and colleagues²⁰² prospectively collected data on 51 pregnant burn victims admitted to a referral burn center in Iran over a 9-year period. The overall maternal mortality rate was 39%, and the fetal mortality rate was 45%. The most significant predictor of maternal and fetal mortality was total body surface area involvement exceeding 40% and the presence of inhalation injury. These patients suffered severe burns; the mean burn surface area was 38%. In nonsurvivors, the mean burn surface area was 69%. Other studies have found similar results.²⁰¹

Management

Management of the pregnant burn patient is similar to that of a nonpregnant patient. Acute management of the burn victim should address aggressive fluid resuscitation, evaluation for inhalation injury and airway maintenance, assessment of carbon monoxide poisoning, anemia, prevention of infection, and wound management.

The initial priority is recognition of smoke inhalation injury, carbon monoxide poisoning, and airway management. Carbon monoxide crosses the placenta easily, and fetal hemoglobin has a higher affinity for carbon monoxide than adult hemoglobin. Hyperbaric oxygen may play a role in treating carbon monoxide poisoning.²⁰⁷ Early intubation should be considered to maximize oxygen delivery in a patient with inhalation injury and to protect against aspiration.

Fluid losses after a serious burn are substantial as a result of third spacing due to edema and evaporative loss from damaged skin. The fluid deficit is easily underestimated in a pregnant patient. The normal physiologic adaptations of pregnancy, including up to 40% increase in blood volume, 40% increase in CO, and 20% decrease in SVR, are not reflected in the fluid replacement strategies recommended for nonpregnant burn patients. One commonly used formula, the Parkland formula, recommends replacement with Ringer's lactate at a rate of 4 mL/kg of body weight per percent of body surface area burned. Fifty percent of the calculated replacement volume is administered over the initial 8 hours and the remainder over the subsequent 16 hours. In one report,²⁰⁸ the Parkland formula underestimated fluid requirement in a pregnant burn patient by almost 10 L. Given the lack of guidelines for pregnant patients, fluid resuscitation should be individualized to achieve hemodynamic stability, adequate urine output, and uterine perfusion. Electrolyte disturbances should also be anticipated and addressed.

Burns are associated with a significant hypermetabolic state and markedly increased nutritional requirements. Hypermetabolism can be minimized by providing adequate pain relief; supplying aggressive wound management with excision, grafting, and occlusive dressings; and managing temperature and adequate fluid replacement. Attention to adequate nutrition is essential and usually requires enteral and parenteral feeds.²⁰⁹

Wound infection and sepsis are significant risks after burn injury. Bacteremia results from colonization of the burn area. The most common organisms encountered are *S. aureus*, *Pseudomonas aeruginosa*, and *Candida albicans*.²¹⁰ Aggressive management of the wound with excision of the eschar, grafting, and occlusive dressings, in addi-

tion to topical and systemic antibiotics, helps to prevent infectious complications. The patient may be at increased risk for venous thromboembolic events.

Assessment of fetal well-being in a viable gestation should not be overlooked. Intravascular depletion, hypoxemia, hypermetabolism, and infection can adversely affect the fetus. Continuous monitoring is recommended in a viable gestation, particularly during the early stages of management. If the abdomen is involved with burn, direct auscultation may be limited and continuous fetal heart rate monitoring not feasible. Sterile coverings are available for the heart rate monitor and ultrasound probes to minimize infection risk. Vaginal ultrasound assessment may also be considered in some settings.

Contractions and preterm labor are to be expected, particularly in a severely burned pregnant patient, although the frequency is unknown. Few data are available to guide the use of tocolytic medications. Tocolysis should therefore be undertaken cautiously and judiciously, with an appreciation of the hemodynamic effects and other side effects of the drug. Hypovolemic patients may not tolerate β -agonists such as terbutaline, because they may already be in a high output state. Given the high fetal mortality rates with severe burns, delivery may be the most judicious alternative in a viable gestation. Most physicians recommend cesarean section for the usual obstetric indications. Delivery by cesarean section through a burned abdomen and vaginal delivery through a burned perineum have been reported.^{208,211-213}

Cardiopulmonary Resuscitation and Perimortem Cesarean Section

Cardiac arrest in a pregnant patient is a rare event. According to the most recent available data on United States maternal mortality, the most likely neonatal outcome in the setting of a maternal death is a live birth.¹² The data do not reflect the frequency of arrest occurring before delivery. In a review of 38 patients delivered perimortem by cesarean section, the causes included trauma, cardiac abnormalities, embolism, magnesium overdose, sepsis, intracranial hemorrhage, anesthetic complications, eclampsia, and uterine rupture.²¹⁴ The causes of cardiac arrest in pregnant women are more likely to be acute and therefore may be more amenable to aggressive interventions. Several physiologic changes of pregnancy negatively affect attempts at cardiopulmonary resuscitation (CPR):

- Increased CO and requirement for uterine perfusion
- Aortocaval compression by the gravid uterus in the supine position
- Reduced functional residual capacity and increased oxygen consumption
- Reduced chest wall compliance
- Delayed stomach emptying and decreased esophageal sphincter tone, which increase the aspiration risk

Aortocaval obstruction should be relieved by placing the patient in a more lateral recumbent position or by manually displacing the uterus. CPR can provide only 30% of the CO when the patient is supine.²¹⁵ The effectiveness of compressions increases dramatically when the patient is tilted in the lateral position.²¹⁴ Early intubation is recommended to minimize aspiration risk. The use of sodium bicar-

bonate to correct maternal acidosis should be undertaken with caution because of the potential for worsening fetal acidosis. Electrocardioversion can be performed in a pregnant patient; the recommendations are the same as for nonpregnant patients.²¹⁶

Rapid restoration of maternal circulation and reversal of hypoxia are the most effective ways to minimize negative effects on the fetus. If this is not possible, attention must then be directed to evacuation of the uterus by cesarean section. Cesarean section in the setting of maternal cardiac arrest can improve the likelihood of an intact neonatal outcome and simultaneously improve maternal resuscitative efforts. In 1986, Katz and colleagues²¹⁷ initially advocated performing a cesarean section at 4 minutes after instituting CPR.²¹⁷ This recommendation was based on the theory that emptying the uterus would improve CO generated by chest compressions after the obstructing uterus was emptied. Maternal neurologic injury could be avoided if cerebral perfusion improved by 6 minutes, the time at which cerebral injury occurs after cessation of blood flow. They then reviewed the literature and reported neonatal outcomes at various time intervals after delivery. From these data, delivery within 5 minutes of arrest was most likely to result in good neonatal outcomes.^{52,217}

Subsequently, Katz and coworkers²¹⁴ reviewed 34 published cases of perimortem cesarean section performed between 1985 and 2004 to assess whether the “4-minute rule” was valid. In this series, 79% delivered live infants (30 of 38; 3 sets of twins and 1 set of triplets). Data were available regarding the arrest-to-delivery interval for 25 infants and are presented in Table 57-16. Similar to data presented in earlier series, prolonging the arrest-to-delivery interval decreased the likelihood of intact survival, although apparently normal neonates were delivered even after more than 15 minutes.

Data were also provided about perimortem cesarean section potentially negatively impacting maternal survival. Twenty (59%) of 34 cases provided information regarding maternal hemodynamic status and indicated a beneficial effect on maternal resuscitation efforts after perimortem cesarean. None of the cases had worsening maternal

TABLE 57-16 PERIMORTEM CESAREAN DELIVERIES WITH SURVIVING INFANTS WITH REPORTS OF TIME FROM MATERNAL CARDIAC ARREST TO DELIVERY OF THE INFANT, 1985-2004

Time (min)	Gestational Age		Number of Patients
		(wk)	
0-5	25-42	8 (normal infant)	
		1 (retinopathy of prematurity and hearing loss)

status as a result of perimortem cesarean section; 12 women had “sudden” and “profound” improvement at the time of emptying the uterus.²¹⁴

The following guidelines are being suggested for the management of maternal cardiac arrest with a viable gestation:

1. Begin maternal CPR immediately.
2. Establish an airway.
3. Establish intravenous access simultaneously.
4. Institute cesarean delivery if there is no evidence of a maternal pulse by 4 minutes.
5. Sterile technique is not necessary, and the patient need not be moved to an operating room.
6. Continue CPR efforts during and after delivery.
7. Continuous fetal monitoring is not possible because of interference from resuscitative efforts. The maternal condition dictates whether perimortem cesarean section is necessary.

Cesarean section is not recommended in an unstable patient because of anticipated cardiac arrest. This may inadvertently precipi-

tate a worse maternal outcome. If CPR is effective at restoring circulation, perimortem cesarean section is not recommended.

Brain Death and Somatic Support during Pregnancy

Brain death is defined as the complete absence of brain function, which is determined clinically by lack of consciousness, movement, respiratory effort, and most reflexes. It is confirmed by the lack of activity on electroencephalogram. It is considered distinct from coma and persistent vegetative state (Table 57-17).²¹⁸

Maternal brain death has been rarely reported in the obstetric and critical care literature. Two reviews on the topic identified only 12 reported cases since 1982.^{218,219} Two additional cases were identified.^{220,221} The most common reason for brain death was subarachnoid hemorrhage, followed by trauma and infection.

After brain death occurs, the options include immediate delivery, withdrawal of maternal support, or prolongation of maternal life to

TABLE 57-17 FEATURES OF COMA, PERSISTENT VEGETATIVE STATE, AND BRAIN DEATH

Feature	PVS	Coma	Brain Death
Self-awareness	Absent	Absent	Absent
Suffering	No	No	No
Motor function	No purposeful movement	No purposeful movement	None or only reflex spinal movements
Sleep-wake cycles	Intact	Absent	Absent
Respiratory function	Normal	Depressed, variable	Absent
Electroencephalographic activity	Polymorphic delta or theta, sometimes slow alpha	Polymorphic delta or theta	Electrocerebral silence
Cerebral metabolism	Reduced by 50% or more	Reduced by 50% or more, variable	Absent
Life expectancy	Usually 2-5 yr	Varies	Death within 2-4 wk (Harvard criteria)
Neurologic recovery	Nontraumatic: rare after 3 mo Traumatic: rare after 12 mo	Usually recovery, PVS, or death in 2-4 wk	No recovery

PVS, persistent vegetative state.

Adapted from Ashwal S, Cranford R: Medical aspects of the persistent vegetative state—first of two parts. The Multi-Society Task Force on PVS. *N Engl J Med* 330:1499-1508, 1994.

TABLE 57-18 INTENSIVE CARE MANAGEMENT OF PREGNANT PATIENTS WITH SEVERE NEUROLOGIC INJURY

Condition	Therapy	Physiologic Goal
Respiratory failure	Controlled hyperventilation, PEEP	Physiologic hypercarbia, decrease intracranial pressure, avoid neurogenic pulmonary edema
Fluid-resistant hypotension	Left lateral position, vasopressors	Maintain uteroplacental circulation
Hypothermia	Warming blankets	Prevent fetal bradycardia and IUGR
Hyperthermia	Cooling blankets	Prevent fetal death
Nutritional support	Enteral or parenteral insulin	Maintain positive nitrogen balance (energy intake of 126-147 kJ/kg of ideal body weight), avoid hyperglycemia
Panhypopituitarism	DDAVP, thyroxine, cortisol	Adjust for central diabetes insipidus and adrenocortical insufficiency
Infection prevention	Frequent cultures, catheter line changes	Prevent sepsis
Deep venous thrombosis prophylaxis	Heparin	Prevent pulmonary embolism
Preterm labor	Betamethasone or dexamethasone, consider tocolysis	Prolong gestation
General condition	Expert nursing care	

DDAVP, L-deamino-8-D-arginine vasopressin; IUGR, intrauterine growth restriction; PEEP, positive end-expiratory pressure.

improve the neonatal prognosis by advancing gestational age. The challenges in providing life support to the brain-dead gravida cannot be underestimated and include hemodynamic instability, panhypopituitarism, ventilatory support, temperature regulation, nutrition, infectious complications, hypercoagulability, and premature contractions (Table 57-18).²¹⁵ Given these challenges, it is surprising that two patients experienced a latency exceeding 100 days, with a mean latency of longer than 50 days from the diagnosis of brain death.^{218-220,222,223} Delivery timing is based on assessment of fetal well-being or maturity unless there is evidence of maternal deterioration. Preparation for immediate bedside cesarean section should be made. Discussion of the ethical and legal considerations that surround these cases is beyond the scope of this chapter.

Chapter 58

Neonatal Morbidities of Prenatal and Perinatal Origin

James M. Greenberg, MD, Vivek Narendran, MD, Kurt R. Schibler, MD, Barbara B. Warner, MD, Beth Haberman, MD, and Edward F. Donovan, MD

Obstetric and Postnatal Management Decisions

The nature of obstetric clinical practice requires consideration of two patients: mother and fetus. The intrinsic biologic interdependence of one with the other creates challenges not typically encountered in other realms of medical practice. Often, there is a paucity of objective data to support the evaluation of risks and benefits associated with a given clinical situation, forcing obstetricians to rely on their clinical acumen and experience. Family perspectives must be integrated in clinical decision making, along with the advice and counsel of other clinical providers. In this chapter, we review how to best use neonatologic expertise in the obstetric decision-making process.

Optimal perinatal care often derives from collaboration between the obstetrician and neonatologist during pregnancy and especially around the time of labor to eliminate ambiguity and confusion in the delivery room and to ensure that patients and families understand the rationale for obstetric and postnatal management decisions. The neonatologist can provide information regarding risks to the fetus associated with delaying or initiating preterm delivery and can identify the optimal location for delivery to ensure that skilled personnel are present to support the newborn infant.

In addition to contributing information about gestational age-specific outcomes, the neonatologist can anticipate neonatal complications related to maternal disorders such as diabetes mellitus, hypertension, and multiple gestations or to prenatally detected fetal conditions such as congenital infections, alloimmunization, or developmental anomalies. When a lethal condition or high risk of death in the delivery room is anticipated, the neonatologist can assist with the formulation of a birth plan and develop parameters for delivery room intervention.

Preparing parents by describing delivery room management and resuscitation of a high-risk infant can demystify the process and reduce some of the fear anticipated by the expectant family. Premature infants are susceptible to thermal instability and are moved rapidly after birth to a warming bed to prevent hypothermia while assessing the infant's cardiorespiratory status and vigor. The need for resuscitation is determined by careful evaluation of cardiorespiratory parameters and appropriate response according to published Neonatal Resuscitation Program guidelines.¹

Common Morbidities of Pregnancy and Neonatal Outcomes

Complications of pregnancy that affect infant well-being may be immediately evident after birth, such as hypotension related to maternal hemorrhage, or may manifest hours later, such as hypoglycemia related to maternal diabetes or thrombocytopenia related to maternal preeclampsia. Anemia and thyroid disorders related to transplacental passage of maternal IgG antibodies to platelets or thyroid, respectively, may manifest days after delivery.

Diabetes during pregnancy serves as an example. Infants born to women with diabetes are often macrosomic, increasing the risk of shoulder dystocia and birth injury. After delivery, these infants may have significant hypoglycemia, polycythemia, and electrolyte disturbances, which require close surveillance and treatment. Lung maturation is delayed in the infants born to women with diabetes, increasing the incidence of respiratory distress syndrome (RDS) at a given gestational age. Infants of diabetic mothers may also have delayed neurologic maturation, with decreased tone typically leading to delayed feeding competence. Less common complications include an increased incidence of congenital heart disease and skeletal malformations. These neonatal complications are typically managed without long-term sequelae, but they are not without consequences, such as prolonged hospital stay. Neonatal complications for the infant of a woman with diabetes are a function of maternal glycemic control. Careful antenatal attention to optimal control of blood glucose can reduce neonatal morbidity due to maternal diabetes.

Table 58-1 summarizes other morbidities of pregnancy and their effects on neonatal outcome. The list is not exhaustive and does not take into account how multiple morbidities may interact to create additional complications. All of these problems may contribute to increased length of hospital stay after delivery and to long-term morbidity.

Chorioamnionitis has diverse effects on the fetus and neonatal outcome. It is associated with premature rupture of membranes and preterm delivery. Elevated levels of proinflammatory cytokines may predispose neonates to cerebral injury.² Although suspected or proven neonatal sepsis is more common in the setting of chorioamnio-

TABLE 58-1 MANAGEMENT CONSIDERATIONS ASSOCIATED WITH NEONATAL MANAGEMENT OF CONGENITAL MALFORMATIONS

Malformation	Management Considerations
Clefts	Alternative feeding devices (e.g., Haberman feeder), genetics evaluation, occupational or physical therapy
Congenital diaphragmatic hernia	Skilled airway management, pediatric surgery, immediate availability of mechanical ventilation, nitric oxide, ECMO
Upper airway obstruction or micrognathia	Skilled airway management, otolaryngologic evaluation, genetics evaluation and management, immediate availability of mechanical ventilation
Hydrothorax	Skilled airway management, nitric oxide, ECMO, chest tube placement, immediate availability of mechanical ventilation
Ambiguous genitalia	Endocrinology, urologic consultation, genetic profile available for immediate evaluation
Neural tube defects	Dressings to cover defect, IV fluids, neurosurgery, urologic evaluation, orthopedics evaluation and management
Abdominal wall defects	Saline-filled sterile bag to contain exposed abdominal contents, IV fluids, pediatric surgery, genetics evaluation and management
Cyanotic congenital heart disease	IV access, prostaglandin E ₁ , immediate availability of mechanical ventilation

ECMO, extracorporeal membrane oxygenation; IV, intravenous.

nititis, many neonates born to mothers with histologically proven chorioamnionitis are asymptomatic and appear uninfected. Animal models and associated epidemiologic data suggest that chorioamnionitis can accelerate fetal lung maturation, as measured by surfactant production and function. However, preterm infants born to mothers with chorioamnionitis are more likely to develop bronchopulmonary dysplasia (BPD).³⁻⁵ The neonatal consequences of chorioamnionitis are likely related to the timing, severity, and extent of the infection and the associated inflammatory response.

The effects of preeclampsia on the neonate include intrauterine growth retardation, hypoglycemia, neutropenia, thrombocytopenia, polycythemia, and electrolyte abnormalities such as hypocalcemia. Most of these problems appear related to placental insufficiency, with diminished oxygen and nutrient delivery to the fetus. With delivery and supportive care, most of these problems will resolve with time, although some patients will require treatment with intravenous calcium or glucose, or both, in the early neonatal period. Similarly, severe thrombocytopenia may require platelet transfusion therapy. Preeclampsia may protect against intraventricular hemorrhage (IVH) in preterm infants, perhaps because of maternal treatment or other unknown factors.⁶ Unlike intrauterine inflammation, preeclampsia does not appear to accelerate lung maturation.⁷

Maternal autoimmune disease may affect the neonate through transplacental transfer of autoantibodies. Symptoms are a function of the extent of antibody transfer. Treatment is supportive and based on the affected neonatal organ systems. For example, maternal Graves disease may cause neonatal thyrotoxicosis requiring treatment with propylthiouracil or β -blockers. Maternal lupus or connective tissue disease is linked to congenital heart block that may require long-term pacing after delivery. Myasthenia gravis during pregnancy occasionally results in a transient form of the disease in the neonate. Supportive therapy during the early neonatal period addresses most issues associated with maternal autoimmune disorders. Passively transferred autoantibodies gradually clear from the neonatal circulation with a half-life of 2 to 3 weeks.

Neonatal outcome associated with maternal nutritional status during pregnancy is of growing interest. The Dutch famine of 1944 to 1945 created a unique circumstance for studying the consequences of severe undernutrition during pregnancy (i.e., caloric intake <1000 kcal/

day). Mothers experienced significant third-trimester weight loss, and offspring were underweight.⁸ There is growing evidence that infants undernourished during fetal life are at higher risk for “adult” diseases such as atherosclerosis and hypertension. Poor maternal nutrition during intrauterine life may signal the fetus to modify metabolic pathways and blood pressure regulatory systems, with health consequences lasting into late childhood and beyond.⁹ Conversely, maternal overnutrition (i.e., excessive caloric intake) predisposes mothers to insulin resistance and large-for-gestational-age infants.^{10,11}

Neonatal anemia may be a consequence of perinatal events such as placental abruption, ruptured vasa previa, or fetal-maternal transfusion. At delivery, the neonate may be asymptomatic or display profound effects of blood loss, including high-output heart failure or hypovolemic shock. The duration and extent of blood loss along with any fetal compensation typically determine neonatal clinical status at delivery and subsequent management. In the delivery room, prompt recognition of acute blood loss and transfusion with type O, Rh-negative blood can be a lifesaving intervention.

Neonates from a multifetal gestation are, on average, smaller at a given gestational age than their singleton counterparts. They are also more likely to deliver before term and therefore are more likely to experience the complications associated with low birth weight and prematurity described in this chapter. Monochorionic twins may experience twin-twin transfusion syndrome. The associated discordant growth and additional problems of anemia, polycythemia, congestive heart failure, and hydrops may further complicate the clinical course after delivery, even after amnioreduction or fetoscopic laser occlusion. Cerebral lesions such as periventricular white matter injury and ventricular enlargement may occur more frequently in the setting of twin-twin transfusion syndrome.¹² Additional epidemiologic studies and long-term follow-up are needed to further address this issue.

Congenital malformations present significant challenges for caregivers and families, and prenatal diagnosis is an opportunity to provide anticipatory guidance. The neonatologist can facilitate delivery coverage and ensure availability of appropriate equipment, medications, and personnel. Table 58-1 summarizes some of the important considerations associated with management of congenital malformations and reflects the importance of multidisciplinary input. Typically, these patients are best delivered in a setting where experienced delivery

room attendance is available. If the needed consultative services and equipment are not readily available, arrangement should be made for prompt transfer to a tertiary center. Successful transports depend on clear communication between centers, for example, regarding delivery of an infant with gastroschisis, so that the delivering hospital provides adequate intravenous hydration and protection of exposed abdominal organs, and the referral center can mobilize pediatric surgical intervention immediately on arrival of the infant.

In settings of premature, preterm, or prolonged rupture of membranes and premature labor, mothers are frequently treated with antibiotics and tocolytic agents. Maternal medications administered during pregnancy for non-obstetric diseases can have a significant impact on the neonate. A common challenge in many centers is the treatment of opiate-addicted mothers on methadone. The symptoms of neonatal abstinence syndrome vary as a function of the degree of prenatal opiate exposure and age after delivery. Many infants appear neurologically normal at delivery, only to exhibit symptoms later on the first or second day or extrauterine life. Infants with neonatal abstinence syndrome typically demonstrate irritability, poor feeding, loose and frequent stools, and in severe cases, seizures. Treatment options include nonpharmacologic intervention (e.g., swaddling, minimal stimulation), methadone, or non-narcotic drugs such as phenobarbital. These infants often require hospitalization for many days or weeks until their irritability is under sufficient control to allow for care in a home setting. There is clinical evidence that neonates may also exhibit similar symptoms after withdrawal from antenatal nicotine exposure.^{13,14} The consequences of other illicit drug use during pregnancy have been widely studied but are difficult to assess because of difficulties with diagnosis and confounding variables. Maternal cocaine abuse has been associated with obstetric complications such as placental abruption. Vascular compromise may predispose neonates to cerebral infarcts and bowel injury. Developmental delay and behavioral problems are observed, although associated factors such as poverty, lack of prenatal care, and low socioeconomic status also contribute.

Alloimmune hemolytic disorders such as Rh hemolytic disease and ABO incompatibility can cause neonatal morbidity ranging from uncomplicated hyperbilirubinemia to severe anemia, hydrops, and high-output congestive heart failure. Although it is uncommon, Rh hemolytic disease must be considered as a cause of unexplained hydrops, anemia, or heart failure in infants born to Rh-negative mothers, especially if there is a possibility of maternal sensitization. ABO incompatibility is common, with up to 20% of all pregnancies potentially at risk. The responsible isohemagglutinins have weak affinity for blood group antigens, and the degree of hemolysis and subsequent jaundice varies among patients. Indirect immunoglobulin (Coombs) testing has limited value in predicting clinically significant jaundice. Neonatal morbidity is typically restricted to hyperbilirubinemia requiring treatment with phototherapy.

Prematurity

The mean duration of a spontaneous singleton pregnancy is 280 days or 40 menstrual weeks, 38 weeks after conception. An infant delivered before completion of 37 weeks' gestation is considered to be preterm according to the World Health Organization (WHO) definition. Infant morbidity and mortality increase with decreasing gestational age at birth. The risk of poor outcome, defined as death or lifelong handicap, increases dramatically as gestational age decreases, especially for very low birth weight (VLBW) infants (Fig. 58-1).

Complications of Prematurity

Besides increased mortality risk, prematurity is associated with an increased risk for morbidity in almost every major organ system. BPD, retinopathy of prematurity, necrotizing enterocolitis, and IVH are particularly linked to preterm births. Intrauterine growth restriction and increased susceptibility to infection are not restricted to the preterm infant but are complicated in the immature infant. Table 58-2 summarizes common complications of prematurity by organ system.

The rate of preterm birth increased by 30% between 1983 and 2004, from 9.6% to 12.5%. Three major causes have been identified to explain the rise (see Chapter 29): improved gestational dating associated with increased use of early ultrasound,¹⁶ the substantial rise in multifetal gestation associated with assisted reproductive technology, and an increase in "indicated" preterm births.¹⁷ The latter category is important because decisions affecting the timing and management of preterm delivery can have a profound effect on neonatal outcome. The risk of death before birth hospital discharge doubles when the gestational age decreases from 27.5 weeks (10%) to 26 weeks (20%). Delaying delivery even for a few days may substantially improve outcome, especially before 32 weeks, assuming that the intrauterine environment is safe to support the fetus. However, in some clinical situations with a high potential for preterm delivery, it is difficult to assess the quality of the intrauterine environment. Three common examples are preterm, premature rupture of membranes (see Chapter 31), placental abruption (see Chapter 37), and preeclampsia (see Chapter 35). In each case, prolonging gestation to allow continued fetal growth and maturation in utero is accompanied by an uncertain risk of rapid change in maternal status with a corresponding increased risk of fetal compromise. Tests of fetal well-being are discussed in Chapter 21, and clinical decision making in obstetrics is addressed in Chapters 28 and 29.

Obstetric decisions about the timing of delivery in the setting of uncertain in utero risk are a significant contributing factor to the increase in late preterm births, after 32 to 34 weeks. The contribution of elective delivery must also be considered. Although perinatal mor-

TABLE 58-2 COMMON COMPLICATIONS OF PREMATURETY BY ORGAN SYSTEM

Organ System	Morbidity
Pulmonary	Respiratory distress syndrome Bronchopulmonary dysplasia Pulmonary hypoplasia
Cardiovascular	Apnea of prematurity Patent ductus arteriosus Apnea and bradycardia Hypotension
Gastrointestinal, hepatic	Necrotizing enterocolitis Dysmotility or reflux Feeding difficulties Hypoglycemia
Central nervous system	Intraventricular hemorrhage Periventricular leukomalacia
Visual	Retinopathy of prematurity
Skin	Excess insensible water loss Hypothermia
Immunologic, hematologic	Increased incidence of sepsis and meningitis Anemia of prematurity

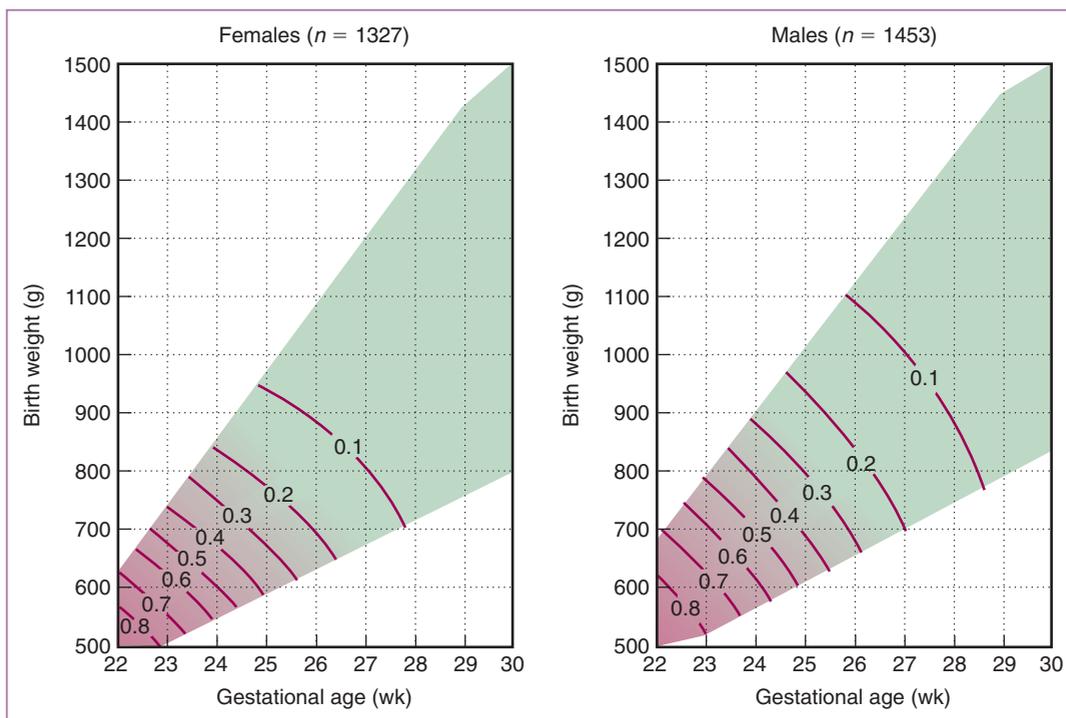

FIGURE 58-1 Estimated mortality risk by birth weight and gestational age based on singleton infants born in National Institute of Child Health and Human Development (NICHD) Neonatal Research Network centers between January 1, 1995, and December 31, 1996. Numeric values represent age- and weight-specific mortality rates per 100 births. (From Lemons JA, Bauer CR, Oh W, et al: Very low birth weight outcomes of the National Institute of Child Health and Human Development Neonatal Research Network, January 1995 through December 1996. NICHD Neonatal Research Network. *Pediatrics* 107:E1, 2001. Used with permission of the American Academy of Pediatrics.)

tality continues to decrease, in part due to a decline in stillbirths,¹⁷ interest in understanding the extent of morbidity associated with late preterm deliveries has intensified because of the large number of these late preterm infants and the potential to avoid morbidities, such as temperature instability, feeding problems, hyperbilirubinemia requiring treatment, suspected sepsis, and respiratory distress. Infants born at 35 weeks' gestation are nine times more likely to require mechanical ventilation than those born at term.¹⁸

Most complications of late preterm delivery are easily treated, but their economic and social effects are substantial, and long-term sequelae are not well understood. For example, brain growth and development proceed rapidly during the third trimester and continue for the first several years of life. An infant born at 35 weeks' gestation has approximately one-half the brain volume of a term infant. Although IVH is unusual after 32 weeks' gestation, regions including the periventricular white matter continue to undergo rapid myelination during this period. Studies by Stein and colleagues¹⁹ and Kirkegaard and coworkers²⁰ demonstrate an association between late preterm delivery and long-term neurodevelopmental problems, including learning disabilities and attention deficit disorders. Careful neurologic and epidemiologic studies will be required to define any mechanistic connection between late preterm delivery and these long-term outcomes.

Our growing recognition of the morbidity and mortality risks associated with preterm delivery clearly deserve close scrutiny and further study. Table 58-3 compares estimates of complication rates between preterm and late preterm infants.

Classic preterm infants, typically defined as those born before 32 weeks' gestation or weighing less than 1500 g, or both, comprise only 1.5% of all deliveries, whereas the late preterm population accounts for 8% to 9% of all births. Even uncommon complications in the later preterm population may represent a significant health care burden. As the number of late preterm infants continues to increase, clinicians and policymakers will likely focus additional attention on the causes and prevention of such deliveries (Fig. 58-2).

Decisions at the Threshold of Viability

Decisions regarding treatment of infants at the "limit of viability" are often the most difficult for families and health care professionals. The difficulty stems in part from the lack of clarity in defining what that limit is, which has fallen by approximately 1 week every decade over the past 40 years. Among developed countries, most identify the limit of viability at 22 to 25 weeks' gestation.²⁹⁻³¹ Making decisions at this early gestation requires accurate information about mortality and morbidity for this population. At 22 weeks (22 0/7 days to 22 6/7 days), survival is rare and typically not included in studies of survival or long-term outcome. Rates of survival to hospital discharge for infants born at 23 weeks' gestation (23 0/7 to 23 6/7 days) range from 15% to 30%. Survival increases to between 30 and 55% for infants born at 24 weeks' gestation.^{15,23,30,32-35} The Vermont-Oxford Network reported weight-based survival for more than 4000 infants born between 401 and 500 g (mean gestational age of 23.3 ± 2.1 weeks) from 1996 to 2000. Survival to hospital discharge was 17%.³⁶ Although mortality

TABLE 58-3 ESTIMATED COMPLICATION RATES FOR PRETERM AND LATE PRETERM INFANTS

Complication of Prematurity	Incidence for Preterm Infants*	Incidence for Late Preterm Infants†
Respiratory distress syndrome	65% surf Rx < 1500 g 80% < 27 wk ²¹	5%
Bronchopulmonary dysplasia	23% < 1500 g ¹⁵	Uncommon
Retinopathy of prematurity	Approx 40% < 1500 g ²²⁻²⁴	
Intraventricular hemorrhage with ventricular dilation or parenchymal involvement	11% < 1500 g ¹⁵	Rare
Necrotizing enterocolitis	5-7% < 1500 g ¹⁵	Uncommon
Patent ductus arteriosus	30% < 1500 g ¹⁵	Uncommon
Feeding difficulty	>90%	10-15% ²⁵
Hypoglycemia	NA	10-15% ²⁵

*Defined as <32 weeks and/or <1500 g.

†Defined as 32-37 weeks and/or 1500-2500 g.

NA, not available; surf Rx, surfactant treatment.

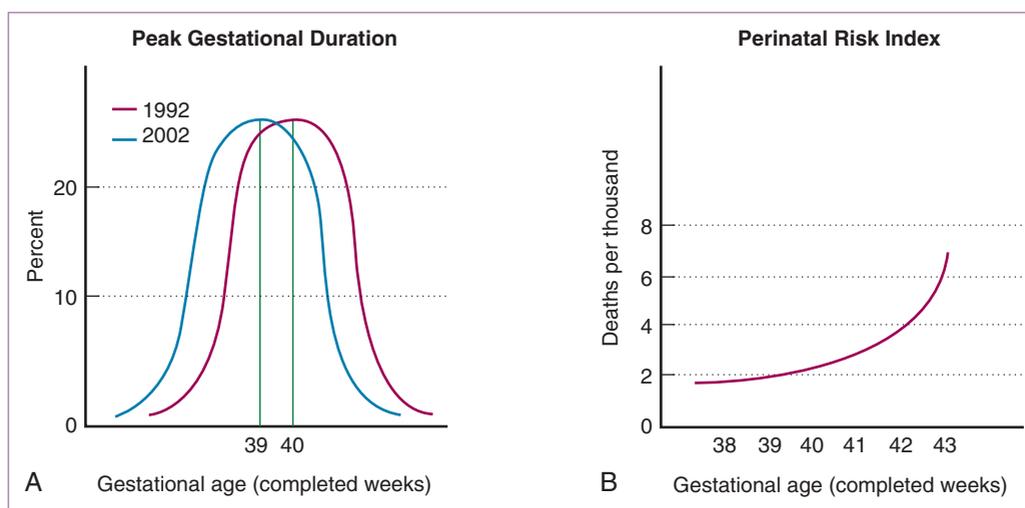

FIGURE 58-2 Peak gestational age duration and risk of intrauterine fetal demise. **A**, Change in peak gestational duration between 1992 and 2002. The duration of gestation decreased by a full week during that decade, from 40 weeks to 39 weeks. **B**, The risk of intrauterine fetal demise increases with increasing gestational age, especially beyond 40 weeks. The risk of intrauterine fetal demise likely influences obstetric decision making regarding the timing of delivery in pregnancies approaching 40 weeks' gestation. (Data from Davidoff MJ, Dias T, Damus K, et al: Changes in the gestational age distribution among U.S: singleton births: Impact on rates of late preterm birth, 1992 to 2002. *Semin Perinatol* 30:8-15, 2006; Yudkin PL, Wood L, Redman CW: Risk of unexplained stillbirth at different gestational ages. *Lancet* 1:1192-1194, 1987; and Smith GC: Life-table analysis of the risk of perinatal death at term and post term in singleton pregnancies. *Am J Obstet Gynecol* 184:489-496, 2001.)

rates decline for each 1-week increase in gestational age at delivery, long-term neurodevelopmental outcomes do not improve proportionately. Of infants born at less than 25 weeks' gestation, 30% to 50% will have moderate to severe disability, including blindness, deafness, developmental delays and cerebral palsy.^{23,30,32} The National Institute of Child Health and Human Development reported neurodevelopmental outcomes for more than 5000 infants born between 22 and 26 weeks' gestation from 1993 to 1998. Bayley mental development index (MDI) and nonverbal development index (NDI) scores improved and blindness was reduced, but rates of severe cerebral palsy, hearing loss, shunted hydrocephalus, and seizures were unchanged.³⁷

Birth weight and gender also affect survival rates. Higher weights within gestational age categories and female sex consistently show a survival advantage and better neurodevelopmental outcomes.^{15,37} Survival and long-term outcomes of very preterm infants are improved

with delivery at a tertiary center, rather than neonatal transfer from an outlying facility.³⁸⁻⁴⁰ When families desire resuscitation or dating is uncertain, every attempt should be made to transfer to a tertiary center for delivery. Maternal transfer to a tertiary center and administration of corticosteroids (see Chapter 23) are the only antenatal interventions that have been significantly and consistently related to improved neonatal neurodevelopmental outcomes.³⁷ Other attempted strategies are discussed in Chapter 29.

Planning for Delivery at the Limits of Viability

Ideally, discussion between physicians and parents should begin before birth in a nonemergent situation, and include both obstetric and neonatal care providers. Even during active labor, communication with the family should be initiated as a foundation for postnatal discussions. The family should understand that plans made before delivery are

influenced by maternal and fetal considerations and are based on limited information. It should be emphasized that information available only after delivery, such as birth weight and neonatal physical findings, may change the infant's prognosis.³⁰

Neonatal Resuscitation at the Limits of Viability

If time allows before delivery of an infant whose gestational age is near the threshold of viability, a thoughtful birth plan developed by the parents in consultation with maternal-fetal medicine specialists and the neonatologist should be established. The neonatologist can assist families in making decisions regarding a birth plan for their infant by providing general information about the prognosis, the hospital course, potential complications, survival information, and general health and well-being of infants delivered at the similar gestational age. When time does not permit such discussions, careful evaluation of gestational age and response to resuscitation are instrumental in assisting families in making decisions regarding viability or nonviability of an extremely premature infant. The presence of an experienced pediatrician at delivery is recommended to assess weight, gestational age and fetal status, and to provide medical leadership in decisions to be made jointly with families.^{29,31} In cases of precipitous deliveries when communication with families has not occurred, physicians should use their best judgment on behalf of the infant to initiate resuscitation until families can be brought into the discussion, erring on the side of resuscitation if the appropriate course is uncertain.^{29,41}

Under ideal circumstances, the health care team and the infant's family should make shared management decisions regarding these infants. The American Medical Association and American Academy of Pediatrics endorse the concept that "the primary consideration for decisions regarding life-sustaining treatment for seriously ill newborns should be what is best for the newborn," and they recognize parents as having the primary role in determining the goals of care for their infant.^{1,29,42} Discussions with the family should include local and national information on mortality as well as long-term outcomes. Parental participation should be encouraged with open communication regarding their personal values and goals.

Decisions about resuscitation should be individualized to the case and the family but should begin with parameters for care that are based on global reviews of the medical and ethical literature and expertise. The Nuffield Council on Bioethics in the United Kingdom has proposed parameters for treating extremely premature infants that parallel guidance from the American Academy of Pediatrics.^{1,29} When gestation or birth weight are associated with almost certain early death and anticipated morbidity is unacceptably high, resuscitation is not indicated. Exceptions to comply with parental requests may be appropriate in specific cases, such as for infants born at less than 23 weeks' gestation or with a birth weight of 400 g. When the prognosis is more uncertain, survival is borderline with a high rate of morbidity, such as at 23 to 24 weeks' gestation, parental views should be supported.

Decisions regarding care of extremely preterm infants is always difficult for all involved. Parental involvement, active listening, and accurate information are critical to an optimal outcome for infants and their families. Although parents are considered the best surrogate for their infant, health care professionals have a legal and ethical obligation to provide appropriate care for the infant based on medical information. If agreement with the family cannot be reached, it may be appropriate to consult the hospital ethics committee or legal council. If the situation is emergent and the responsible physician concludes the parents wishes are not in the best interest of the infant, it is appropriate to resuscitate against parental objection.³⁵

Respiratory Problems in the Neonatal Period

No aspect of the transition from fetal to neonatal life is more dramatic than the process of pulmonary adaptation. In a normal term infant, the lungs expand with air, pulmonary vascular resistance rapidly decreases, and vigorous, consistent respiratory effort ensues within a minute of separation from the placenta. The process depends on crucial physiologic mechanisms, including production of functional surfactant, dilation of resistance pulmonary arterioles, bulk transfer of fluid from air spaces, and physiologic closure of the ductus arteriosus, foramen ovale. Complications such as prematurity, infection, neuromuscular disorders, developmental defects, or complications of labor may interfere with neonatal respiratory function. Common respiratory problems of neonates are reviewed in the following sections.

Transient Tachypnea of the Newborn

Definition

Transient tachypnea of the newborn (TTN), commonly known as *wet lungs*, is a mild condition affecting term and late preterm infants. This is the most common respiratory cause of admission to the special care nursery. Transient tachypnea is self-limiting, with no risk of recurrence or residual pulmonary dysfunction. It rarely causes hypoxic respiratory failure.⁴³

Pathophysiology

During the last trimester, a series of physiologic events led to changes in the hormonal milieu of the fetus and its mother to facilitate neonatal transition.⁴⁴ Rapid clearance of fetal lung fluid is essential for successful transition to air breathing. The bulk of this fluid clearance is mediated by transepithelial sodium re-absorption through amiloride sensitive sodium channels in the respiratory epithelial cells.⁴⁵ The mechanisms for such an effective "self-resuscitation" soon after birth are not completely understood. Traditional explanations based on Starling forces and vaginal squeeze for fluid clearance account only for a fraction of the fluid absorbed.

Risk Factors

Transient tachypnea is classically seen in infants delivered near term, especially after cesarean birth before the onset of spontaneous labor.^{46,47} Absence of labor is accompanied by impaired surge of endogenous steroids and catecholamines necessary for a successful transition.⁴⁸ Additional risk factors such as multiple gestations, excessive maternal sedation, prolonged labor, and complications resulting from excessive maternal fluid administration have been less consistently observed.

Clinical Presentation

The clinical features of TTN include a combination of grunting, tachypnea, nasal flaring, and mild intercostal and subcostal retractions along with mild central cyanosis. The grunting can be fairly significant and sometimes misdiagnosed as RDS resulting from surfactant deficiency. The chest radiograph usually shows prominent perihilar streaks that represent engorged pulmonary lymphatics and blood vessels. The radiographic appearance and clinical symptoms rapidly improve within the first 24 to 48 hours. The presence of fluid in the fissures is a common nonspecific finding. TTN is a diagnosis of exclusion and it is important that other potential causes of respiratory distress in the

newborn are excluded. The differential diagnosis of TTN includes pneumonia or sepsis, air leaks, surfactant deficiency, and congenital heart disease. Other rare diagnoses are pulmonary hypertension, meconium aspiration, and polycythemia.

Diagnosis

TTN is primarily a clinical diagnosis. Chest radiographs typically demonstrate mild pulmonary congestion with hazy lung fields. The pulmonary vasculature may be prominent. Small accumulations of extrapleural fluid, especially in the minor fissure on the right side, may be seen.

Management

Management is mainly supportive. Supplemental oxygen is provided to keep the oxygen saturation level greater than 90%. Infants are usually given intravenous fluids and not fed orally until their tachypnea resolves. Rarely, infants may need continuous positive airway pressure to relieve symptoms. Diuretic therapy has been shown to be ineffective.⁴⁹

Neonatal Implications

TTN can lead to significant morbidity related to delayed initiation of oral feeding, which may interfere with parental bonding and establishment of successful breastfeeding. The hospital stay is prolonged for mother and infant. The existing perinatal guidelines⁵⁰ recommend scheduling elective cesarean births only after 39 completed weeks' gestation to reduce the incidence of TTN (Fig. 58-3).

Pulmonary Hypoplasia

Lung development begins during the first trimester when the ventral foregut endoderm projects into adjacent splanchnic mesoderm (see Chapter 15). Branching morphogenesis, epithelial differentiation, and acquisition of a functional interface for gas exchange ensue through the remainder of gestation and are not completed until the second or

third year of postnatal life. Clinical conditions associated with pulmonary hypoplasia and approaches to prevention and treatment are discussed here.

Perturbation of lung development at anytime during gestation may lead to clinically significant pulmonary hypoplasia. Two general pathophysiologic mechanisms contribute to pulmonary hypoplasia: extrinsic compression and neuromuscular dysfunction. Infants with aneuploidy such as trisomy 21 and those with multiple congenital anomalies or hydrops fetalis have a high incidence of pulmonary hypoplasia.

Oligohydramnios, whether caused by premature rupture of membranes or diminished fetal urine production, can lead to pulmonary hypoplasia. The reduction in branching morphogenesis and surface area for gas exchange may be lethal or clinically imperceptible. Clinical studies link the degree of pulmonary hypoplasia to the duration and severity of the oligohydramnios. Similarly, pulmonary hypoplasia is a hallmark of congenital diaphragmatic hernia (CDH), caused by extrinsic compression of the developing fetal lung by the herniated abdominal contents. The degree of pulmonary hypoplasia in CDH is directly related to the extent of herniation. Large hernias occur earlier in gestation. In most cases, the contralateral lung is also hypoplastic.

Lindner and associates⁵¹ report a significant mortality risk for infants born to women with premature rupture of membranes and oligohydramnios before 20 weeks' gestation. Their retrospective analysis demonstrated 69% short-term mortality risk. However, the remaining infants fared well and were discharged with apparently normal pulmonary function. Prediction of clinical outcome is difficult for these infants.

Prenatal diagnosis and treatment of pulmonary hypoplasia are discussed in Chapters 18 and 24. Postnatal treatment for pulmonary hypoplasia is largely supportive. A subset of infants with profound hypoplasia have insufficient surface area for effective gas exchange. These patients typically display profound hypoxemia, respiratory acidosis, pneumothorax, and pulmonary interstitial emphysema. At the other end of the spectrum, some infants have no clinical evidence of pulmonary insufficiency at birth but have diminished reserves

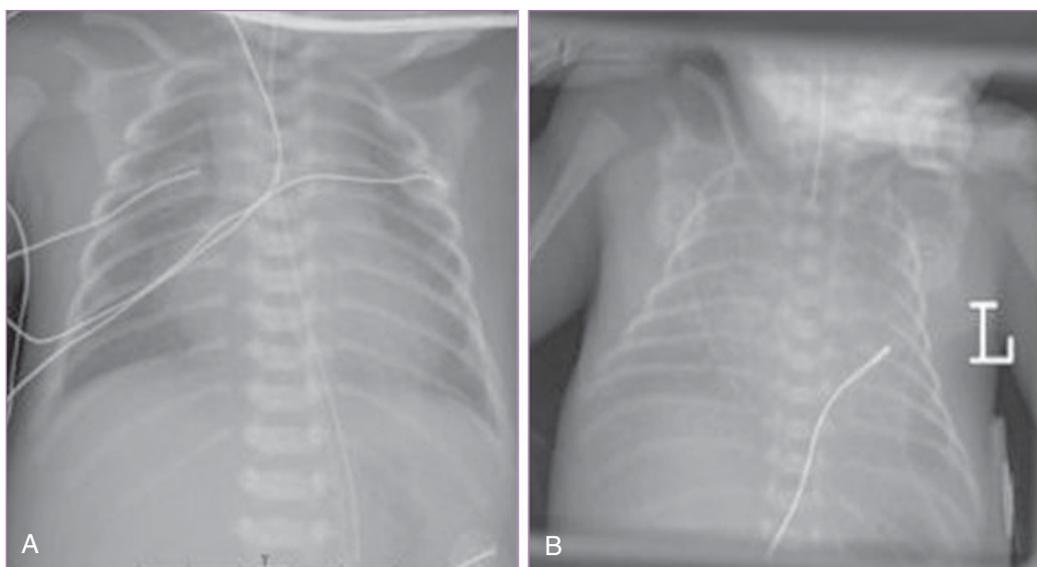

FIGURE 58-3 Radiographic appearance of transient tachypnea of the newborn (TTN) (A) and respiratory distress syndrome RDS (B). The radiographic characteristics of TTN include perihilar densities with fairly good aeration, bordering on hyperinflation. In contrast, neonates with RDS have diminished lung volumes on chest radiographs reflecting atelectasis associated with surfactant deficiency. Diffuse “ground-glass” infiltrates along with air bronchograms make the cardiothymic silhouette indistinct.

when stressed. In between is a cohort of patients with respiratory insufficiency responsive to mechanical ventilation and pharmacologic support. Typically, these patients have adequate oxygenation and ventilation, suggesting adequate gas exchange capacity. However, many develop pulmonary hypertension. The pathophysiologic sequence begins with limited cross-sectional area of resistance arterioles, followed by smooth muscle hyperplasia in these same vessels. Early use of pulmonary vasodilators such as nitric oxide is the mainstay of management for increased pulmonary vasoreactivity. Optimizing pulmonary blood flow reduces the potential for hypoxemia thought to stimulate pathologic medial hyperplasia. If oxygenation, ventilation, and acid-base balance are maintained, nutritional support and time can allow sufficient lung growth to support the infant's metabolic demands. In many cases, the process is lengthy, requiring mechanical ventilation and treatment with pulmonary vasodilators such as sildenafil, bosentan, or prostacyclin for weeks to months. Just as prenatal prognosis is difficult to assess, predicting outcome for patients with pulmonary hypoplasia managed in the neonatal intensive care unit is hampered by limited data.

Respiratory Distress Syndrome

RDS is a significant cause of early neonatal mortality and long-term morbidity. However, in the past 3 decades, significant advances have been made in the management of RDS, with consequent decreases in associated morbidity and mortality.

Perinatal Risk Factors

The classic risk factors for RDS are prematurity and low birth weight. Factors that negatively affect surfactant synthesis include maternal diabetes, perinatal asphyxia, cesarean delivery without labor, and genetic factors (i.e., white race, history of RDS in siblings, male sex, and surfactant protein B deficiency).⁵² Congenital malformations that lead to lung hypoplasia such as diaphragmatic hernia are also associated with significant surfactant deficiency. Prenatal assessment of fetal lung maturity and treatment to induce fetal lung maturity are discussed in detail in Chapter 23.

Clinical Presentation

Symptoms are typically evident in the delivery room, including tachypnea, nasal flaring, subcostal and intercostal retractions, cyanosis, and expiratory grunting. The characteristic expiratory grunt results from expiration through a partially closed glottis, providing continuous distending airway pressure to maintain functional residual capacity and thereby prevent alveolar collapse. These signs of respiratory difficulty are not specific to RDS and have a variety of pulmonary and nonpulmonary causes, such as transient tachypnea, air leaks, congenital malformations, hypothermia, hypoglycemia, anemia, polycythemia, and metabolic acidosis. Progressive worsening of symptoms in the first 2 to 3 days, followed by recovery, characterizes the typical clinical course. This timeline (curve) is modified by administration of exogenous surfactant with a more rapid recovery. Classic radiographic findings include low-volume lungs with a diffuse reticulogranular pattern and air bronchograms. The diagnosis can be established chemically by measuring surfactant activity in tracheal or gastric aspirates, but this is not routinely done.⁵³

Management

Infants are managed in an incubator or under a radiant warmer in a neutral thermal environment to minimize oxygen requirement and consumption. Arterial oxygen tension (PaO_2) is maintained between

50 and 80 mm Hg, with saturations between 88% and 96%. Hypercarbia and hyperoxia are avoided. Heart rate, blood pressure, respiratory rate, and peripheral perfusion are monitored closely. Because sepsis cannot be excluded, screening blood culture and complete blood cell counts with differential counts are performed, and infants are started on broad-spectrum antibiotics for at least 48 hours.

SURFACTANT THERAPY

Surfactant replacement is one of the safest and most effective interventions in neonatology. The first successful clinical trial of surfactant use was reported in 1980 using surfactant prepared from an organic solvent extract of bovine lung to treat 10 infants with RDS.⁵⁴ By the early 1990s, widespread use of surfactant leads to a progressive decrease in RDS-associated mortality. Two strategies for treatment are commonly used: prophylactic surfactant, in which surfactant is administered before the first breath to all infants at risk for developing RDS, and rescue therapy, in which surfactant is given after the onset of respiratory signs. The advantages of prophylactic administration include a better distribution of surfactant when instilled into a partially fluid filled lung along with the potential to decrease trauma related to resuscitation. Avoiding treatment of unaffected infants and related cost savings are the advantages of rescue therapy. Biologically active surfactant can be prepared from bovine, porcine, human, or synthetic sources. When administered to patients with surfactant deficiency and RDS, all these preparations show improvement in oxygenation and a decreased need for ventilatory support, along with decreased air leaks and death.⁵⁵ The combined use of antenatal corticosteroids and postnatal surfactant improves neonatal outcome more than postnatal surfactant therapy alone.

CONTINUOUS POSITIVE AIRWAY PRESSURE

In infants with acute RDS, continuous positive airway pressure (CPAP) appears to prevent atelectasis, minimize lung injury, and preserve surfactant function, allowing infants to be managed without endotracheal intubation and mechanical ventilation. Early delivery room CPAP therapy decreases the need for mechanical ventilation and the incidence of long-term pulmonary morbidity.^{56,57} Increasing use of CPAP has led to decreased use of surfactant and decreased incidence of BPD.⁵⁸ Common complications of CPAP include pneumothorax and pneumomediastinum. Rarely, the increased transthoracic pressure leads to progressive decrease in venous return and decreased cardiac output. Brief intubation and administration of surfactant followed by extubation to CPAP is an additional RDS treatment strategy increasingly used in Europe and Australia.⁵⁹ Prospective, randomized trials enrolling extremely low birth weight (ELBW) infants and comparing early delivery room CPAP with early prophylactic surfactant therapy are being conducted in the National Institute of Child Health and Human Development (NICHD) Neonatal Network (i.e., SUPPORT trial).

MECHANICAL VENTILATION

The goal of mechanical ventilation is to limit volutrauma and barotrauma without causing progressive atelectasis while maintaining adequate gas exchange. Complications associated with mechanical ventilation include pulmonary air leaks, endotracheal tube displacement or dislodgement, obstruction, infection, and long-term complications such as BPD and subglottic stenosis.

Complications

Acute complications include air leaks such as pneumothorax, pneumomediastinum, pneumopericardium, and pulmonary interstitial

emphysema. The incidence of these complications has decreased significantly with surfactant treatment. Infection, intracranial hemorrhage, and patent ductus arteriosus occur more frequently in VLBW infants with RDS. Long-term complications and comorbidities include BPD, poor neurodevelopmental outcomes, and retinopathy of prematurity. Incidence of these complications is inversely related to decreasing birth weight and gestation.

Promising new therapies for the treatment of RDS include early inhaled nitric oxide and supplementary inositol for prevention of long-term pulmonary morbidity (e.g., BPD).⁶⁰⁻⁶² Noninvasive respiratory support techniques such as synchronized nasal intermittent positive ventilation (SNIPPV) and high-flow nasal cannulas are being studied to decrease ventilator-associated lung injury.^{63,64}

Bronchopulmonary Dysplasia

The classic form of BPD was first described⁶⁵ in a group of preterm infants who were mechanically ventilated at birth and who later developed chronic respiratory failure with characteristic radiological findings. These infants were larger, late preterm infants with lung changes attributed to mechanical trauma and oxygen toxicity. Smaller, extremely preterm infants with lung immaturity who have received antenatal glucocorticoids have developed a milder form, called *new BPD*.⁶⁶ This disease primarily occurs in infants weighing less than 1000 g who have very mild or no initial respiratory distress. The clinical diagnosis is based on the need for supplemental oxygen at 36 weeks' corrected gestational age.⁶⁷ A physiologic definition of BPD based on the need for oxygen at the time of diagnosis has been developed.⁶⁸

Clinically, the transition from RDS to BPD is subtle and gradual. Radiologically, classic BPD is marked by areas of shifting focal atelectasis and hyperinflation with or without parenchymal cyst formation. Chest radiographs of infants with the new BPD show bilateral haziness, reflecting diffuse microatelectasis without multiple cystic changes. These changes lead to ventilation-perfusion mismatching and increased work of breathing. Preterm infants with BPD gradually wean off respiratory support and oxygen or continue to worsen with progressively severe respiratory failure, pulmonary hypertension, and a high mortality risk.

Pathophysiology

Risk factors predisposing preterm infants to BPD include extreme prematurity, oxygen toxicity, mechanical ventilation, and inflammation.⁶⁹ The pathologic findings characterized by severe airway injury and fibrosis in the old BPD have been replaced in the new BPD with large, simplified alveolar structures, impaired capillary configuration, and various degrees of interstitial cellularity or fibroproliferation.⁷⁰ Airway and vascular lesions tend to be associated with more severe disease.

Oxygen-induced lung injury is an important contributing factor. Exposure to oxygen in the first 2 weeks of life and as chronic therapy has been associated in clinical studies with the severity of BPD.^{71,72} In animal models, hyperoxia has been shown to mimic many of the pathologic findings of BPD. Two large, randomized trials in preterm infants suggested that the use of supplemental oxygen to maintain higher saturations resulted in worsening pulmonary outcomes.^{73,74} Barotrauma and volutrauma associated with mechanical ventilation have been identified as major factors causing lung injury in preterm infants.^{75,76} Surfactant replacement therapy is beneficial in decreasing symptoms of RDS and improving survival. The efficacy of surfactant to decrease the incidence of subsequent BPD is less well established. Chronic inflammation and edema associated with positive-pressure ventilation cause surfactant protein inactivation.

Because intrauterine inflammation is increasingly recognized as a cause of preterm parturition, antenatal inflammation is gaining more attention in the pathogenesis of BPD and other morbidities of prematurity.⁷⁷ Chorioamnionitis has been strongly associated with impaired pulmonary and vascular growth, a typical finding in the new BPD.

Most deliveries before 30 weeks' gestation are associated with histologic chorioamnionitis, which except for preterm initiation of labor is otherwise clinically silent. The more preterm the delivery, the more often histologic chorioamnionitis is detected. Increased levels of proinflammatory mediators in amniotic fluid, placental tissues, tracheal aspirates, lung, and serum of ELBW preterm infants support an important role for both intrauterine and extrauterine inflammation in the development and severity of BPD. The proposed interaction between the proinflammatory and anti-inflammatory influences on the developing fetal and preterm lung is detailed in Figure 58-4. Several animal models and preterm studies demonstrate that mediators of inflammation, including endotoxins, tumor necrosis factor, IL-1, IL-6, IL-8, and transforming growth factor α can enhance lung maturation but concurrently impede alveolar septation and vasculogenesis, contributing to the development of BPD.⁷⁸⁻⁸¹ Chorioamnionitis alone is associated with BPD, but the probability is increased when these infants receive a second insult such as mechanical ventilation or postnatal infection.⁸²⁻⁸⁴

Maternal genital mycoplasmal infection, particularly with *Mycoplasma hominis* and *Ureaplasma urealyticum*, is associated with preterm delivery.⁸⁵ Numerous studies have isolated these organisms from amniotic fluid and placentas in women with spontaneous preterm birth (i.e., preterm birth due to preterm labor or preterm rupture of membranes). After birth, these organisms are known to colonize and elicit a proinflammatory response in the respiratory tract, leading to BPD.

The unpredictable variation in the incidence of BPD, despite adjusting for low birth weight and prematurity, suggests a genetic predisposition to the occurrence and the severity of BPD. Expression of genes critical to surfactant synthesis, vascular development, and inflammatory regulation are likely to play a role in the pathogenesis of BPD. Twin studies have shown that the BPD status of one twin, even after correcting for contributing factors, is a highly significant predictor of BPD in the second twin. In this particular cohort, after controlling for covariates, genetic factors accounted for 53% of the variance in the liability for BPD.⁸⁶ Genetic polymorphisms in the inflammatory response are increasingly recognized as important in the pathogenesis of preterm parturition (see Chapter 28), and may be similarly important in the genesis of inflammatory morbidities in the preterm neonate as well.

Long-Term Complications

Infants with BPD have significant pulmonary sequelae during childhood and adolescence. Reactive airway disease occurs more frequently, with increased risk of bronchiolitis and pneumonia. Up to 50% of infants with BPD require readmission to hospital for lower respiratory tract illness in the first year of life.⁸⁷

BPD is an independent predictor of adverse neurologic outcomes. Infants with BPD exhibit lower average IQs, academic difficulties, delayed speech and language development, impaired visual-motor integration, and behavior problems.⁸⁸ Sparse data also suggest an increased risk for attention deficit disorders, memory and learning deficits. Delayed growth occurs in 30% to 60% of infants with BPD at 2 years. The degree of long-term growth delay is inversely proportional to birth weight and directly proportional to the severity of BPD.

Prevention Strategies

Several strategies to decrease the incidence of BPD have been tried, including administration of surfactant in the delivery room, antioxidant superoxide dismutase and vitamin A supplementation, optimizing fluid and parenteral nutrition, aggressive treatment of patent ductus arteriosus, minimizing mechanical ventilation, limiting exposure to high levels of oxygen, and infection prevention. Table 58-4 enumerates current strategies and their relative effectiveness in preventing BPD.⁸⁹ Large, controlled clinical trials and meta-analysis have not demonstrated a significant impact of these pharmacologic and nutritional interventions.⁹⁰ The multifactorial nature of BPD suggests that targeting individual pathways is unlikely to have a significant effect on outcome. Strategies to address several pathways simultaneously are more promising (Fig. 58-4).

Meconium-Stained Amniotic Fluid and Meconium Aspiration Syndrome

The significance and management of meconium-stained amniotic fluid has evolved with time. Meconium is present in the fetal intestine by the second trimester. Maturation of intestinal smooth muscle and

the myenteric plexus progresses through the third trimester. Intrauterine passage of meconium is unusual before 36 weeks and does not typically occur for several days after preterm delivery. The potential for intrauterine meconium passage increases with each week of gestation thereafter.⁹¹ The physiologic stimuli for passage of meconium are still incompletely understood. Clinical experience and epidemiologic data suggest that a stressed fetus may pass meconium before birth. Infants born through meconium-stained amniotic fluid have a lower pH and are likely to have nonreassuring fetal heart tracings.⁹² Meconium-stained amniotic fluid at delivery occurs in 12% to 15% of all deliveries and occurs more frequently in post-term gestation and in African Americans.⁹³

In contrast to meconium-stained amniotic fluid, meconium aspiration syndrome is unusual. Meconium aspiration syndrome is a clinical diagnosis that includes delivery through meconium-stained amniotic fluid along with respiratory distress and a characteristic appearance on chest radiographs. Approximately 2% of deliveries with meconium-stained amniotic fluid are complicated by meconium aspiration syndrome, but the reported incidence varies widely.^{94,95} The severity of the syndrome varies. The hallmarks of severe disease are the need for positive-pressure ventilation and the presence of pulmonary hypertension. Severe meconium aspiration is associated with significant mortality and morbidity risk, including air leak, chronic lung disease, and developmental delay.

A relationship between meconium-stained amniotic fluid and meconium aspiration syndrome has been presumed since the 1960s, when the strategy of tracheal suctioning in the delivery room to prevent meconium aspiration was proposed.⁹⁶ By the 1970s, this practice was clinically established and affirmed by retrospective reviews. Oropharyngeal suctioning on the perineum before delivery of the chest to complement tracheal suctioning was also recommended. However, additional studies did not verify the benefit of tracheal suctioning. Tracheal suctioning did not affect the incidence of meconium aspiration syndrome in vigorous infants in large, prospective, randomized trial.⁹⁷ Another prospective, randomized, controlled study in 2514 infants to determine the efficacy of oropharyngeal suctioning before delivery of the fetal shoulders in infants born through meconium-stained amniotic fluid also found no reduction in meconium aspiration syndrome.⁹⁸ Amnioinfusion during labor to dilute the concentration of meconium has also been studied to prevent meconium aspiration, but a randomized trial found no reduction in the incidence or severity of meconium aspiration.⁹⁹ These well-designed clinical trials support the notion that meconium-stained amniotic fluid may

Intervention	Relative Effectiveness	Evidence or Quality of Data

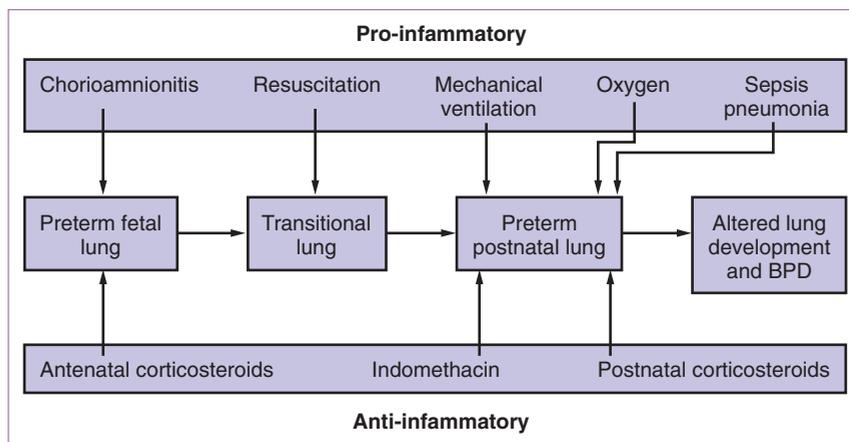

FIGURE 58-4 Role of inflammation in the pathogenesis of bronchopulmonary dysplasia (BPD).

not have a true mechanistic, pathophysiologic connection with meconium aspiration syndrome.

In 2001, Ghidini and Spong¹⁰⁰ questioned the connection between meconium-stained amniotic fluid and meconium aspiration syndrome. Reports describe infants born through clear amniotic fluid with respiratory distress with pulmonary hypertension and other clinical characteristics of meconium aspiration syndrome.¹⁰¹ Experimental data suggest that factors promoting fetal acidosis and hypoxemia promote remodeling of resistance pulmonary arteries. These same factors can promote intrauterine meconium passage. However, the remodeling, perhaps exacerbated by inflammation from infection or by meconium, produces a clinical syndrome called *meconium aspiration syndrome*.^{102,103} The incidence of meconium aspiration syndrome has decreased in several centers over the past several years, perhaps a consequence of improvements in obstetric assessment and management,^{104,105} including a reduction in the incidence of post-term deliveries. Our center has experienced a decline in meconium aspiration syndrome while concurrently pursuing a policy of no routine tracheal suctioning for infants born through meconium-stained amniotic fluid.

Treatment of severe meconium aspiration syndrome has dramatically improved in recent years, leading to decreases in morbidity and mortality. Significant advances have come from treatment of pulmonary hypertension with selective pulmonary vasodilators, including inhaled nitric oxide, sildenafil, and bosentan. These improve oxygenation and enable less injurious ventilator strategies with reduced subsequent morbidity from air leak and chronic lung disease. Exogenous surfactant administration may be another useful treatment modality. Although the mechanism is unclear, this intervention reduces ventilation-perfusion mismatch and probably reduces the risk of ventilator-associated lung injury.¹⁰⁶

The current state of knowledge regarding meconium-stained amniotic fluid and meconium aspiration syndrome presents challenges for obstetricians and neonatologists. The incidence of meconium aspiration syndrome has decreased, but the reasons for the decline are not readily apparent. The Neonatal Resuscitation Program³⁵ protocol for delivery room management no longer recommends tracheal suctioning for vigorous infants, implying that airway management leading to establishment of ventilation should take precedence. Meconium or other material obstructing the airway should be cleared, but suctioning an unobstructed airway at the expense of delaying initiation of effective ventilation may be deleterious. A collaborative approach between obstetrician and neonatologist is paramount. Personnel skilled in establishment of ventilation and airway patency should attend any infant expected to be depressed at delivery.

Pulmonary Hypertension

At delivery the normal transition from fetal to neonatal pulmonary circulation is mediated by a rapid, dramatic decrease in pulmonary vascular resistance. Endothelial cell shape change, relaxation of pulmonary arteriolar smooth muscle, and alveolar gaseous distention all contribute to this process. Several pathologic processes, including congenital malformations, sepsis, and pneumonia, can alter this sequence to produce neonatal pulmonary hypertension. It typically accompanies pulmonary hypoplasia when diminished surface area for gas exchange and inadequate pulmonary blood flow lead to hypoxia and remodeling of the resistance pulmonary arterioles. These vessels are more prone to constriction under conditions of acidosis and hypoxemia, resulting in the right to left shunting of deoxygenated blood characteristic of neonatal persistent pulmonary hypertension. In neonates, pulmonary

hypertension tends to mimic prenatal physiology when pulmonary vascular resistance is necessarily high.

First principles of management include optimal oxygenation and ventilation through elimination of ventilation-perfusion mismatch. When positive-pressure ventilation is employed, overdistention must be avoided to minimize the risk of lung injury and BPD. Treatment of pulmonary hypertension has been revolutionized by pharmacologic interventions that specifically reduce pulmonary vascular resistance. Of these, nitric oxide is the best studied, with clear evidence of efficacy for treatment of pulmonary hypertension in the setting of meconium aspiration syndrome or sepsis.¹⁰⁷ Clinical experience with other pulmonary vasodilators, including sildenafil, bosentan, and prostacyclin, is increasing and has proved useful in certain clinical situations.¹⁰⁸

Excessive proliferation of medial smooth muscle or its presence in vessels ordinarily devoid of smooth muscle complicates the treatment of pulmonary hypertension. This pathologic remodeling can occur in utero or during postnatal life. The stimuli for this process are not understood, but typically include hypoxic stress of extended duration and volutrauma associated with mechanical ventilation. Pulmonary vasodilators become less effective as remodeling progresses, prompting clinicians to pursue “gentle” ventilation strategies.¹⁰⁹ By focusing on preductal rather than postductal oxygen saturations, lower ventilator settings can be achieved, reducing the risk of remodeling.

Gastrointestinal Problems in Neonatal Period

Necrotizing enterocolitis (NEC) is a devastating complication of prematurity and the most common gastrointestinal emergency in the neonatal period. It affects 1% to 5% of infants admitted to neonatal intensive care units.¹¹⁰ The reported incidence is 4% to 13%¹¹¹ in VLBW infants (<1500 g). NEC is characterized by an inflammation of the intestines, which can progress to transmural necrosis and perforation. The onset typically occurs within the first 2 to 3 weeks of life, but it can occur well beyond the first month. The mortality rate related to NEC ranges from 10% to 30% for all cases and up to 50% for infants requiring surgery.¹¹¹⁻¹¹⁴ As more preterm and low-birth-weight infants survive the initial days of life, the number of infants at risk for NEC has increased. From 1982 to 1992, although overall U.S. neonatal mortality rates declined, the mortality rates for NEC increased.²⁶

A variety of antenatal and postnatal exposures have been suggested as risk factors for the development of NEC.^{112,113,115} Gestational age and birth weight are consistently related to NEC. Among prenatal factors, indomethacin tocolysis has been most often reported. Some studies report reduced incidence of NEC in infants treated with antenatal steroids.¹¹⁶⁻¹¹⁸

Initial trials on use of indomethacin as a tocolytic showed no adverse neonatal effects although sample sizes were small.^{119,120} Although some subsequent case reports and retrospective reviews suggested indomethacin might be associated with adverse neonatal outcomes, including NEC,^{121,122} others found no association^{123,124} of indomethacin tocolysis with NEC when used as a single agent but did find an increased risk when used as part of double-agent tocolytic therapy, even after controlling for neonatal sepsis. A meta-analysis of randomized, controlled trials and observational studies from 1966 through 2004 found no significant association between indomethacin tocolysis and NEC in either study type, although the pooled sample

size of the published randomized, controlled trials limited statistical power.¹²⁵ There is insufficient evidence to alter use of antenatal indomethacin in relationship to NEC (see Chapter 29).

Postnatal interventions to prevent the development of NEC include alterations in feeding type and advancements, oral antibiotics, immune globulin use and vitamin supplementation. Decreased incidence of NEC has been demonstrated only for human milk. A meta-analysis of randomized, controlled trials evaluating use of human milk and NEC found a fourfold decrease (relative risk [RR] = 0.25; 95% confidence interval [CI], 0.06 to 0.98) with the use of human milk.¹²⁶ Mothers of infants at risk, particularly those less than 32 weeks' gestation, should be encouraged to supply breast milk for their infant. Providing early prenatal and postnatal counseling on use of human milk increases the initiation of lactation and neonatal intake of mother's milk without increasing maternal stress or anxiety.¹²⁷ Newer preventive interventions being explored include the use of probiotics and growth factors aimed at protecting the gut epithelium.¹²⁸

NEC may present slowly or as a sudden catastrophic event. Abdominal distention occurs early, with bloody stools present in 25% of cases.¹¹⁰ The radiographic hallmark is the presence of pneumatosis intestinalis or portal venous gas (see Fig. 58-2). Progression may be rapid, resulting in bowel perforation with evidence of free air on the radiograph. Early management consists of bowel decompression, intravenous antibiotics, and respiratory and cardiovascular support as indicated. The single absolute indication for surgical intervention is pneumoperitoneum (Fig. 58-5).

For infants who survive NEC, morbidity is high, including high rates of growth failure, chronic lung disease, and nosocomial infections.¹²⁹⁻¹³¹ Lengths of stay and hospital costs are significantly lengthened, particularly in surgical NEC.¹³¹ Long-term neurologic outcomes

are adversely affected. NEC is an independent risk factor for development of cerebral palsy and developmental delay.^{129,130,132} For infants with surgical NEC, depending on the amount of bowel lost, there is risk of short gut syndrome requiring parenteral nutrition and, ultimately, small bowel or liver transplantation. NEC is the single most common cause of the short gut syndrome in children.²⁷⁻²⁹

Hyperbilirubinemia

Hyperbilirubinemia is common; 60% of term infants and 80% of preterm infants develop jaundice in the first week of life.¹³³ Bilirubin levels are elevated in neonates due to increased production coupled with decreased excretion. Increased production is related to higher rates of red cell turnover and shorter red cell life span.¹³⁴ Rates of excretion are lower because of diminished activity of glucuronosyl-transferase, limiting bilirubin conjugation, and increased enterohepatic circulation. In most cases, jaundice has no clinical significance because bilirubin levels remain low, and it is transient. Less than 3% develop levels greater than 15 mg/dL.¹³³ Risk factors for development of severe jaundice are outlined in Table 58-5.

Several important risk factors have their origin in the prenatal and perinatal environment. Hyperbilirubinemia is seen more frequently in infants of mothers who are diabetic (IDM). The pathogenesis of increased bilirubin in IDM infants is uncertain but has been attributed to polycythemia as well as increased red cell turnover.^{136,137} Prenatally, maternal blood group immunization may result from blood transfusion or fetal maternal hemorrhage. Although the prevalence of Rh(D) immunization has significantly decreased with the advent of prevention programs, including use of Rh immune globulin, antibodies to other blood group antigens may still occur. ABO hemolytic disease, a common cause of severe jaundice in the newborn, rarely causes hemo-

TABLE 58-5 COMMON CLINICAL RISK FACTORS FOR SEVERE HYPERBILIRUBINEMIA

Jaundice in the first 24 hours
Visible jaundice before discharge
Previous jaundiced sibling
Exclusive breastfeeding
Bruising, cephalohematoma
East Asian, Mediterranean, or Native American origin or ethnicity
Maternal age >25 years
Male sex
Unrecognized hemolysis (i.e., ABO, Rh, c, C, E, Kell, and other minor blood group antigens)
Glucose-6-phosphate dehydrogenase deficiency
Infant of a diabetic mother

Adapted from Centers for Disease Control and Prevention: Kernicterus in full-term infants; United States, 1994-1998. Report No.: 50(23), 2001.

lytic disease in the fetus. Other antibodies associated with hemolytic disease in the fetus and newborn are discussed in Chapter 26. A fetus who is apparently unaffected in utero may have continued hemolysis postnatally; physicians caring for the newborn should be notified of any maternal sensitization.

Other perinatal factors associated with severe hyperbilirubinemia include delivery before 38 weeks. Infants born at 36 to 37 weeks' gestation have an almost sixfold increase of significant hyperbilirubinemia¹³⁸ and require close surveillance and monitoring, especially if breastfed.¹³⁹ Feeding difficulties, also common for the near term infant, increase this risk still further and may result in delayed hospital discharge or readmission for the infant. The presence of bruising or a cephalohematoma, more common after instrumented or difficult deliveries, will also increase risk. Polymorphisms of genes coding for enzymes mediating bilirubin catabolism may also contribute to the development of severe hyperbilirubinemia.¹⁴⁰

The primary consequence of severe hyperbilirubinemia is potential neurotoxicity. Kernicterus is a neurologic syndrome resulting from deposition of unconjugated bilirubin in the basal ganglia and brainstem nuclei, and neuronal necrosis.¹⁴¹ Clinical features may be acute or chronic, resulting in tone and movement disorders such as choreoathetosis and spastic quadriplegia, mental retardation, and sensorineural hearing loss.¹⁴² A number of factors influence the neurotoxic effects of bilirubin, making prediction of outcome difficult. Bilirubin more easily enters the brain if it is not bound to albumin, is unconjugated, or there is increased permeability of the blood brain barrier.¹⁴² Conditions such as prematurity that alter albumin levels or that alter the blood brain barrier such as infection, acidosis, and prematurity affect bilirubin entry into the brain. As a result, there is no serum level of bilirubin that predicts outcome. In early studies of infants with Rh hemolytic disease, kernicterus developed in 8% of infants with serum bilirubin concentrations of 19 to 24 mg/dL, 33% with levels of 25 to 29 mg/dL, and 73% of infants with levels of 30 to 40 mg/dL.¹⁴¹

Levels of indirect bilirubin below 25 mg/dL in otherwise term healthy infants without hemolytic disease are unlikely to result in kernicterus without other risk factors, as indicated in a study of 140 term and near-term infants with levels above 25 mg/dL, in which no cases of kernicterus occurred.¹⁴³ Kernicterus has however been reported in otherwise healthy breastfed term newborns at levels above 30 mg/dL.¹⁴⁴ One of the most important of these risk factors is prematurity. The less mature the infant the greater the susceptibility of the neonatal

brain.¹⁴¹ At what level more subtle neurologic abnormalities appear remains unclear.¹³⁹

Management of hyperbilirubinemia is aimed at the prevention of bilirubin encephalopathy while minimizing interference with breastfeeding and unnecessary parental anxiety. Key elements in prevention include systematic evaluation of newborns before discharge for the presence of jaundice and its risk factors, promotion and support of successful breastfeeding, interpretation of jaundice levels based on the hour of life, parental education, and appropriate neonatal follow-up based on time of discharge.¹³⁹ Treatment of severe hyperbilirubinemia should be initiated promptly when identified. Guidelines for treatment with phototherapy and exchange transfusion vary with gestational age, the presence or absence of risk factors, and the hour of life. Nomograms to guide patient management are available from the American Academy of Pediatrics.¹³⁹ Kernicterus is largely preventable. It requires close collaboration between prenatal and postnatal caretakers for accurate dissemination of information regarding risk factors for parents and caregivers.

Feeding Problems

Feeding problems related to complications of prematurity, congenital anomalies, or gastrointestinal disorders contribute significantly to length of stay for hospitalized newborns. In a study of children referred to an interdisciplinary feeding team, 38% were born preterm.¹⁴⁵ Premature infants with a history of neonatal chronic lung disease or neurologic injury such as IVH or periventricular leukomalacia (PVL) and those with a history of NEC are at the highest risk for long-term feeding problems. These medically complex infants often have other comorbidities, such as tracheomalacia, chronic aspiration, and gastroesophageal reflux (GER), that interfere with normal maturational patterns of feeding. Premature infants with complex medical problems often require prolonged intubation and mechanical ventilation with delayed initiation of enteral feeding, all of which have been associated with subsequent feeding difficulties. These infants often have difficulty integrating sensory input because of medical interventions and neurologic immaturity. All of these factors combine to increase the risk of developing oral aversion.

Infants with congenital anomalies are also at high risk for feeding disorders. Infants with tracheoesophageal fistula with esophageal atresia often have difficulty feeding due to tracheomalacia, recurrent esophageal stricture, and GER, which are known associates of this disorder. Infants with CDH have an extremely high incidence of oral aversion and growth problems in addition to the pulmonary complications. Surviving infants and children with CDH have a 60% to 80% incidence of associated GER which has been shown to persist into adulthood.¹⁴⁶⁻¹⁵¹ Often, GER is severe, refractory to medical therapy, and requires a surgical antireflux procedure. Infants with CDH often have inadequate caloric intake due to fatigue or oral aversion and increased energy requirements leading to poor growth. Often these infants require supplemental tube feedings by nasogastric, nasojejunal, or gastrostomy feeding tube. These feeding difficulties may last several years and are often accompanied by a behavioral-based feeding component.

Infants with congenital or acquired gastrointestinal abnormalities often have associated feeding difficulties. Infants with conditions such as gastroschisis with or without associated intestinal atresias often require prolonged hospitalization because of a slow tolerance of enteral feedings and a higher risk for NEC after gastroschisis repair.^{152,153} They often have dysmotility and severe GER with oral aversion.¹⁵⁴ A small percentage of patients have long-term intolerance of enteral feedings

and require prolonged total parenteral nutrition (TPN). Patients requiring long-term TPN may develop liver injury or cholestasis and ultimately may require liver or small bowel transplantation. Infants who develop short bowel syndrome resulting from NEC also have difficulties tolerating enteral feeds, depending on the length and function of the remaining bowel. Like patients with gastroschisis, infants with severe short bowel syndrome may require prolonged TPN and go on to develop liver or intestinal failure requiring transplantation.

In summary, premature infants and infants with congenital anomalies or acquired gastrointestinal abnormalities are at high risk for long-term feeding problems. It is important to counsel families regarding this risk. Minimizing iatrogenic oral aversion is crucial. Involving a feeding specialist early in a medically complex infant's course may help reduce these problems.

Neurologic Problems in the Neonatal Period

Hypoxic-Ischemic Encephalopathy

Injury to the brain sustained during the perinatal period was once thought to be one of the most common causes of death or severe, long-term neurologic deficits in children.¹⁵⁵ However, data show that only 10% of brain injury is related to perinatal or intrapartum events.^{156,157} There is increasing recognition that events occurring well before labor contribute significantly to the cause of brain injury. Despite improvements in perinatal practice, the incidence of hypoxic-ischemic encephalopathy has remained stable at 1 or 2 cases per 1000 term births.^{158,159} Strategies for prevention of brain injury have been mainly supportive because prevention has been difficult because of the lack of clinically reliable indicators and the occurrence of the initiating event well before the onset of labor. However, because brain injury initiated by a hypoxic-ischemic event is also affected by a "reperfusion phase" of injury, strategies targeting this process of ongoing injury are being developed for neuroprotection.^{160,161}

Definition of Asphyxia

The brain injury referred to as hypoxic-ischemic encephalopathy occurs due to impaired cerebral blood flow likely as a consequence of interrupted placental blood flow leading to impaired gas exchange.¹⁶² If gas exchange is persistently impaired, hypoxemia and hypercapnia develop with resultant fetal acidosis or what has been referred to as *asphyxia*. Severe fetal acidemia, defined as an umbilical arterial pH of less than 7.00, is associated with an increased risk of adverse neurologic outcome.^{163,164} However, even with this degree of acidemia, only a small portion of infants develop significant encephalopathy and subsequent sustained neurologic injury.¹⁶⁵⁻¹⁶⁷ Fetal scalp blood sampling and umbilical cord gas data do not have great sensitivity to predict long-term neurologic impairment.

Clinical Markers

Other clinical measures to identify fetal stress (such as fetal heart rate abnormalities, meconium-stained amniotic fluid, low Apgar scores, and need for cardiopulmonary resuscitation CPR) in the delivery room do not reliably identify infants at high risk for brain injury when used in isolation. Despite the widespread use of electronic fetal heart rate monitoring (EFM) which detects changes in fetal heart rate related to fetal oxygenation, there has been no reduction in the incidence of cerebral palsy.¹⁶³ In 2005, an American College of Obstetricians and

Gynecologists (ACOG) practice bulletin called "Clinical Management Guidelines for Obstetrician-Gynecologists"¹⁶⁴ concluded that EFM has a high false-positive rate to predict adverse outcomes and is associated with an increase in operative deliveries without any reduction in cerebral palsy. Meconium-stained amniotic fluid is commonly seen during labor, but no data exist to associate it with adverse neurologic outcome. Apgar scores were originally introduced to identify infants in need of resuscitation, not to predict neurologic outcome. Apgar scores are not specific to an infant's acid-base status but can reflect drug use, metabolic disorder, trauma, hypovolemia, infection, neuromuscular disorder, and congenital anomalies. However, a persistently low Apgar score after 5 minutes despite intensive CPR has been associated with increased morbidity and mortality.^{162,168-170} The combination of a low 5-minute Apgar score with other markers such as fetal acidemia and the need for CPR in the delivery room, predicts a significantly increased risk of brain injury.^{171,172} Perlman and Risser¹⁷² found a 340-fold increased risk of seizures and associated moderate to severe encephalopathy in association with a 5-minute Apgar score of 5, delivery room intubation or CPR, and an umbilical arterial cord pH less than 7.00.

Neonatal Encephalopathy

Neonatal encephalopathy is clinically characterized by depressed level of consciousness, abnormal muscle tone and reflexes, abnormal respiratory pattern, and seizures.¹⁵⁵ These findings may result from a hypoxic-ischemic event but can also be due to other conditions such as metabolic disorders, neuromuscular disorders, toxin exposure, and chromosomal abnormalities or syndromes. Not all infants with neonatal encephalopathy go on to develop permanent neurologic impairment. The Sarnat staging system is frequently used to classify the degree of encephalopathy and predict neurologic outcome.¹⁶⁶ Infants with mild encephalopathy (Sarnat stage 1) generally have a favorable outcome. Infants with moderate encephalopathy (Sarnat stage 2) develop long-term neurologic compromise in 20% to 25% of cases, and infants with severe encephalopathy (Sarnat stage 3) have a greater than 80% risk of death or long-term neurologic sequelae.¹⁵⁵

Multiorgan Injury

In addition to neurologic compromise, the interruption of placental blood flow can result in systemic organ injury. Animal models and clinical studies have demonstrated that the kidney is exquisitely sensitive to reductions in renal blood flow.^{173,174} The result of decreased renal perfusion is acute tubular necrosis with varying degrees of oliguria and azotemia. Other organ systems are also sensitive to reduced blood flow. Decreased blood flow to the gastrointestinal tract can lead to luminal ischemia and increased risk for NEC. Decreased pulmonary blood flow can result in persistent pulmonary hypertension of the newborn. Lack of blood flow to the liver can result in hepatocellular injury and impaired synthetic function, leading to hypoglycemia and disseminated intravascular coagulation. Fluid retention and hyponatremia can develop due to the combination of impaired renal function and the release of antidiuretic hormone. Suppression of parathyroid hormone release can lead to hypocalcemia and hypomagnesemia. These electrolyte abnormalities can further affect myocardial function. Muscle can be affected by electrolyte abnormalities and direct cellular injury, leading to rhabdomyolysis.¹⁶²

Neuropathology

The reduction in cerebral blood flow associated with a hypoxic-ischemic event sets off a complex cascade of regional circulatory factors and biochemical changes at the cellular level. Hypoxia induces a switch from normal oxidative phosphorylation to anaerobic metabolism,

leading to depletion of high-energy phosphate reserves, accumulation of lactic acid, and inability to maintain cellular functions.^{161,175} The end result is cellular energy failure, metabolic acidosis, release of glutamate and intracellular calcium, lipid peroxidation, build-up of nitric oxide, and eventual cell death.^{155,161,176} It is this process of cellular injury that is being targeted for neuroprotection strategies.

Neuroimaging

Diffusion-weighted magnetic resonance imaging (MRI) has become the gold standard to define the extent and potentially the timing of the brain injury. Diffusion-weighted techniques can detect signal changes due to reduced brain water diffusivity within the first 24 to 48 hours of the insult.^{162,177-179} Magnetic resonance spectroscopy can also detect alterations in metabolites such as lactate, *N*-acetyl aspartate, choline, and creatinine in specific regions of the brain indicating injury.^{177,180} However, MRI is difficult to perform in an unstable patient, and computed tomography (CT) may be preferable as the initial study for term infants and ultrasound for preterm infants.

Neuroprotection Strategies

Brain cooling by selective cooling of the head or systemic hypothermia has been studied as a potential therapy for neonates with hypoxic-ischemic encephalopathy. The Cool Cap Study Group found no significant improvement in survival or severe neurodevelopmental disability in 234 term infants with moderate to severe neonatal encephalopathy and abnormal amplitude integrated electroencephalography (aEEG) in a multicenter, randomized trial of selective head cooling.¹⁶⁵ However, there was improvement in infants with less severe aEEG changes in a subgroup analysis.¹⁶⁵ A large, multicenter, randomized trial of brain cooling using whole-body hypothermia for infants of 36 weeks' gestation with moderate or severe encephalopathy found that systemic hypothermia resulted in an 18% reduction of death or moderate or severe disability at 18 to 22 months of age.¹⁸¹ Proposed reasons for the greater benefit in the latter study from the NICHD Neonatal Research Network are earlier initiation of cooling and possible differences in the severity of brain injury (Cool Cap study required the additional evidence of an abnormal aEEG).¹⁶⁵ There are insufficient data to suggest that one method of brain cooling is superior to the other. Until more data are available, treatment with brain cooling is best considered an experimental technique.¹⁶⁷

Because the therapeutic window for effective treatment may be limited to within 6 hours of delivery, future efforts are being focused on early identification of infants at the greatest risk for hypoxic-ischemic injury. Infants at highest risk are those with evidence of a sentinel event during labor, pronounced respiratory and neuromuscular depression at delivery with persistently low Apgar scores, the need for delivery room resuscitation, severe fetal acidemia (umbilical artery pH less than 7.00 or base deficit of 16 mEq/L), and evidence of an early abnormal neurologic examination, seizures, or an abnormal aEEG.^{161,172,182-184}

Summary of Hypoxic-Ischemic Brain Injury

Hypoxic-ischemic brain injury due to intrapartum asphyxia is a rare but serious cause of long-term neurodevelopmental disability. It is often difficult to define a specific intrapartum event because the initiating event may occur before the onset of labor. Early identification of at-risk newborns by neuroimaging techniques, aEEG findings, history, and clinical examination may provide an opportunity to ameliorate the effects of ongoing brain injury using neuroprotective strategies. The goal of these therapeutic interventions is the reduction of long-term neurodevelopmental disabilities, including cerebral palsy.

Intraventricular Hemorrhage

IVH (i.e., germinal matrix hemorrhage) occurs most commonly in preterm infants and is a major cause of mortality and long-term disability. Bleeding originates in the subependymal germinal matrix but may rupture through the ependyma into the ventricular system. IVH is graded into four categories:

- Grade I: Bleeding is localized to the germinal matrix
- Grade II: Bleeding into the ventricle but the clot does not distend the ventricle
- Grade III: Bleeding into the ventricle with ventricular dilation
- Grade IV: Intraparenchymal extension

Incidence

Diagnosis is made most commonly by cranial ultrasound, with most hemorrhages occurring within 6 hours of birth and 90% within the first 5 days of life.¹⁸⁵ The incidence of IVH has decreased significantly with improvements in perinatal care such as maternal transfer and antenatal steroids. From 1990 to 1999, the incidence of IVH reported for infants with birth weights of less than 1000 g was 43%, and 13% were grade III or grade IV. In 2000 and 2002, the overall incidence of IVH decreased to 22%; only 3% were severe despite improvements in survival.¹⁸⁶ Lower gestational age is associated with an increased risk of severe IVH.¹⁶⁸

Pathogenesis

Anatomic and physiologic factors have been implicated in the pathogenesis of IVH. The germinal matrix is composed of thin-walled blood vessels that lack supportive tissue. These fragile vessels have a tendency to rupture spontaneously or in response to stress, such as hypoxia-ischemia, changes in blood pressure or cerebral perfusion, and pneumothoraces. In addition to these structural factors, premature infants have an immature cerebrovascular autoregulation system (so-called pressure-passive circulation) in response to systemic hypotension, which makes them more susceptible to hemorrhage.^{174,185,187} Immaturities in the coagulation system and increased fibrinolytic activity of premature infants may also play a role.^{169,188-190}

Outcomes

Although it has been generally thought that infants with grade I or II IVH have similar outcomes to those without cranial ultrasound abnormalities, extremely-low-birth-weight infants with grade I or II IVH had worse neurodevelopmental outcomes at 20 months corrected age compared with those with normal cranial ultrasound scans in a 2006 report.¹⁹¹ About 35% of infants with grade III IVH have adverse neurologic outcomes. In those who develop post-hemorrhagic hydrocephalus requiring surgical intervention, the disability rate increases to about 60%.¹⁶⁹ Grade IV IVH is associated with the highest mortality rates, and 80% to 90% are associated with poor neurologic outcomes.¹⁷⁰

Antenatal Prevention

The only therapies shown to decrease the incidence of IVH in premature infants are antenatal corticosteroid administration and maternal transfer to a tertiary care center for delivery. Multiple studies have shown that the administration of corticosteroids before preterm delivery to induce lung maturity has significantly reduced the incidence of RDS, mortality, and severe IVH. According to a meta-analysis of four trials that included 596 infants of 24 to 33 weeks' gestation, prenatal corticosteroid therapy was associated with a relative risk reduction for

IVH of 0.57 (95% CI, 0.41 to 0.78).¹⁷¹ Maternal transfer to a tertiary care center for gestational age less than 32 weeks decreased the incidence of death or major morbidity, including IVH.³⁹ Antenatal phenobarbital, vitamin K, and magnesium sulfate have failed to demonstrate a consistent decrease in overall IVH, severe IVH, or death.¹⁹²⁻¹⁹⁴

Postnatal Prevention

The goal of postnatal prevention has been blood pressure stabilization to prevent fluctuations in cerebral perfusion, correction of coagulation disturbances, and stabilization of germinal matrix vasculature.¹⁸⁵ Postnatal administration of phenobarbital and muscle paralysis have been shown to stabilize blood pressure, but neither has been found to decrease the incidence of IVH or neurologic impairment.^{195,196} Fresh-frozen plasma and ethamsylate to promote platelet adhesiveness and correct coagulation disorders also do not reduce the incidence of IVH.^{194,197-199} Indomethacin remains the most promising preventive therapy for IVH because of its ability to constrict the cerebral vasculature, inhibit prostaglandin and free radical production, and mature the germinal matrix vasculature.^{197,200-202} Prophylactic indomethacin decreases the incidence of severe IVH. Follow-up studies have shown slight improvement in cognitive function in infants who received prophylactic indomethacin but no difference in the incidence of cerebral palsy.²⁰³⁻²⁰⁵ Prophylactic indomethacin is reserved for preterm infants at high risk for IVH until further studies clarify the appropriate candidates for prophylaxis.

Post-hemorrhagic Hydrocephalus

The most serious complication of IVH is post-hemorrhagic hydrocephalus due to obstruction of cerebrospinal fluid (CSF) flow. This occurs when multiple blood clots obstruct CSF reabsorption channels, leading to transforming growth factor $\beta 1$ (TGF- $\beta 1$)–stimulated production of extracellular matrix proteins such as fibronectin and laminin, which ultimately lead to scar formation.²⁰⁶ Progressive ventricular dilatation can worsen brain injury because of damage to periventricular white matter resulting from increased intracranial pressure and edema.¹⁷² Therapies such as serial lumbar punctures, diuretics, and intraventricular fibrinolytic therapy are ineffective and may even be harmful.²⁰⁷ Although surgical shunt placement carries significant risk of shunt complications and infection, it remains the definitive therapy for progressive post-hemorrhagic hydrocephalus.

Summary of Intraventricular Hemorrhage

IVH due to a fragile germinal matrix and an unstable cerebrovascular autoregulatory system remains a significant cause of neurologic morbidity in preterm infants. Infants with cardiorespiratory complications are at highest risk. Antenatal corticosteroids are the most effective preventive therapy available. Despite significant reduction in the incidence of severe IVH, new prevention and treatment therapies for hydrocephalus are needed.

Periventricular Leukomalacia

PVL refers to injury to the deep cerebral white matter in two characteristic patterns, described as *focal periventricular necrosis* and *diffuse cerebral white matter injury*. This type of brain injury typically affects premature infants and is a common cause of cerebral palsy. Preterm infants who have suffered an IVH or have cardiopulmonary instability are at the highest risk. Other intrauterine factors, such as infection, premature prolonged rupture of membranes, first-trimester hemorrhage, placental abruption, and prolonged tocolysis, have been associated with increased risk of PVL.^{174,208-211} The reported incidence of PVL

detected by ultrasound examination in VLBW infants is 5% to 15%.²¹² However, ultrasound often fails to identify the more subtle evidence of diffuse white matter injury. The incidence of PVL diagnosed at autopsy is much higher, indicating that the true incidence of PVL is likely underestimated.

Neuropathology

Focal necrosis most commonly occurs in the cerebral white matter at the level of the trigone of the lateral ventricles and around the foramen of Monro.²¹² These sites make up the border zones of the long penetrating arteries. Classically, these lesions undergo a coagulative necrosis that results in cyst formation or focal glial scars.¹⁷⁴ The more diffuse type of injury may also occur in conjunction with focal necrosis but is more frequently recognized as an independent entity. Diffuse white matter injury seems to affect premyelinating oligodendrocytes and leads to global loss of these cells and an increase in hypertrophic astrocytes in response to the diffuse injury.^{174,212-214} This loss of oligodendrocytes leads to white matter volume loss and ventriculomegaly.

Pathogenesis

The pathogenesis of PVL primarily occurs by hypoxia-ischemia leading to neuronal injury due to free radical exposure, cytokine toxicity, and exposure to excessive excitatory neurotransmitters such as glutamate.¹⁷⁴ Vascular anatomic factors also seem to play a role. PVL tends to occur in arterial end zones or so-called border zones.²¹⁵ The arterial supply is composed of long penetrating arteries that terminate deep in the periventricular white matter, basal penetrating arteries, which supply the immediate periventricular area, and short penetrating arteries, which supply the subcortical white matter. Focal necrosis occurs most commonly in the anterior and posterior periventricular border zones because in premature infants these vessels are immature. Diffuse white matter injury may also occur due to vascular immaturity. At early gestations (24 to 28 weeks), there are few anastomoses between the long and short penetrators. Arterial border zones may occur in the subcortical and remote periventricular areas, resulting in a more diffuse type of injury.²¹²

The preterm brain is vulnerable to ischemia because of impaired cerebrovascular regulation. Preterm infants exhibit a pressure-passive circulation; a decrease in systemic blood pressure is associated with a decrease in cerebral perfusion, leading to ischemia.^{212,216,217} Immature oligodendrocytes seem to be more sensitive to free radical injury, cytokine effects, and the presence of glutamate.

Clinical Outcomes

The most common long-term sequela of PVL is spastic diplegia, a form of cerebral palsy in which the lower extremities are more affected than the upper extremities. The descending fibers of the motor cortex, which regulate function of the lower extremities, traverse the periventricular area and are most likely to be injured. More severe injury with lateral extension may be associated with spastic quadriplegia or other manifestations such as cognitive, visual, or auditory impairments.

Summary of Periventricular Leukomalacia

PVL is a major cause of neurologic morbidity in premature infants, especially those who weigh less than 1000 g at birth. Prevention is the only strategy to treat PVL. Avoidance of fluctuations in blood pressure and cerebral vasoconstrictors, such as extreme hypocarbia, is important because of the known immaturity in cerebrovascular autoregulation of preterm infants. Investigational strategies targeting the cascade of oligodendroglial death may be promising.

Perinatal Stroke

Arterial ischemic stroke (AIS) in neonates is defined as a cerebrovascular event around the time of birth with resultant clinical or radiographic evidence of focal cerebral arterial infarction. Most occur in the distribution of the middle cerebral artery.^{176,218-220} AIS accounts for most perinatal ischemic strokes. When the diagnosis is based on symptoms in the neonatal period, the reported incidence is 1 case in 4000 live births.^{176,221,222} The incidence of perinatal ischemic strokes that were asymptomatic in the neonatal period and diagnosed at a later time is unknown.

Clinical Presentation

Neonatal seizures are the most common clinical presentation and usually are focal in origin without other signs of neonatal encephalopathy.^{176,223} However, some infants are systemically ill, and the diagnosis is made with neuroimaging to rule out evidence of hypoxic-ischemic injury or bleeding. Neonates with focal neurologic signs account for less than 25% of cases.^{218,222,224,225}

Perinatal stroke may also be identified retrospectively in initially well-appearing infants who present in later months with signs of hemiparesis, developmental delay, or seizures.^{176,226} In these cases, neuroimaging reveals a remote injury, often occurring in the middle cerebral artery territory.

Pathophysiology and Risk Factors

The mechanisms of perinatal stroke are thought to be multifactorial. Regional ischemia with subsequent hypoxia and infarction plays a role. A relative hypercoagulable state in newborns due to the presence of fetal hemoglobin, polycythemia, and activation of coagulation factors in the fetus and mother around the time of birth seems to increase the risk of a thromboembolic event leading to stroke.^{176,227} Risk factors for perinatal stroke include maternal and placental disorders, neonatal hypoxic-ischemic injury, hematologic disorders, infection, cardiac disorders, trauma, and drugs. Often, a combination of risk factors is identified.

Neuroimaging and Electroencephalographic Assessment

Although cranial ultrasound is the easiest to perform, it is not a sensitive indicator of perinatal stroke.¹⁷⁵ Little information exists on prenatal cranial ultrasound, but prenatal ultrasound scans may show areas of unilateral echolucencies, which may represent areas later identified as perinatal stroke. CT imaging can usually be performed readily in neonates and usually does not require sedation. CT evidence of perinatal ischemic stroke includes focal hypodensity with or without intraparenchymal hemorrhage, abnormal gray-white differentiation, and evidence of volume loss or porencephaly if the injury is remote from the time of delivery¹⁷⁶ (Fig. 58-6).

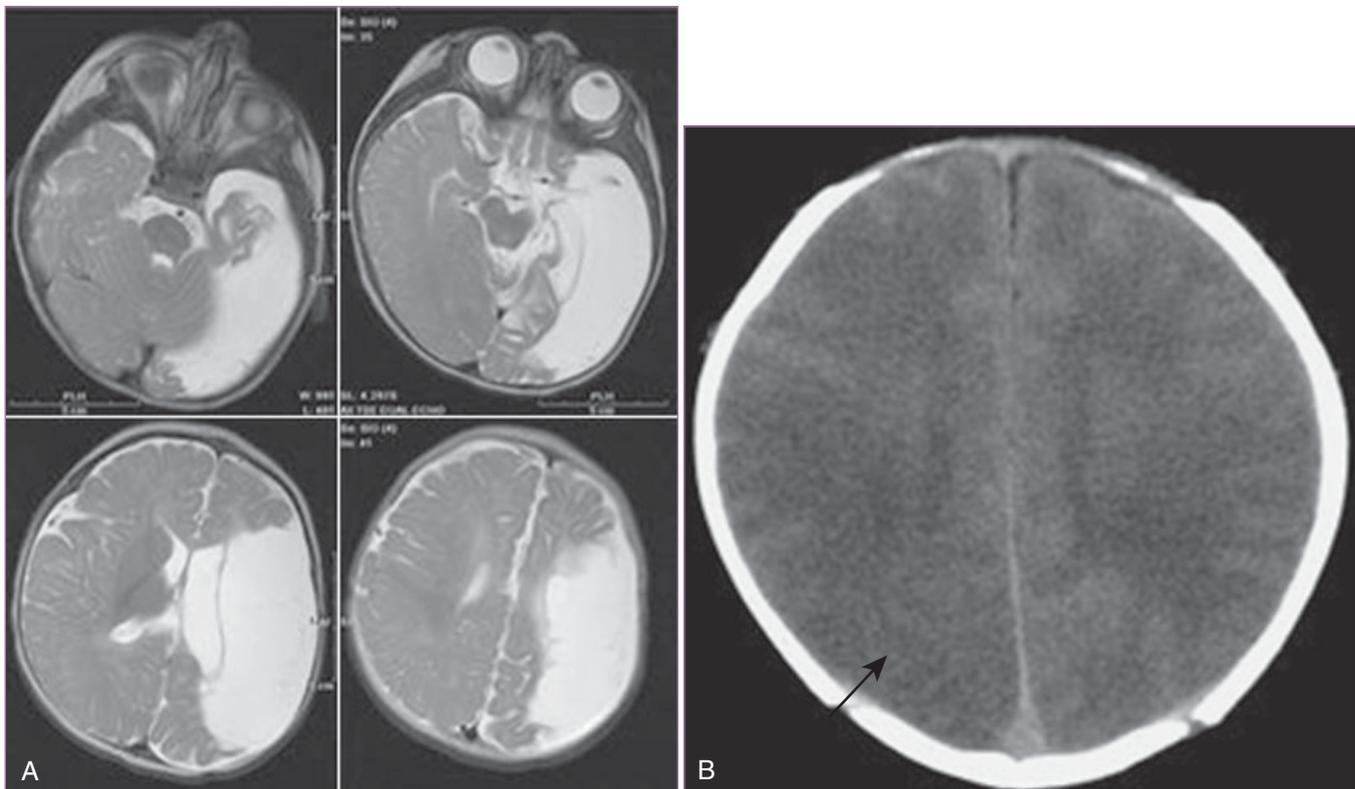

FIGURE 58-6 Diagnostic imaging studies of neonatal stroke. **A**, Magnetic resonance imaging study of a 6-month-old infant demonstrates a large region of encephalomalacia involving most of the left temporal lobe and large regions of the left frontal and parietal lobes. The distribution is consistent with a remote infarction of the left middle cerebral artery. The infant had a history of sepsis and disseminated intravascular coagulation during the early neonatal period. An ultrasound scan when the infant was 1 day old was unremarkable. **B**, Computed tomography of a 1-day-old term infant who presented with a focal seizure. The perinatal history was unremarkable. There is loss of gray-white matter differentiation involving the right parietal and occipital regions (arrow). There is a smaller area of involvement in the right frontal region. A cranial ultrasound examination was normal.

MRI with diffusion-weighted imaging is the most sensitive, especially in the setting of early infarction. MRI may be able to demonstrate restricted diffusion within a vascular distribution for acute stroke as well as chronic changes such as encephalomalacia, gliosis, and ventriculomegaly for remote events (see Fig. 58-6). MR angiography may be useful in some cases to confirm arterial occlusion although it is not commonly used unless a vascular malformation is suspected. Functional MRI may be valuable in the future to understand how the brain reorganizes after perinatal stroke.^{218,228,229} EEG may be useful to detect subclinical seizures that may cause secondary brain injury.²¹⁸

Further diagnostic studies focused on risk factors for perinatal ischemic stroke should include blood tests for coagulation disturbances and genetic predispositions, urine toxicology for metabolic disorders and toxins such as cocaine, echocardiography, infectious workup including lumbar puncture, maternal testing for acquired coagulation disorders such as antiphospholipid antibodies, and an assessment of the placenta.¹⁷⁶

Outcomes

Perinatal ischemic stroke is the most common cause of hemiplegic cerebral palsy (CP).¹⁷⁶ Although not all survivors of perinatal stroke suffer long-term disabilities, 50% to 75% of infants who suffered a perinatal stroke will have a neurologic deficit or seizures.^{215,218,230-232} Lee and colleagues²¹⁵ reported a population-based study of neonatal AIS showing that 32% of infants with AIS who presented with symptoms in the neonatal period went on to develop CP, whereas 82% of infants diagnosed retrospectively developed CP. Because patients identified retrospectively presented because of hemiparesis, they were more likely to be classified as having CP.

Summary of Perinatal Stroke

Perinatal ischemic stroke is a major cause of long-term neurologic disability. Treatment is purely supportive, and management is rehabilitation focusing on muscle strengthening and prevention of contractures. Neuroprotective strategies and approaches to prevention are needed. Advanced neuroimaging techniques to better understand how the brain reorganizes after this type of injury are being used as research tools.

Cerebral Palsy

Cerebral palsy (CP) is a clinical diagnosis that refers to a group of nonprogressive motor impairments. As early as 1862, William John Little described the relationship between children with motor abnormalities and pregnancy complications such as difficult labor, neonatal asphyxia, and premature birth.¹⁷⁷ In 2005, the International Committee on Cerebral Palsy Classification defined CP as “a group of developmental disorders of movement and posture, which cause activity limitations that are attributed to nonprogressive disturbances that occurred in the developing fetal or infant brain. The motor disorders of cerebral palsy are often accompanied by disturbances of sensation, cognition, communication, perception, and behavior and by a seizure disorder.”¹⁷⁸ Despite improvements in perinatal care, the prevalence of CP has remained relatively unchanged over the past 50 years, with an incidence of 1.5 to 2.5 cases per 1000 live births.^{155,233,234}

Classification

Traditionally, CP has been classified by topography based on the affected limb involvement (i.e., monoplegia, hemiplegia, diplegia, triplegia, and quadriplegia) and a description of the predominant type of tone or movement abnormality (i.e., spastic, dyskinetic, ataxic,

TABLE 58-6 COMPONENTS OF CEREBRAL PALSY CLASSIFICATION

1. Motor abnormalities
 - A. Nature and typology of the motor disorder: the observed tonal abnormalities assessed on examination (e.g., hypertonia, hypotonia) and the diagnosed movement disorders, such as spasticity, ataxia, dystonia, or athetosis
 - B. Functional motor abilities: the extent to which the individual is limited in his or her motor function in all body areas, including oromotor and speech function
2. Associated impairments
 - A. Presence or absence of associated nonmotor neurodevelopmental or sensory problems, such as seizures, hearing or vision impairments, and attentional, behavioral, communicative, or cognitive deficits
 - B. Extent to which impairments interact in individuals with cerebral palsy
3. Anatomic and radiologic findings
 - A. Anatomic distribution: parts of the body (e.g., limbs, trunk, bulbar region) affected by motor impairments or limitations
 - B. Radiologic findings: neuroanatomic findings on computed tomography or magnetic resonance imaging, such as ventricular enlargement, white matter loss, or brain anomaly
4. Causation and timing
 - A. Whether there is a clearly identified cause, as is usually the case with postnatal cerebral palsy (e.g., meningitis, head injury), or when brain malformations are present
 - B. Presumed time frame during which the injury occurred, if known

Adapted from Bax M, Goldstein M, Rosenbaum P, et al: Proposed definition and classification of cerebral palsy, April 2005. *Dev Med Child Neurol* 47:571-576, 2005.

hypotonic, or mixed). The International Committee on Cerebral Palsy Classification proposed a new classification system that takes into account the presence or absence of associated impairments, other anatomic involvement besides limbs, radiologic findings, and causation (Table 58-6).

Etiology

Cerebral palsy is a result of injury to the developing brain that occurs prenatally, perinatally, or postnatally. Between 75% and 80% of cases of CP have been attributed to events during pregnancy. Ten percent are attributable to intrapartum events such as birth asphyxia,^{156,235,236} and 10% follow postnatal causes such as head injury or central nervous system infection.^{179,180} Risk factors for cerebral palsy include prematurity, multiple gestation, growth restriction, intracranial hemorrhage, PVL, infections, placental pathology, genetic syndromes, structural brain abnormalities, birth asphyxia or trauma, and kernicterus. The origins of CP tend to be multifactorial, but in some cases, no cause is identified. Some of the more common risk factors will be discussed in detail. The roles of intracranial hemorrhage, PVL, and birth asphyxia contributing to CP have been discussed in a previous section of this chapter.

Prematurity

Prematurity and low birth weight seem to be the most important risk factors for CP, with an increased prevalence of CP associated with decreasing gestational age and decreasing birth weight as compared with term infants. It is important first to consider the rates of CP and neurosensory impairments in term infants. Msall and coworkers²³⁷

reported rates of disability in term infants as follows: 0.2% for CP, 2% to 3% for cognitive impairment, 0.1% to 0.3% for hearing loss, and 0.1% for visual impairment.²³⁷ With improvements in survival for ELBW infants, defined as less than 1000 g, there are concerns that disability rates will increase as well. Several investigators have reported neurodevelopmental disability rates among ELBW infants born in the 1990s. Reported rates range from 8% to 19% with CP, 19% to 49% with developmental disability, 1% to 4% with hearing impairment, and 1% to 4% with visual impairment.^{23,32,132,238-240} When extreme prematurity is considered, Shankaran and associates¹⁸¹ showed that surviving infants born at the threshold of viability (i.e., birth weight <750 g, gestational age <24 weeks, and a 1-minute Apgar of 3), had neurodisability rates of 60%, with almost one third of infants having CP. The increase in disability rates may be related to heavy use of postnatal steroids to treat neonatal chronic lung disease and high rates of sepsis during this period. Poor neurodevelopmental outcomes have been associated with widespread use of postnatal steroids in the 1990s, and routine use of this therapy to treat chronic lung disease is now discouraged.^{31,241-243} The association between sepsis and cerebral palsy has also been identified in many studies and is discussed in a later section.

Because further reduction in mortality of ELBW infants is unlikely, strategies to reduce neonatal morbidity are increasingly important. Decreased rates of CP have been reported in ELBW infants born between 2000 and 2002, a period associated with increased use of antenatal steroids, decreased use of postnatal steroids, and decreased incidence of nosocomial sepsis.¹⁸⁶ Chronic lung disease is an independent risk factor for neurodevelopmental disability for which improved strategies are needed. Inhaled nitric oxide for preterm infants with respiratory failure has been studied, and improved cognitive outcome in infants treated with inhaled nitric oxide has been reported,^{244,245} but this effect has not been consistently observed in ELBW infants.^{246,247}

Multiple Births

The risk of developing CP is significantly higher in multiple gestations compared with singleton births. Data from CP registries show that the risk for developing CP in twins is four or five times greater than singletons. For triplets the risk is 12 to 13 times greater.^{183,248-250} Although twins comprise only 1.6% of the population, they have a 5% to 10% incidence of CP.²⁵¹ The higher rate of CP in multiple births may relate to preterm birth and to other complications associated with multiple gestation such as placental and cord abnormalities, intra-placental shunting, structural anomalies, and difficulties at delivery.

The incidence of CP increases as birth weight decreases. Only 0.9% of singletons weigh less than 1500 g at birth, compared with 9.4% of twins, 32.2% of triplets, and 73.3% of quadruplets.^{183,252} Population-based registries have also broken down the risks of CP related to birth weight groups as follows: 66.5 per 1000 surviving infants born weighing less than 1000 g, 57.4 per 1000 surviving infants with birth weights between 1000 and 1499 g, and 8.9 per 1000 surviving infants with birth weights between 1500 and 2499 g.¹⁸² However, twins with birth weight above 2500 g still have a threefold to fourfold increased risk of developing CP compared with singletons.¹⁸³ It is unclear why this risk remains increased near term, but it may be linked to an increased risk of asphyxia or fetal growth restriction, which occurs more commonly in multiples.

The risk of CP is increased with the fetal death of a co-twin and is higher for same-sex twins than for different-sex twins.²⁵³⁻²⁵⁶ When both twins are born alive and one twin dies in infancy, the risk is even greater than if one twin died in utero, with same-sex twins having a greater risk than different-sex twins.¹⁸³ These data suggest that mono-

chorionic placentation has a significant role in the pathogenesis of CP, likely because of placental vascular anastomoses.

Multiple gestations have significantly increased because of assisted reproductive technology (ART). The increased risk of CP associated with ART is likely because of the higher rate of preterm births because ART is typically not associated with monozygosity unless monozygotic division occurs. However, the increased risk of CP associated with ART requires further study. A Danish study suggests that IVF pregnancies may carry an increased risk of CP not attributable to birth weight or gestation¹⁸⁴ (see Chapter 29).

Growth Restriction

There is much debate in the literature about whether infants with fetal growth restriction have an increased incidence of CP. Many investigators have reported an increased risk of CP for infants who are small for gestational age (SGA).²⁵⁷⁻²⁶² However, fetal growth restriction is a separate entity from SGA (see Chapter 34). *Fetal growth restriction* refers to failure of a fetus to grow at an optimal predicted rate, using fetal growth standards derived from ultrasound measurements of healthy fetuses in utero at each gestational age. Fetal growth curves can account for variables, including fetal sex, ethnicity, parity, and maternal height and weight.²⁶³⁻²⁶⁵ SGA refers to infants who weigh less than a given percentile (usually the 10th) for gestational age and does not take into account potential etiologies of SGA such as constitutional small stature, chromosomal anomalies, congenital infections, or structural malformations. Studies of risk of cerebral palsy often use birth weight alone to define their population of interest, which may explain the observed increased risk of CP associated with low birth weight. This increased risk of CP may result from the effects of intrauterine growth restriction, because these cohort studies include more mature SGA term infants and preterm infants with equivalent birth weights.^{266,267} The terminology used affects how the data may be interpreted.

Many studies have demonstrated that SGA term or preterm infants beyond 33 weeks' gestation have the highest risk of developing CP.²⁵⁹⁻²⁶¹ The Surveillance of Cerebral Palsy in Europe (SCPE) Collaborative Group reported that infants born between 32 and 42 weeks' gestation with a birth weight below the 10th percentile were four to six times more likely to develop CP than infants with a birth weight between the 25th and 75th percentile.^{267,268} For infants born before 33 weeks' gestation with fetal growth restriction, the association is less clear, because this population has the highest risk of adverse neurodevelopmental outcome. It is therefore difficult to separate the risk purely due to growth restriction from the effect of prematurity in general. Other factors that increase the risk of CP are the severity of SGA, male sex, and perinatal asphyxia.²⁶⁹

Growth-restricted infants may be more susceptible to intrapartum hypoxia, which leads to adverse neurologic outcome. Data from the Collaborative Perinatal Project showed that infants with intrauterine growth restriction (IUGR) had similar incidences of CP compared with non-IUGR infants when examined at 7 years of age in the absence of intrapartum hypoxia. However, when intrapartum hypoxia was identified, children with IUGR had an increased incidence of neurodevelopmental disability compared with those without IUGR.¹⁹⁷ The relative risk of CP due to intrapartum hypoxia was actually lower in a study of infants who were SGA compared with appropriate for gestational age (AGA) infants.²⁶² Based on conflicting results it seems clear that other factors may be involved.

Perinatal Infections

Maternal, intrauterine, and neonatal infections have all been associated with cerebral palsy. Congenital viral infections such as toxoplas-

mosis, rubella, cytomegalovirus (CMV), herpes simplex virus, and syphilis may account for 5% to 10% of CP cases.²⁷⁰ Maternal infection and inflammation has been associated with an increased incidence of preterm birth and are risk factors for the development of CP. Intra-amniotic infection, also referred to as clinical chorioamnionitis, has been associated with preterm labor, preterm premature rupture of the fetal membranes, and subsequent preterm birth.^{271,272} Chorioamnionitis also has been associated with an increased risk for developing CP through several likely mechanisms. An increased risk of IVH and PVL has been associated with maternal chorioamnionitis and premature rupture of membranes in numerous studies.^{210,211,273-275} Histologic chorioamnionitis without clinical signs of intra-amniotic infection has also been linked to increased risk of IVH, PVL, and CP.²⁷⁶⁻²⁸⁰

Laboratory and clinical evidence has emerged that supports the hypothesis that intrauterine infection and inflammation leads to the production of proinflammatory cytokines, which are responsible for white matter brain injury and ultimately for CP. These cytokines are potentially toxic to developing oligodendrocytes in fetal white matter and cause reduced myelination and subsequent white matter injury.^{270,273,281,282} Various cytokines may have a direct toxic effect on cerebral white matter by increasing the production of nitric oxide synthase, cyclooxygenase, other associated free radicals, and excitatory amino acids.^{270,282-285} This relationship between elevated cytokine levels and the development of white matter injury has been seen in both preterm and term infants. A fourfold to sixfold increased risk for white matter injury has been associated with elevated levels of interleukin (IL) 1 β from amniotic fluid and from umbilical cord blood in preterm infants.^{2,286} In a study of term infants who went on to develop CP, stored blood samples had significantly increased levels of the cytokines IL-1, IL-8, IL-9, tumor necrosis factor β , and RANTES.²⁸⁷ The combination of intrauterine infection and intrapartum hypoxia has been correlated with a dramatic increase in the incidence of CP.²⁸⁸

Neonatal infection has been associated with the development of CP due to direct central nervous system damage, e.g., in meningitis, or to a systemic inflammatory response syndrome (SIRS) that leads to sepsis, shock, and multiorgan system failure.²⁷⁰ Preterm infants who develop infection seem to be at higher risk.^{289,290} A study of 6093 ELBW survivors born between 1993 and 2001 found an 8% incidence of CP among infants who did not develop a postnatal infection and a 20% incidence of CP in infants whose hospital course was complicated by sepsis, NEC, or meningitis.²⁴⁰ The infected infants also had an extremely high risk of cognitive impairment, defined as a Bayley MDI score less than 70 at 18 months compared with noninfected infants (33% to 42% versus 22%).²⁴⁰ Another study of ELBW survivors found that NEC requiring surgical intervention was associated with a significant increase in both the incidence of CP and developmental disabilities compared with those without NEC.¹²⁹

Placental Abnormalities

Because the placenta supplies nutrients to the developing fetus and serves as a barrier that protects the fetus from influences such as infectious organisms, toxins, trauma, and immune mediators, placental abnormalities can predispose fetuses to adverse outcomes. Placental abnormalities associated with CP can fall into three categories. The first encompasses events that occur during or before labor, also known as *sentinel lesions*, that can cause fetal hypoxia. These lesions include uteroplacental separation, fetal hemorrhage, and umbilical cord occlusion.²⁹¹ The next category is made up of thromboinflammatory processes that affect fetal circulation and include fetal thrombotic vasculopathy, chronic villitis, meconium-associated fetal vascular necrosis, and fetal vasculitis related to chorioamnionitis.^{291,292} The third

category includes processes that cause decreased placental reserve, such as chronic placental insufficiency, chronic villitis, chronic abruption, chronic vascular obstruction, and perivillous fibrin deposition.²⁹³ Evaluation of the placenta in the cause of neonatal encephalopathy may provide some insight into the fetal intrauterine environment and its contribution to the neurologic impairment.

Coexisting Impairments

Historically, CP has been defined strictly by the location and degree of motor impairment. However, associated coimpairments such as disturbances in sensation, cognition, communication, perception, and behavior are common, as are seizures. A new definition that includes coimpairments has been proposed.^{178,234} A Dutch population study of children with CP reported that 40% had seizures, 65% had cognitive deficits (IQ < 85), and 34% had visual impairments.²⁹⁴ Hearing impairments and feeding difficulties are also common.

Strategies to Reduce Cerebral Palsy

Strategies to reduce CP have focused on asphyxia and premature birth because these factors seem to be the most amenable to intervention to prevent CP. Strategies commonly used to reduce intrapartum hypoxia such as fetal heart monitoring, maternal oxygen administration, repositioning, and strict guidelines for oxytocin use have not affected the rate of CP. Fetal heart rate monitoring increases the rate of operative interventions without reducing the rate of CP¹⁶⁴ and may theoretically increase the prevalence of CP by increasing the risk of chorioamnionitis.^{295,296} Reduction of perinatal intracranial injuries associated with the decreased use of forceps and vacuum extraction in the past 20 years is a positive trend that may contribute to a reduction in the incidence of CP.^{155,297}

Preterm birth accounts for approximately 35% of cerebral palsy cases.²⁹⁸ Strategies to reduce the incidence of preterm birth have been sought to reduce the incidence of CP, provided the risk of an in utero insult is not increased by prolonging pregnancy. Prevention of preterm birth has proved elusive, making strategies to reduce morbidity more immediately promising. Antenatal steroids decrease the incidence of several morbidities strongly associated with cerebral palsy, including IVH, PVL,^{171,299} RDS, and chronic lung disease. Postnatal steroids used to treat neonatal chronic lung disease, however, are associated with a significantly increased risk of CP.^{241,300-302}

Another strategy under study to reduce CP in preterm infants is the administration of magnesium sulfate before delivery. The proposed beneficial mechanism is the ability of magnesium sulfate to stabilize vascular tone, reduce reperfusion injury, and reduce cytokine mediated injury.^{303,304} Several observational studies have found an association between maternal administration of magnesium sulfate (given for preeclampsia or preterm labor) and a reduced risk of CP.³⁰⁵⁻³⁰⁸ However, other investigators have reported no protective effect of magnesium.³⁰⁹⁻³¹⁴ The Australasian Collaborative Trial of Magnesium Sulphate examined the efficacy of magnesium sulfate given to women at risk for preterm birth less than 30 weeks' gestation solely for neuroprotection. This study was a much larger, randomized, controlled trial ($N = 1062$), and the investigators reported a lower incidence of CP, although the difference was not statistically significant (6.8% versus 8.2%), and no serious harmful effects to women or their children.¹⁹⁴ Although the use of prenatal magnesium sulfate cannot be recommended based on this study alone, this intervention is being further investigated (see Chapter 29). A large, 10-year NIH trial of intrapartum administration of magnesium sulfate as neuroprotective agent found a reduced rate of moderate to severe cerebral palsy among survivors at 2 years of age who received antenatal magnesium.³¹⁵

Summary of Cerebral Palsy

Cerebral palsy is a significant adverse event with origins in pregnancy. Many risk factors have been identified, although sometimes no etiologic factor is found. Strategies to reduce asphyxia and prevent preterm birth have not shown a significant decrease in rates of CP. Because most CP is related to extremely preterm birth and the survival rates of these ELBW infants is improving, strategies to reduce neonatal brain injury, such as the use of antenatal steroids, are the most promising. Future trials of antenatal neuroprotection for preterm infants may prove beneficial to combat inflammation- or cytokine-mediated brain injury.

Infectious Disease Problems in the Neonatal Period

Neonatal infection is a significant cause of neonatal morbidity and mortality in preterm and term infants. The risk of infection is inversely related to gestational age. The clinical manifestations of neonatal infection vary by pathogen and age of acquisition. The spectrum of pathogens causing neonatal infection is broad and has changed over the decades.³¹⁶ However, the cornerstones of management remain prevention when possible, early detection, and focused treatment.

Compared with older children and adults, neonatal host defense is blunted by incomplete development and experience with self versus non-self discrimination.³¹⁷ All components of the immune system are deficient. Nonspecific immunity is defective at several levels. Skin and mucosal barriers are immature, especially in preterm infants. Levels of nonspecific antibacterial proteins such as lysozyme and lactoferrin are low. Neutrophil numbers are low, with limited storage pools available to clear bacteria. Key neutrophil functions, including chemotaxis, phagocytosis, and intracellular killing, are limited. The neonate is poorly equipped to clear transient bacteremia and localize bacterial infection. Specific humoral and cell-mediated immune functions are also limited. Circulating immunoglobulin levels are very low compared with adult levels. The neonate acquires virtually all of its circulating IgG from the mother through transplacental transport. The bulk of this antibody is transferred during the third trimester, making the preterm infant profoundly deficient. B-cell function is immature as well. The primary antibody response to infection mediated by the infant is production of IgM. Although T lymphocytes are present at birth, their function is almost undetectable by standard functional assays.

The nature of neonatal immune function accounts for the clinical manifestations of most early-onset infections. Nonspecific signs such as lethargy, poor feeding, temperature instability, decreased tone, apnea, and altered perfusion may or may not be present. Fever is uncommon, as are localized processes such as cellulitis, abscesses, or osteomyelitis. When present, they are usually accompanied by bacteremia. Similarly, bacteremia must always be suspected in neonates with meningitis or urinary tract infections.

Chorioamnionitis

The relationship between chorioamnionitis and neonatal infection is complex and remains incompletely understood. Some studies demonstrate a direct correlation between chorioamnionitis and neonatal infection. Other poor neonatal outcomes, including RDS and BPD, are associated with chorioamnionitis.^{84,318} However, other clinical series and studies using animal model systems reach essentially the opposite conclusion—that chorioamnionitis protects against these same outcomes.^{319,320} Some of the confusion is grounded in definitions of cho-

riooamnionitis. Clinical chorioamnionitis, as characterized by maternal fever and uterine tenderness, is probably a very different disease from clinically silent histologic chorioamnionitis commonly seen in preterm deliveries. Whether these represent different disease entities or different manifestations of the same disease spectrum is not evident. The fetal response to infection has important consequences for neonatal outcome. Studies using proteomic analysis of amniotic fluid show promise for relating the diagnosis of chorioamnionitis to the neonatal clinical course.^{321,322}

Group B β -Hemolytic Streptococci

Infection with group B β -hemolytic streptococci (GBS) was first recognized as a cause of early-onset neonatal sepsis in the 1970s. By the 1990s, GBS was a leading cause of serious neonatal infections. The organism is a common colonizing constituent of the vagina and rectum in 10% to 30% of pregnant women. GBS colonization is more common in African-American women and those with a previous history of a neonate with GBS disease or a history of a GBS urinary tract infection. Epidemiologic studies demonstrate that most invasive, early-onset neonatal GBS disease involves vertical transmission from the mother to the fetus during labor. This observation led to studies of intrapartum antibiotic prophylaxis with penicillin G or ampicillin. The success of this strategy prompted the publication of guidelines for intrapartum antibiotic prophylaxis by the Centers for Disease Control and Prevention.³²³ A follow-up study completed in 2005 confirmed the success of this strategy.³²⁴ Most infants with invasive, serious GBS now seen are born to mothers with negative GBS screening cultures who have presumably converted to GBS-positive carrier status in the interval between screening and delivery.³²⁵ In the future, rapid GBS screening technology may allow for identification of these women when they present in labor.³²⁶ There is some concern that intrapartum antibiotic prophylaxis may be associated with a higher incidence of serious bacterial infections later in infancy. This was most pronounced when broad-spectrum antibiotics were used for intrapartum prophylaxis rather than penicillin G.³²⁷ The advantages of intrapartum antibiotic prophylaxis to reduce the risk of invasive neonatal GBS disease clearly outweigh any risks, especially if penicillin is employed.

Viral Infections

Cytomegalovirus

Human cytomegalovirus (CMV) is transmitted horizontally (i.e., direct person-to-person contact with virus-containing secretions) and vertically (i.e., from mother to infant before, during, or after birth) and through transfusion of blood products or organ transplantation from previously infected donors. Vertical transmission of CMV to infants occurs by one of the following routes of transmission: in utero by transplacental passage of maternal blood borne virus, through an infected maternal genital tract, and postnatally by ingestion of CMV-positive human milk.^{328,329}

Approximately 1% of all liveborn infants are infected in utero and excrete CMV at birth. Risk to the fetus is greatest in the first half of gestation. Although fetal infection can occur after maternal primary infection or after reactivation of infection during pregnancy, sequelae are far more common in infants exposed to maternal primary infection, with 10% to 20% of infants manifesting neurodevelopmental impairment or sensorineural hearing loss in childhood.³³⁰

Congenital CMV infection is usually clinically silent. Some infected infants who appear healthy at birth are subsequently found to develop

hearing loss or learning disabilities. Approximately 10% of infants with congenital CMV infection exhibit evidence of profound involvement at birth, including intrauterine growth restriction, jaundice, purpura, hepatosplenomegaly, microcephaly, intracerebral calcifications, and retinitis.³³¹ Although ganciclovir has been used to treat some infants with congenital CMV infection, it is not recommended routinely because of insufficient efficacy data. One study of ganciclovir treatment provided to infants with congenital CMV with central nervous system involvement suggested that treatment decreased progression of hearing impairment.³³² Because of the potential toxicity of long-term ganciclovir therapy, additional investigation is required before a recommendation can be made.

Infection acquired during pregnancy from maternal cervical secretions or after delivery from human milk usually is not associated with clinical illness. Infections resulting from transfusion of blood products with CMV-seropositive donors and from human milk to preterm infants have been associated with serious systemic infections, including lower respiratory tract infection. Transmission of CMV by transfusion to newborn infants has been reduced by using CMV-antibody negative donors, by freezing erythrocytes in glycerol, or by removal of leukocytes by filtration before administration.³³³ CMV transmission by human milk can be decreased by pasteurization.³³⁴ However, freeze-thawing is probably not effective.³³⁵ If fresh donor milk is needed for infants born to CMV-antibody negative mothers, provision of these infants with milk from only CMV-antibody negative women should be considered.

Hepatitis B

HBV is a DNA virus whose important components include an outer lipoprotein envelope containing antibody to hepatitis B surface antigen (HBsAg) and an inner nucleocapsid containing the hepatitis B core antigen. Only antibody to HBsAg (anti-HBs) provides protection from HBV infection. Perinatal transmission of HBV is highly efficient and usually occurs from blood exposure during labor and delivery. In utero transmission of HBV is rare, accounting for less than 2% of perinatal infections in most studies. The risk of an infant acquiring HBV from an infected mother as a result of perinatal exposure is 70% to 90% for infants born to mothers who are HBsAg and HBeAg positive. The risk is 5% to 20% for infants born to mothers who are HBeAg negative. Age at the time of acute infection is the primary determinant of risk of progression to chronic HBV infection. More than 90% of infants with perinatal infection will develop chronic HBV infection. Between 25% and 50% of children infected between 1 to 5 years of age become chronically infected, whereas only 2% to 6% of older children or adults develop chronic HBV infection.³³⁶

The goals of HBV prevention programs are to prevent the acute HBV infection and to decrease the rates of chronic HBV infection and HBV-related chronic liver disease. Over the past 2 decades a strategy has been progressively implemented in the United States to prevent HBV transmission. This includes the following components: universal immunization of infants beginning at birth, prevention of perinatal HBV infection by routine screening of all pregnant women and appropriate immunoprophylaxis of infants born to HBsAg-positive women and infants born to women with unknown HBsAg status, routine immunization of children and adolescents who have previously not been immunized, and immunization of previously nonimmunized adults at increased risk of infection.

Two types of products are available for hepatitis B immunoprophylaxis. Hepatitis B immune globulin (HBIG) provides short-term protection (3 to 6 months) and is indicated only in postexposure circumstances. Hepatitis B vaccine is used for pre-exposure and post-

exposure protection and provides long-term protection. Pre-exposure immunization with hepatitis B vaccine is the most effective means to prevent HBV transmission. To decrease the HBV transmission rate universal immunization is necessary. Postexposure prophylaxis with hepatitis B vaccine and HBIG or hepatitis B vaccine alone effectively prevents infection after exposure to HBV. The effectiveness of postexposure immunoprophylaxis is related to the time elapsed between exposure and administration. Immunoprophylaxis is most effective if given within 12 to 24 hours of exposure. Serologic testing of all pregnant women for HBsAg is essential for identifying women whose infants will require postexposure prophylaxis beginning at birth.

Hepatitis B vaccines are highly effective and safe. These vaccines are 90% to 95% efficacious for preventing HBV infection. Studies in preterm infants and low-birth-weight infants (<2000 g) have demonstrated decreased seroconversion rates after administration of hepatitis B vaccination. However, by 1 month chronological age medically stable preterm infants should be immunized, regardless of initial birth weight or gestational age. Routine postimmunization testing for anti-HBs is not necessary for most infants. However, postimmunization testing for HBsAg and anti-HBs at 9 to 18 months is recommended for infants born to HBsAg-positive mothers.

Immunization of pregnant women with hepatitis B vaccine has not been associated with adverse effects on the developing fetus. Because HBV infection may result in severe disease in the mother and chronic infection in the newborn infant, pregnancy is not considered a contraindication to immunization. Lactation is also not a contraindication to immunization.

Herpes Simplex Virus

Neonatal herpes simplex virus infections range from localized skin lesions to overwhelming disseminated disease. The latter has a case-fatality rate in excess of 50%, even with prompt initiation of antiviral therapy. Vertical transmission is the likely mode of transmission for most cases. Mothers with a history of previous disease appear to convey at least some type-specific immunity to the neonate. Most mothers of severely infected infants have no recognized history of HSV and no evidence of active disease on physical examination. No screening protocols for HSV are available, and there is no vaccine.^{337,338}

Human Immunodeficiency Virus

Landmark studies^{339,340} in the 1990s demonstrated the value of intrapartum antiretroviral therapy to reduce the risk of maternal to fetal transmission of human immunodeficiency virus (HIV). Improvements in the quality and availability of rapid HIV testing holds promise for timely and accurate identification of infected women and their newborn infants. The risk of congenital HIV is reduced to approximately 1% when HIV-positive mothers receive antiretroviral therapy during labor and treatment is continued for the neonate within 12 hours of delivery. Breastfeeding is contraindicated, unless there is no access to clean water and infant formula.

Laboratory diagnosis of HIV infection during infancy depends on detection of virus or viral nucleic acid. Cord blood should not be used for this early test because of possible contamination by maternal blood. A positive result identifies infants who have been infected in utero. Approximately 93% of infected infants have detectable HIV DNA at 2 weeks, and almost all HIV-infected infants have positive HIV DNA PCR assay results by 1 month of age. A test within the first 14 days of age can facilitate decisions regarding initiation of antiretroviral therapy. Transplacental passage of antibodies complicates use of antibody-

based assays for diagnosis of infection in infants because all infants born to HIV-seropositive mothers have passively acquired maternal antibodies.

Antiretroviral therapy is indicated for most HIV-infected children. Initiation of therapy depends on virologic, immunologic, and clinical criteria. Because HIV infection is a rapidly changing area, consultation with an expert in pediatric HIV is recommended.

Rubella

Humans are the only source of infection. Peak incidence of infection is in late winter and early spring. Before widespread use of rubella vaccine, rubella was an epidemic disease with most cases occurring in children. The incidence of rubella has decreased 99% from the prevaccine era. Although the number of susceptible people has decreased since introduction and widespread use of rubella vaccine, serologic surveys indicate that approximately 10% of the U.S. population older than 5 years is susceptible. The percentage of susceptible people who are foreign born or from areas with poor vaccine coverage is higher. The risk of congenital rubella syndrome is highest among infants of women born outside the United States. Epidemiologic data suggests that rubella is no longer endemic in the United States.³⁴¹

Congenital rubella syndrome is characterized by a constellation of anomalies, which may include ophthalmologic (i.e., cataracts, microphthalmos, pigmentary retinopathy, and congenital glaucoma), cardiac (i.e., patent ductus arteriosus and peripheral pulmonary artery stenosis), auditory (i.e., sensorineural hearing impairment), and neurologic (i.e., meningoencephalitis, behavioral abnormalities, and mental retardation) abnormalities. Neonatal manifestations of congenital rubella syndrome include growth retardation, interstitial pneumonia, radiolucent bone disease, hepatosplenomegaly, thrombocytopenia, and dermal erythropoiesis, also called blueberry muffin lesions. The occurrence of congenital defects varies with timing of the maternal infection.

Detection of rubella-specific IgM antibody usually indicates recent postnatal infection or congenital infection in a newborn infant, but false-positive and false-negative results occur. Congenital infection can be confirmed by stable or increasing rubella-specific IgG over several months. Rubella virus can be isolated most consistently from throat or nasal swabs by inoculation of appropriate cell culture. Blood, urine, CSF, and pharyngeal swab specimens can also yield virus in congenitally infected infants.

Infants with congenital rubella should be considered contagious until at least 1 year old, unless nasopharyngeal and urine cultures are repeatedly negative for rubella virus. Infectious precautions should be considered for children up to 3 years old who are hospitalized for congenital cataract extraction. Caregivers of these infants and children should be made aware of the potential hazard to susceptible pregnant contacts.

Sexually Transmitted Infections

Chlamydia

In the newborn period, *Chlamydia trachomatis* is associated with conjunctivitis and pneumonia. Acquisition of *C. trachomatis* occurs in approximately 50% of infants born vaginally to infected mothers and in some infants delivered by cesarean section with intact membranes.³⁴² Neonatal chlamydial conjunctivitis is characterized by ocular congestion, edema, and discharge developing a few days to several weeks after birth and usually lasting 1 to 2 weeks. Pneumonia in infants is usually an insidious afebrile illness occurring between 2 and 20 weeks after

birth. It is characterized by a staccato cough, tachypnea, and rales on physical examination. Pulmonary hyperinflation and infiltrates are demonstrated on the chest radiograph.

Topical prophylaxis with silver nitrate, erythromycin, or tetracycline for all newborn infants to avert gonococcal ophthalmia does not prevent chlamydial conjunctivitis or extraocular infections.³⁴³ Infants with chlamydial conjunctivitis are treated with oral erythromycin base or ethylsuccinate (50 mg/kg per day in four divided doses) for 14 days. Alternatively, oral sulfonamides may be used after the immediate neonatal period for infants who do not tolerate erythromycin. Because the efficacy of treatment is about 80%, follow-up of infants is recommended. In some instances, a second course of therapy may be required.

Chlamydial pneumonia is treated with oral azithromycin (20 mg/kg/day) for 3 days or erythromycin base or ethylsuccinate (50 mg/kg per day in four divided doses) for 14 days. Detection and treatment of *C. trachomatis* infections before delivery is the most effective way to reduce the risk of neonatal conjunctivitis and pneumonia.

Gonococcal Infections

Infection with *Neisseria gonorrhoeae* in the newborn infant usually involves the eyes. Other types of gonococcal infections include arthritis, disseminated disease with bacteremia, meningitis, scalp abscess, or vaginitis.

Microscopic examination of Gram-stained smears of exudates from the eyes, skin lesions, synovial fluid, and, when clinically warranted, CSF may be useful in the initial evaluation. Identification of gram-negative intracellular diplococci in these smears can be helpful, in particular if the organism is not recovered in culture. *N. gonorrhoeae* can be cultured from normally sterile sites such as blood, CSF, and synovial fluid.

For routine ophthalmia neonatorum prophylaxis of infants immediately after birth, a 1% silver nitrate solution, 1% tetracycline, or 0.5% erythromycin ophthalmic ointment is instilled into each eye. Prophylaxis may be delayed for as long as 1 hour after birth to facilitate parent-infant bonding. Topical antimicrobial agents cause less chemical irritation than silver nitrate. None of the topical agents is effective against *C. trachomatis*.³⁴³

When prophylaxis is administered, infants born to mothers with known gonococcal infection rarely develop gonococcal ophthalmia. However, because gonococcal ophthalmia or disseminated disease occasionally can occur in this situation, infants born to mothers known to have gonorrhea should receive a single dose of ceftriaxone (125 mg) given intravenously or intramuscularly. Preterm and low-birth-weight infants are given 25 to 50 mg/kg of ceftriaxone to a maximum dose of 125 mg.

Infants with clinical evidence of ophthalmia neonatorum, scalp abscess, or disseminated disease should be hospitalized. Cultures of the blood, eye discharge, or other sites of infection such as CSF should be performed to confirm the diagnosis and determine antimicrobial susceptibility. Tests for concomitant infection with *C. trachomatis*, syphilis, and HIV infection should be performed. Recommended treatment, including for ophthalmia neonatorum, is ceftriaxone (25 to 50 mg/kg, given intravenously or intramuscularly, not to exceed 125 mg) given once. Infants with gonococcal ophthalmia should receive eye irrigations with saline solution immediately and at frequent intervals until the discharge is eliminated. Topical antimicrobial treatment alone is inadequate and is unnecessary when recommended systemic antimicrobial treatment is provided. Infants with gonococcal ophthalmia should be hospitalized and evaluated for disseminated infection. Recommended therapy for arthritis and septicemia is ceftriaxone or cefo-

taxime for 7 days. If meningitis is documented, treatment should continue for a total of 10 to 14 days.

Syphilis

Congenital syphilis is contracted from an infected mother through transplacental transmission of *Treponema pallidum* at any time during the pregnancy or birth. Intrauterine syphilis can result in stillbirth, hydrops fetalis, or preterm birth. The infant can present with edema, hepatosplenomegaly, lymphadenopathy, mucocutaneous lesions, osteochondritis, pseudoparalysis, rash, or snuffles at birth or within the first 2 months of life. Hemolytic anemia or thrombocytopenia may be identified on laboratory evaluation. Untreated infants, regardless of whether they have manifestations in infancy, may develop late manifestations, usually after 2 years of age and involving the bones, central nervous system, eyes, joints, and teeth. Some consequences of intrauterine infection may not become apparent until many years after birth.

Definitive diagnosis is established by identification of spirochetes by microscopic dark field examination or by direct fluorescent antibody tests of lesion exudates or tissue such as the placenta or umbilical cord. Presumptive diagnosis is possible using nontreponemal and treponemal tests. The use of only one type of test is insufficient for diagnosis, because false-positive nontreponemal test results occur with various medical conditions and false-positive treponemal test results can occur with other spirochetal diseases.

No newborn infant should be discharged from the hospital without determination of the mother's serologic status for syphilis.³⁴⁴ All infants born to seropositive mothers require a careful examination and a quantitative nontreponemal syphilis test. The test performed in the infant should be the same as that performed on the mother so that comparison of titer results is facilitated. An infant should be evaluated for congenital syphilis if the maternal titer has increased fourfold, if the infant titer is fourfold greater than the mother's titer, or if the infant has clinical manifestations of syphilis. The infant should be evaluated if born to a mother with positive nontreponemal and treponemal test results if the mother has any of the following conditions. First, the syphilis has not been treated or treatment has not been documented. Second, syphilis during pregnancy was treated with a nonpenicillin regimen. Third, syphilis was treated less than 1 month before delivery because treatment failures occur and efficacy cannot be assumed. Fourth, syphilis was treated before pregnancy but with insufficient follow-up to assess the response to treatment and current infection status.

Evaluation for syphilis in an infant should include a physical examination, quantitative nontreponemal syphilis test of serum from the infant, VDRL test of the CSF and analysis of the CSF for cells and protein concentration, long bone radiographs, and a complete blood cell and platelet counts. Other clinically indicated tests may include a chest radiograph, liver function tests, ultrasonography, ophthalmologic examination, and an auditory brainstem response test. Pathologic examination of the placenta or umbilical cord using specific anti-treponemal antibody staining is also recommended.

Infants should be treated for congenital syphilis if they have proven or probable disease demonstrated by one or more of the following: physical, laboratory, or radiographic evidence of active disease; positive placenta or umbilical cord test results for treponemes using direct fluorescent antibody *T. pallidum* staining or dark-field test; a reactive result on VDRL on testing of CSF; or 4a serum quantitative nontreponemal titer is at least fourfold higher than the mother's titer using the same test and preferably the same laboratory. If the infant's titer is less than four times that of the mother, congenital syphilis still can be

present. When circumstances warrant evaluation of an infant for syphilis, the infant should be treated if test results cannot exclude infection, if the infant cannot be adequately evaluated, or if adequate follow-up cannot be ensured.

Infants with proven congenital syphilis should be treated with aqueous crystalline penicillin G. The dosage should be based on chronological age, not gestational age. The dose of penicillin G is 100,000 to 150,000 U/kg per day, administered as 50,000 U/kg per dose intravenously every 12 hours during the first 7 days of life and then every 8 hours thereafter for a total of 10 days. Alternatively, penicillin G procaine (50,000 U/kg/day) given intramuscularly for 10 days may be considered, but adequate CSF concentrations may not be achieved with this regimen.

- Aortic atresia, hypoplastic left heart syndrome with, 329
- Aortic insufficiency, anesthesia with, 1156
- Aortic regurgitation, 813–814
- Aortic root, fetal echocardiography of, 309, 314–315
- Aortic stenosis
fetal, 330, 330f
invasive fetal therapy for, 277t, 445, 446t
maternal, 805–806, 806f, 813, 813f
anesthesia with, 1155
hemodynamics of, 1171
- Aortic valve, fetal echocardiography of, 309, 314
- Aortic valvuloplasty, fetal, 277t, 445, 446t
- APACHE (Acute Physiologic and Chronic Health Evaluation) scoring system, 1167
- aPC (activated protein C)
in anticoagulant system, 828, 828f
for septic shock, 763, 1179
- aPC (activated protein C) resistance, and fetal loss, 625, 626t
- Apgar score, with intrauterine growth restriction, 646
- APL (acute promyelocytic leukemia), in pregnancy, 899
- Aplastic anemia, 875–876
- Apocrine miliaria, 1132
- Apolipoprotein E gene (*APOE*), 34
- Appendectomy, 1047
- Appendicitis, 1046–1047, 1047t
- APS. *See* Antiphospholipid syndrome (APS).
- Aptivus (tipranavir), for HIV infection, 772t
- APV (absent pulmonary valve), tetralogy of Fallot with, 332–333, 333f
- Aquaporins (AQPs), 51
- Aqueductal stenosis, 280, 280f
- Arachidonic acid cascade, 74–75, 75f
- Arachidonic acid metabolites, in fetal cardiovascular regulation, 166
- ARBD (alcohol-related birth defects), 354
- Arborized crystals, due to premature rupture of the membranes, 602, 602f
- ARCN (acute renal cortical necrosis), 908–909
- Arcuate uterus, 1143, 1144t
- ARDS (acute/adult respiratory distress syndrome), 1174
with acute pyelonephritis, 755
- Areolae
anatomy of, 129–130, 129f
development of, 127f, 128
- L-Arginine, as uterine relaxant, 80
- Arginine vasopressin (AVP)
for diabetes insipidus, 1024
in fetal cardiovascular regulation, 165
- Aripiprazole (Abilify), dosage of, 1116t
- Armenti, Vincent T., 920
- ARNND (alcohol-related neurodevelopmental abnormalities), 354
- Aromatase deficiency, 117
- Arrest disorders, 695–696
- Arrhythmias
fetal, 336–340, 337f–340f
hydrops fetalis due to, 507–508
medications for, 336, 336t
“respiratory,” 368f
maternal, 818
- ART (assisted reproductive technologies)
and cerebral palsy, 1215
perinatal risks of, 260–261
and preterm birth, 558
- Arterial blood gases
fetal, 162, 162t, 386, 386t
in pregnancy, 1173, 1173t
for pulmonary embolus, 859
umbilical cord, 402–405, 403t–405t
- Arterial blood pressure, during pregnancy, 102
- Arterial circulation, fetal, with intrauterine growth restriction, 644
- Arterial ischemic stroke (AIS), perinatal, 1213–1214, 1213f
- Arterial occlusive disease, intracranial, 1095–1096, 1095f
- Arterial oxygen content (CaO₂), 928
- Arteriolar narrowing, in preeclampsia, 661
- Arteriovenous fistulas, spinal, 1099
- Arteriovenous shunts, intracranial, 1098–1099
- Arteritis, Takayasu, 1085
diagnosis of, 1080–1081, 1080t
epidemiology of, 1079
- Arthritis
juvenile, 1079, 1080, 1080t
psoriatic, 1085
rheumatoid, 1084–1085
diagnosis of, 1080, 1080t
epidemiology of, 1079
fertility with, 1081
labor and delivery with, 1084–1085
pathogenesis of, 1079
pregnancy loss with, 1084
- Artificial heart valves, pregnancy with, 819–820, 820t, 864
- ASB (asymptomatic bacteriuria), 750–753, 752t, 905–906
and preterm labor and birth, 568, 751
- Ascending aorta, fetal echocardiography of, 309, 314–315
- Ascites, fetal, 307, 307f
due to nonimmune hydrops, 506, 506f
- ASCs (atypical squamous cells), 887
- ASD (atrial septal defect)
fetal, 321, 322
maternal, 800–802, 802f
anesthesia with, 1157
- ASH (asymmetrical septal hypertrophy), anesthesia with, 1159
- Asherman syndrome, and pregnancy loss, 622
- Ashkenazi Jewish population, carrier screening in, 238t, 240–243, 241t, 242t

- Aspartate transaminase (AST), in pregnancy, 1059, 1060t
- Aspartoacylase deficiency, carrier screening for, 238t, 242
- Asphyxia, 1210
and cerebral palsy, 1216
defined, 401t
fetal heart rate with, 410f, 411t
- Aspiration pneumonia, 930
- Aspirin
for antiphospholipid antibody syndrome, 830–831, 1084, 1084t
for intrauterine growth restriction, 645
for pregnancy loss, 628t
for prevention of preeclampsia, 675
for rheumatic disease, 1082t
- Assisted reproductive technologies (ART)
and cerebral palsy, 1215
perinatal risks of, 260–261
and preterm birth, 558
- AST (aspartate transaminase), in pregnancy, 1059, 1060t
- Asthma, 937–945
anesthesia with, 1151
breastfeeding with, 945
classification of, 938, 938t
diagnosis of, 938
effects of pregnancy on, 938
effects on pregnancy of, 938–939, 939t
epidemiology of, 937
management of, 939–945
for acute exacerbations, 943, 943t, 944t
antenatal, 942–945, 943t, 944t
assessment and monitoring in, 939–940
avoiding or controlling asthma triggers in, 940
exacerbated by allergic rhinitis, 942
during labor and delivery, 943–945
patient education in, 940
pharmacologic therapy in, 940–942, 940t, 941t
overview during pregnancy of, 945
- Asthma triggers, 940
- Asymmetrical septal hypertrophy (ASH), anesthesia with, 1159
- Asymptomatic bacteriuria (ASB), 750–753, 752t, 905–906
and preterm labor and birth, 568, 751
- Asynchronous delivery, 463
- AT. *See* Antithrombin (AT).
- Atazanavir (Reyataz), for HIV infection, 772t
- Atherosclerotic disease, intracranial, 1095, 1095f
- Atherosclerotic heart disease, and diabetes, 961–962
- Atherosclerosis, in preeclampsia, 660, 660f, 661
- Atopic dermatitis, 1131
- Atopic eruption of pregnancy, 1125t, 1126–1127, 1127f, 1131
- Atopy, breastfeeding and, 1131
- Atosiban, for preterm labor, 564
- ATP8B1* gene, 1060
- Atrial bigeminy, blocked, in fetus, 338
- Atrial bradycardia, in fetus, 338
- Atrial contractions, premature, 336–337, 337f
- Atrial flutter, in fetus, 338, 340
- Atrial natriuretic factor (ANF), in preeclampsia, 665
- Atrial natriuretic peptide (ANP), in fetal cardiovascular regulation, 165–166
- Atrial septal defect (ASD)
fetal, 321, 322
maternal, 800–802, 802f
anesthesia with, 1157
- Atrial septostomy, fetal, 446t
- Atrial septum, fetal echocardiography of, 312, 313f
- Atrioventricular block, maternal, 810
- Atrioventricular canal (AVC) defect, 324–326, 325f, 326f
- Atrioventricular valves, fetal echocardiography of, 308f, 312–313
- Atripla (efavirenz + emtricitabine + tenofovir), for HIV infection, 772t
- Attention deficit hyperactivity disorder, biophysical profile score and, 389t
- Atypical glandular cells (AGCs), 887
- Atypical squamous cells (ASCs), 887
- Augmentation mammoplasty, breastfeeding after, 132
- Auscultation, electronic fetal monitoring vs., 413
- Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS) trial, 979–980, 984
- Autoimmune disease, maternal, neonatal outcomes with, 1198
- Autoimmune hemolytic anemia, 874–875
- Autoimmune hepatitis, 1069
- Autoimmune progesterone dermatitis, 1125t, 1130
- Autoimmune thrombocytopenic purpura, 837–840
- Autoimmune thyroid disease
miscarriage due to, 620, 1001
postpartum, 1009–1011, 1010f
- Autoimmunity, in rheumatic diseases, 1079–1080
- Autologous transfusion device (Cell Saver), 1182
- Automated Lumadex-FSI, 420
- Autonomic hyperreflexia, 1103–1104
anesthesia with, 1149–1150
- Autonomic nervous system, in fetal cardiovascular regulation, 163–165
- Autosomal deletions, 15, 16t
- Autosomal dominant inheritance, 23–24, 24f
- Autosomal dominant myotonic dystrophy, 30
- Autosomal dominant polycystic kidney disease (ADPKD)
pregnancy with, 913, 916t
prenatal diagnosis of, 248t, 295–296
- Autosomal duplications, 15
- Autosomal recessive inheritance, 24, 24f
- Autosomal recessive polycystic kidney disease, 295, 296f
- Autosomes, 7
- AVC (atrioventricular canal) defect, 324–326, 325f, 326f
- Avon Longitudinal Study of Parents and Children (ALSPAC), 153
- AVP (arginine vasopressin)
for diabetes insipidus, 1024
in fetal cardiovascular regulation, 165
- Axillary dissection, 893
- Axillary staging, of breast cancer, 892
- Azathioprine
for inflammatory bowel disease, 1049
for renal transplantation, 918, 919, 920
for rheumatic disease, 1081, 1082t
- Azithromycin
for *Chlamydia trachomatis*, 748, 748t
for HIV infection, 771
- AZT (zidovudine), for HIV infection, 771, 772t, 773
- Aztreonam
for acute pyelonephritis, 756t
for pelvic abscess, 762
- B
- Bacillus Calmette-Guérin (BCG) vaccine, 935
- Bacteremia
due to burns, 1187–1188
defined, 1176t
- Bacterial pneumonia, 930–932, 931f
- Bacterial vaginosis (BV), 741–742, 742f, 742t, 743t
and premature rupture of the membranes, 599
and preterm birth, 556, 568, 570, 741, 742, 742t
- Bacteriuria
asymptomatic, 750–753, 752t, 905–906
and preterm labor and birth, 568, 751
postcesarean, 709
- Balanced complete atrioventricular canal defect, 325, 325f
- “Banana sign,” in neural tube defects, 281, 283f
- Banding patterns, 12, 12f
- Barbiturates, effect on fetus and neonate of, 1091
- Bariatric surgery, 1051–1052, 1051t
- Baroreceptors, in fetal heart rate, 398
- Baroreflex regulation, of fetal cardiovascular system, 164
- Base deficit, fetal, 400, 401t
- Base excess, fetal, 400, 401t
during labor, 402t
- Baseline features, of fetal heart rate patterns, 405–406
- Baseline fetal heart rate, 405, 406–407, 407f
- BCG (bacillus Calmette-Guérin) vaccine, 935
- Beating four-chamber view, in fetal echocardiography, 307–308, 308f, 311–314, 312f–314f
- Becker muscular dystrophy, prenatal diagnosis of, 248t
- Beclomethasone, for asthma, 941, 941t
- Bed rest, for prevention of preterm labor and birth, 569
with multiple gestation, 460
- Behavior(s), fetal
absent, 363–364, 364f
basic functions of, 361
coupled, 362, 362f
individual, 361
normal, 361–362
patterned, 361–362
and transition to neonatal behavior, 362
- Behavioral state(s), fetal, 362
- Behavioral state activity, fetal, 171–174
animal studies of, 171–172, 172f
developmental changes in, 173–174, 173t
effect of hypoxia and intrauterine growth restriction on, 174, 174f
human studies of, 172–173, 173f
- Bell, Charles, 1106
- Bell palsy, 1106–1107
- Bendectin (doxylamine succinate and pyridoxine hydrochloride with or without dicyclimine hydrochloride)
for nausea and vomiting, 1042, 1042t
as teratogen, 347
- Benign intracranial hypertension, 1094–1095
- Benzathine penicillin G, for syphilis, 781, 781t
- Bernard-Soulier syndrome, 844t–846t, 845–846
- Beta error, 213–214
- Betamethasone
developmental effects of, 153–154
fetal biophysical effects of, 425–426
and fetal lung development, 196f
for hemolytic disease of the fetus and newborn, 494

- Betamethasone (*Continued*)
 for induction of fetal pulmonary maturity
 dosage of, 423, 423t
 experimental results of, 203, 203f
 maternal consequences of, 426
 neonatal outcomes of, 424–425, 424f, 425f
 repeated courses of, 427
 after preterm premature rupture of the membranes, 605
 for rheumatic disease, 1081, 1082t
- Bias, 211
- Bicarbonate (HCO_3^-)
 for diabetic ketoacidosis, 962t
 in fetal acid-base balance, 400
 during labor, 402t
 during pregnancy, 1173, 1173t
- Bicornuate uterus, 1143, 1144, 1144t
 and pregnancy loss, 622t
- Biliary cirrhosis, primary, 1069
- Biliary colic, 1073
- Biliopancreatic diversion, 1051, 1051t
- Bilirubin
 in anemia, 869–870, 870t
 in jaundice, 1060t, 1209
 in pregnancy, 1059, 1060t
- Binding proteins, in placental tissues, 117t
- Biologic agents, for inflammatory bowel disease, 1049
- Biophysical profile score (BPS), 175, 364–369
 in diabetic pregnancy, 983t
 with Doppler ultrasound abnormalities, 371, 372t
 factors that influence, 369, 369t
 and fetal pH on cordocentesis, 383–384, 384f
 with intrauterine growth restriction, 644
 and neurologic outcome, 389, 389f, 389t
 outcome prediction using, 364, 365f
 and perinatal mortality, 369, 369f, 387–388, 388t
 scoring technique for, 366–369, 368t, 387–388, 388t
 systematic application of, 366, 368t
 variable(s) in, 364, 365–366
 amniotic fluid measurement as, 365–366, 365t, 366f
 cardiotocogram as, 365t, 366, 367f, 368f
 fetal breathing movements as, 365t, 366
 fetal movement and tone as, 365t, 366
- Biopsy(ies)
 breast, 892
 cervical, 887, 888
 cervical insufficiency due to, 586–587
 for prenatal diagnosis, 259
 renal, 912
 thyroid, 1008–1009, 1009f
- Biparietal diameter
 and fetal pulmonary maturity, 420
 in intrauterine growth restriction, 642
- Bipolar disorder
 diagnostic criteria for, 1113, 1114t, 1115t
 epidemiology of, 1113
 identification of, 1113–1114
 impact on pregnancy outcomes of, 1114, 1115
 treatment of
 clinical approach to, 1119
 dosage for, 1116t
 during lactation, 1119–1120
 perinatal complications of, 1119
 risks of, 1116–1117
- Birth. *See* Labor and delivery.
 preterm. *See* Preterm labor and birth.
- Birth defects, with in vitro fertilization, 260–261
- Birth injury, diabetes and, 966–967, 966f
- Birth weight
 and adult disease, 151–154, 152f
 extremely low. *See* Extremely low birth weight (ELBW).
 and gestational age, 636, 636t
 low. *See* Low birth weight (LBW).
 maternal obesity and, 144
 with multiple gestation, 454
 and survival and morbidity with preterm birth, 550–551, 550f, 551f
 very low. *See* Very low birth weight (VLBW).
- Bisacodyl, for constipation, 1052t
- Bishop score, for post-term pregnancy, 616
- Bisphosphonates, for hypercalcemia, 1034, 1034t

 maternal infections during, 135–138, 136t–137t
 medications while, 126, 139–141, 139t, 140f, 140t
 milk production in, 127f, 130–131, 130t, 131f
 and necrotizing enterocolitis, 1208
 with nipple piercing, 126
 and osteoporosis, 1036
 with phenylketonuria, 1101–1102
 postpartum issues in, 134
 after premature or multiple births, 134
 with prolactinoma, 1020
 promotion of, 126–127
 psychotropic medications during, 1119–1120
 recommendations on, 134
 with renal transplantation, 920
 timing of, 133
 with vitamin B₁₂ deficiency, 1101
- Breathing movements, fetal, 172f–174f, 175, 176–177, 361, 362, 362f
 in biophysical profile score, 365t, 366
- Breech delivery
 umbilical cord acid-base balance with, 405
 vaginal, 704–705, 705t
- Breech presentation, 703–706, 705t
- Breech-breech twins, 462–463
- Breech-vertex twins, 462–463
- Bromocriptine
 for acromegaly, 1021
 to inhibit lactation, 1020
 for migraines, 1093
 for prolactinoma, 1018–1019
- Bronchogenic cyst, 285, 286f
- Bronchopulmonary dysplasia (BPD), 1205–1206
 long-term complications of, 1205
 pathophysiology of, 1205, 1206f
 prematurity and, 1201t
 prevention of, 1206, 1206t
 risk factors for, 1205
- Bronchopulmonary sequestration (BPS), 286, 286f
- Brow presentation, 706–707
- B-type natriuretic peptide (BNP), in fetal cardiovascular regulation, 165–166
- Budd-Chiari syndrome, 1070
- Budesonide, for asthma, 941, 941t
- Buffers, in fetal acid-base balance, 400
- Bulk-forming laxatives, for constipation, 1052, 1052t
- Bupropion (Wellbutrin), dosage of, 1117t
- Burkholderia cepacia*, with cystic fibrosis, 947
- Burkitt lymphoma, 898, 899
- Burns, 1186–1188, 1187f, 1187t
- Butoconazole, for vulvovaginal candidiasis, 740t
- BV (bacterial vaginosis), 741–742, 742f, 742t, 743t
 and premature rupture of the membranes, 599
 and preterm birth, 556, 568, 570, 741, 742, 742t
- C
- C bands, 12
- CA 125 (cancer antigen 125), 1140–1141
- Cabergoline, for prolactinoma, 1019
- CAD (coronary artery disease), maternal, 816–817
 anesthesia with, 1158–1159
- CAH (congenital adrenal hyperplasia)
 pregnancy with, 1028–1030, 1029f
 prenatal diagnosis of, 248t, 262
- Calcitonin
 in fetus, 1032
 for hypercalcemia, 1034, 1034t
 in lactation, 1032
- Calcitonin gene-related peptide (CGRP)
 in fetal cardiovascular regulation, 166–167
 as uterine relaxant, 80
- Calcitriol, for hypoparathyroidism, 1035
- Calcitriol (1 α ,25-dihydroxycholecalciferol), 1032
- Calcium
 elemental, for hypocalcemia, 1035
 in myometrial contraction, 78, 78f
- Calcium channel blockers
 for preterm labor, 562–563
 as uterine relaxants, 81
- Calcium chelation, for hypercalcemia, 1034, 1034t
- Calcium excretion, during pregnancy, 106
- Calcium gluconate, for hypocalcemia, 1035
- Calcium metabolism, parathyroid glands and, 1032, 1032f, 1033f
- Calcium salts, for hypoparathyroidism, 1035
- Calcium supplementation
 during pregnancy, 146, 146t
 for prevention of preeclampsia, 675
- Caldesmon, in myometrial contraction, 78
- Caliceal dilation, during pregnancy, 105
- Calmodulin (CaM), in myometrial contraction, 78
- Caloric intake, with multiple gestation, 455
- Calorie restriction, for diabetes, 974
- Calponin, in myometrial contraction, 78
- Camptomelic dysplasia, 298
- Campylobacter jejuni*, Guillain-Barré syndrome due to, 1107
- Canadian Critical Care Clinical Trials Group study, 1170
- Canalicular stage, of fetal lung development, 194, 194f, 194t
- Canavan disease, carrier screening for, 238t, 242, 242t
- Cancer, 885–899
 breast, 891–895, 892t, 893f
 cervical, 886–889, 886t
 colon, 895–896
 epidemiology of, 885
 gestational trophoblastic neoplasia as, 891
 hematologic, 896–899, 897t
 malignant melanoma as, 895
 ovarian, 885–886, 886t
 treatment of, 889–891, 889t
- Cancer antigen 125 (CA 125), 1140–1141
- Candidiasis, 739–741, 740t
 breastfeeding with, 135, 136t, 137t, 138–139
 with HIV infection, 771
- CaO₂ (arterial oxygen content), 928
- CAOS (chronic abruption-oligohydramnios sequence), 732
- CAP(s) (contraction-associated proteins), 79
- CAPD (continuous ambulatory peritoneal dialysis), 917–918
- Capillary fluid shift, in fetal blood volume control, 398
- Capillary glucose levels, target, 975–976, 975f, 976f, 976t
- Capillary glucose monitoring, timing of, 974–975, 975t
- Capreomycin, for tuberculosis, 937t
- Carbamazepine (Tegretol)
 dosage of, 1116t
 as teratogen, 348, 351t, 352, 1117
- Carbohydrate(s), in diet, 147
- Carbohydrate counting, 978
- Carbohydrate restriction, for diabetes, 974
- Carbon dioxide arterial partial pressure (PaCO₂), during pregnancy, 927
- Carbon dioxide partial pressure (PCO₂)
 fetal, in labor, 402t
 during pregnancy, 104, 1173
- Carbon dioxide transfer, placental, 190–191
- Carbon monoxide poisoning, 1187
- Carbonic acid (H₂CO₃), in fetal acid-base balance, 400
- Carbonic anhydrase, during pregnancy, 927
- Carboprost tromethamine, for postpartum hemorrhage, 698–699
- Cardiac anomalies, 278–279, 278t
- Cardiac arrest, 1188–1189
- Cardiac arrhythmias. *See* Arrhythmias.
- Cardiac disease. *See* Heart disease.
- Cardiac looping, 279
- Cardiac output (CO)
 with aortic stenosis, 1171
 fetal, 161–162, 161f, 162f, 162t
 and fetal oxygenation, 188–189, 189f
 during labor, 104, 1153
 with mitral stenosis, 1170, 1171
 noninvasive assessment of, 1173
 nonpregnant, 1171t
 postpartum, 104
 in preeclampsia, 661
 during pregnancy, 101–102, 102f, 103t, 799, 1171t
- Cardiac performance, during pregnancy, 799
- Cardiac rhabdomyoma, 335, 335f
- Cardiac surgery, during pregnancy, 820–821
 anesthesia for, 1153–1154
- Cardiac transplantation, pregnancy after, 817
- Cardiac tumors, 335–336, 336f, 337f
- Cardioactive drugs, during pregnancy, 801t
- Cardiogenic pulmonary edema, 1174–1175
- Cardiomyopathy
 in infants of diabetic mothers, 967
 maternal, 814–816, 815f
 anesthesia with, 1159
- Cardiopulmonary bypass, during pregnancy, 1154
- Cardiopulmonary resuscitation (CPR), 1188–1189
- Cardiotachometer, 399
- Cardiotocogram (CTG)
 of abruptio placentae, 732
 in biophysical profile score, 365t, 366, 367f, 368f
 computerized, 370–371, 371f
- Cardiovascular adaptations
 to multiple gestation, 455
 to pregnancy, 799, 1152–1153
- Cardiovascular anomalies. *See* Congenital heart disease (CHD).

- Cardiovascular causes, of hydrops fetalis, 507–509, 508t
- Cardiovascular changes, in preeclampsia, 661–662, 662f
- Cardiovascular complications
of diabetes, 961–962, 961f
of prematurity, 1199t
- Cardiovascular disease
low birth weight and, 152, 152f
preeclampsia and subsequent, 655–656, 656f
- Cardiovascular drugs
during pregnancy, 800, 801t
while breastfeeding, 139t
- Cardiovascular system
fetal, 159–167
blood flow patterns and oxygen delivery in, 159–162, 160f–162f, 162t
cardiac output and its distribution in, 161–162, 161f, 162f, 162t
control of, 164–167
ductus arteriosus in, 160f, 167
intracardiac and vascular pressures in, 162, 163f
myocardial function in, 162–164
venous return to heart in, 159–160, 160f, 161f
during pregnancy, 101–104, 102f, 103t
- Carotid angiogram, of intracranial aneurysm, 1098f
- Carpal tunnel syndrome, 1105, 1106f
- Carrier screening, 238–246
for cystic fibrosis, 238–240, 238t–240t, 242t
for fragile X syndrome, 245–246, 246t
for hemoglobinopathies, 238t, 243–245, 244t
informed consent for, 238
in Jewish population, 238t, 240–243, 241t, 242t
recommendations on, 238, 238t
- Cartilage oligomeric matrix protein (COMP), in skeletal growth, 297
- Cascara, for constipation, 1052t
- Case reports, 207–208
- Case series, 207–208
- Case-control studies, 208, 208t
on safety of exposures, 350
- Castor oil, for cervical ripening, 702t
- Catagen, 1124
- Catecholamines, in pheochromocytoma, 1030
- Catecholestrogens, in pregnancy, 115–116
- CBC (complete blood count), in anemia, 869
- CCAM (congenital cystic adenomatoid malformation), 286–287, 287f
hydrops fetalis due to, 444, 509
invasive fetal therapy for, 277t, 444
- CCAM volume ratio (CVR), 444
- CCTG (computerized cardiography), 370–371, 371f
- CDH. *See* Congenital diaphragmatic hernia (CDH).
- Cefazolin
for acute pyelonephritis, 756t
for group B *Streptococcus* infection, 768
for mastitis, 764
for puerperal endometritis, 761
- Cefepime, for acute pyelonephritis, 756t
- Cefixime, for gonorrhea, 745, 746
- Cefotaxime
for acute pyelonephritis, 756t
for gonorrhea, 745, 745t
- Cefotetan
for acute pyelonephritis, 756t
for puerperal endometritis, 760
- Cefoxitin, for gonorrhea, 745
- Ceftizoxime, for gonorrhea, 745, 745t
- Ceftriaxone
for acute pyelonephritis, 756, 756t
for gonorrhea, 745, 745t, 746
for ophthalmia neonatorum, 1219
- Cefuroxime, for acute pyelonephritis, 906
- Celecoxib, for rheumatic disease, 1082t
- Celexa (citalopram), dosage of, 1117t
- Celiac disease, 28, 1050–1051

 structure of, 7
- Chromosome abnormalities, 14–18
 in abortuses and stillbirths, 21, 21t, 22t
 fetal loss due to, 619–620, 623, 626
 hydrops fetalis due to, 508t, 509
 and intrauterine growth restriction, 227t, 638
 in multiple gestation, 256, 256t, 458–459, 458t
 selective termination for, 469–470
 in number, 14–15, 15f
 prevalence of, 20–21, 21t
 sex, 19–20, 20t
 in structure, 15–18, 16f–19f, 16t
- Chromosome analysis, 10–14, 12f–14f
 indications for, 21–22
- Chromosome paint probe, 12–13
- Chronic abortion-oligohydramnios sequence (CAOS), 732
- Chronic kidney disease (CKD), 910–912
 antenatal strategy and decision making with, 911–912
 impact of pregnancy on, 910–911, 911t
 and perinatal outcome, 911
 postpartum care with, 912
 preconception counseling with, 910–911
 due to preeclampsia, 907
 stages of, 910, 910t
- Chronic lymphocytic thyroiditis, 1007
- Chronic renal disease, in preeclampsia, 653t
- Chylothorax, in fetus, 289, 289f
- Cigarette smoking
 and abruptio placentae, 731
 and biophysical profile score, 369t
 intrauterine growth restriction due to, 640
 neonatal outcomes of, 1199
 and preterm birth, 554, 568, 572
 teratogenicity of, 348, 351t, 355–356, 355f, 356f
- Cimetidine, for peptic ulcer disease, 1046
- CIN (cervical intraepithelial neoplasia), 887
 and preterm birth, 557–558
- Ciprofloxacin
 for asymptomatic bacteriuria, 753
 for gonorrhea, 745
 for inflammatory bowel disease, 1049
- Circulation
 fetal, 159–160, 160f
 maternal
 fetal cell-free RNA in, 263
 prenatal diagnosis using fetal cells in, 261–262
- Cirrhosis, 1070–1071
 primary biliary, 1069
- Citalopram (Celexa), dosage of, 1117t
- CKD. *See* Chronic kidney disease (CKD).
- Cleft lip and palate, 27, 27t, 284–285
 neonatal management of, 1198t

- Clindamycin
 for bacterial vaginosis, 741, 742t
 for group B *Streptococcus* infection, 768
 for mastitis, 764
 for pelvic abscess, 762
 for puerperal endometritis, 760, 761
 for septic shock, 763
- Clinical research, 207–217
 importance of, 207
 on screening and diagnosis in, 214–217, 215t, 216f
 sources of error in, 210–214, 212t, 213t
 types of studies in, 207–210, 208t, 209f, 210f
- Clinical trial, randomized, 208–209
- Clo miphen, and preterm birth, 558
- Clomipramine (Anafranil), dosage of, 1117t
- Clonidine, for chronic hypertension, 678t
- Clostridium difficile* colitis, 1048, 1049f
- Clostridium tetani*, 1100
- Clotrimazole, for vulvovaginal candidiasis, 740t
- Clotting cascade, 826, 827f
- Clozapine (Clozaril)
 dosage of, 1116t
 during lactation, 1120
- Clubfoot, early amniocentesis and, 251
- CMV. *See* Cytomegalovirus (CMV).
- CNS. *See* Central nervous system (CNS).
- CNVs (copy number variations), 3, 14, 31, 32
- CO. *See* Cardiac output (CO).
- CO₂. *See* Carbon dioxide *entries*.
- Coagulation, disseminated intravascular
 due to abruptio placentae, 624
 in preeclampsia, 662–663, 674
- Coagulation cascade, 826, 827f
- Coagulation disorder(s), 825–848
 after abruptio placentae, 733, 733t
 bleeding disorders as, 844t–846t, 847–848
 neonatal, due to maternal use of
 anticonvulsants, 1091
- platelet disorder(s) as, 837–847
 acquired, 837–843
 Bernard-Soulier syndrome as, 844t–846t, 845–846
 congenital, 843–847
 drug-induced thrombocytopenia and
 functional platelet defects as, 843
 idiopathic thrombocytopenic purpura as, 837–840
 neonatal alloimmune thrombocytopenia as, 840–842, 840t
 of platelet secretion, 844t, 846–847
 thrombotic thrombocytopenic purpura and
 hemolytic uremic syndrome as, 842–843, 843t
 von Willebrand disease as, 843–845, 844t–846t
- in preeclampsia, 662–663, 674, 1148
- thrombophilia(s) as, 829–837
 acquired, 829–831, 830t
 inherited, 831–835
 due to antithrombin deficiency, 831t, 834
 due to factor V Leiden mutation, 831–833, 831t
 hyperhomocysteinemia as, 833–834
 due to mutations in fibrinolytic pathway
 genes, 835
 due to other factor V mutations, 833
 due to protein C deficiency, 831t, 834
 due to protein S deficiency, 831t, 834–835
 due to protein Z-dependent protease
 inhibitor and protein Z deficiency, 835
- Coagulation disorder(s) (*Continued*)
 due to prothrombin gene mutation, 831t, 833
 screening for, 835–837
- Coagulation factors, in preeclampsia, 658, 662–663
- Coarctation of the aorta, 330–331, 331f
 maternal, 808–809
- Cocaine, as teratogen, 356
- Cocaine abuse, neonatal outcomes with, 1199
- Cochrane Database of Systemic Reviews, 209–210, 209f, 210f
- Cochrane Review, on tocolytic agents, 562–566
- Coding strand, 5
- Codominant trait, 23
- Codons, 5
- Cohort studies, 208, 208t
- Coitus, and preterm birth, 555, 569
- Colic, biliary, 1073
- Colitis
Clostridium difficile, 1048, 1049f
 ulcerative, 1047–1049
 clinical characteristics of, 1047–1048, 1048f, 1048t
 diagnostic testing for, 1048, 1048f, 1049f
 effect of pregnancy on, 1048
 effect on pregnancy of, 1048
 treatment of, 1048–1049, 1049t
- Collaborative Group on Antenatal Steroid
 Therapy, 427
- Collagen, in platelet plug formation, 825
- Collagen disorders, cervical insufficiency due to, 585–586
- Collagen gene loci, in skeletal growth, 297
- Collodion fetus, 1132
- Colloid osmotic pressure (COP)
 abnormalities of, 1174
 nonpregnant, 1171t
 during pregnancy, 103t, 1171t, 1174
- Colloid solutions, for hemorrhagic shock, 1180–1181, 1180t
- Colon, in pregnancy, 1041
- Colon cancer, 895–896
- Colonoscopy, 895, 1053
- Colorectal cancer, 895–896
- Colposcopy, 887
- Colton antigen, 495t
- Coma, 1189–1190, 1189t
- Combivir (zidovudine and lamivudine), for HIV
 infection, 771–772, 772t
- Common carotid arteriogram, 1095f
- Common pathway of parturition, 521–524, 522f, 524f
- COMP (cartilage oligomeric matrix protein), in
 skeletal growth, 297
- Complete atrioventricular canal defect, 325–326, 325f, 326f
- Complete blood count (CBC), in anemia, 869
- Complete heart block (CHB), in fetus, 338, 338f
- Bradycardia due to, 408f
- Complex inheritance, 26–27, 27t
- Compound presentation, 707
- Computed tomography (CT)
 of appendicitis, 1047, 1047t
 of perinatal stroke, 1213, 1213f
- Computed tomography pulmonary angiography
 (CTPA), for pulmonary embolus, 859, 860, 861, 861f, 862
- Computerized cardiography (CCTG), 370–371, 371f
- Condyloma acuminatum, 748
- Cone biopsy, 887, 888
- Confidence intervals, 212
- Confined placental mosaicism, 254–255
- Confounding, 210–211
- Congenital adrenal hyperplasia (CAH)
 pregnancy with, 1028–1030, 1029f
 prenatal diagnosis of, 248t, 262
- Congenital anomalies
 antenatal recognition of, 275–276, 276f
 of anterior abdominal wall, 293–294, 294f
 antidepressants and, 1118
- cardiovascular. *See* Congenital heart disease (CHD).
 central nervous system, 279–282, 279f–283f
 craniofacial, 284–285, 285f
 defined, 275
 diabetes and, 963–964, 963t
 feeding problems due to, 1209
 fetal heart rate with, 413
 of gastrointestinal tract, 290–293, 290f–293f
 of genitourinary tract, 294–297, 295f–297f
 incidence and recurrence of, 278t
 intracranial cystic lesions as, 282–284, 283f, 284f
 and intrauterine growth restriction, 638
 of lungs, 285–289, 286f–289f
 major, 275
 management of, 277–278, 277t, 278t
 in multiple gestation, 456, 457–459, 458t
 selective termination for, 469–470
 of neck and chest, 285–290, 286f–289f
 neonatal outcomes with, 1198–1199, 1198t
 population frequency of, 275
 prognosis for, 277
 progression of, 277–278
 skeletal, 297–299, 298t
- Congenital cystic adenomatoid malformation
 (CCAM), 286–287, 287f
 hydrops fetalis due to, 444, 509
 invasive fetal therapy for, 277t, 444
- Congenital deafness, carrier screening for, 242t
- Congenital diaphragmatic hernia (CDH),
 287–289
 and aneuploidy, 227t
 feeding problems due to, 1209
 incidence of, 440
 invasive fetal therapy for, 277t, 288, 434t, 442–444
 lung area to head circumference ratio in, 288, 441, 442t, 443f
 postnatal management of, 442, 1198t
 prenatal diagnosis of, 287, 288f, 440, 441f
 prognosis for, 287–289, 441, 442t, 443f
 pulmonary arterial hypotension due to, 441–442
 pulmonary hypoplasia due to, 196–197, 1203
 types of, 440
- Congenital heart disease (CHD)
 anesthesia with, 1156–1158
 and aneuploidy, 227t
 aortic stenosis as
 fetal, 330, 330f
 maternal, 805–806, 806f
 anesthesia with, 1155
 atrial septal defect as
 fetal, 321, 322
 maternal, 800–802, 802f
 anesthesia with, 1157
 atrioventricular block as, maternal, 810
 atrioventricular canal defect as, fetal, 324–326, 325f, 326f
 cardiac tumors as, fetal, 335–336, 335f, 336f
 coarctation of the aorta as
 fetal, 330–331, 331f
 maternal, 808–809

- Congenital heart disease (CHD) (*Continued*)
 cyanotic, neonatal management of, 1198t
 double-outlet right ventricle as, fetal, 333
 Ebstein anomaly as
 fetal, 326–327, 326f, 327f
 maternal, 810, 810f
 Eisenmenger syndrome as, maternal, 804–805, 804f
 anesthesia with, 1157
 epidemiology of, 28–29, 28t
 fetal, 305–340
 aortic stenosis as, 330, 330f
 arrhythmia(s) as, 336–340, 336f
 antiarrhythmic medications for, 336, 336t
 premature atrial contractions as, 336–337, 337f
 sustained bradycardia as, 338, 338f
 sustained tachycardia as, 338–340, 339f, 340f
 atrial septal defect as, 321, 322
 atrioventricular canal defect as, 324–326, 325f, 326f
 cardiac tumors as, 335–336, 335f, 336f
 classification of, 320t
 coarctation of the aorta as, 330–331, 331f
 double-outlet right ventricle as, 333
 Ebstein anomaly as, 326–327, 326f, 327f
 echocardiography of, 310–317
 atrial septum in, 312, 313f
 atrioventricular valves in, 312–313
 beating four-chamber view in, 307–308, 308f, 311–314, 312f–314f
 congestive heart failure in, 315–316, 316f
 general imaging in, 310
 great arteries and ductal and aortic arches in, 309, 309f, 314–315, 314f–316f
 during heart beating, 308
 heart size in, 307–308
 heart structure in, 308
 heart symmetry in, 308
 hydrops in, 310
 indications for, 306
 outflow tracts in, 309, 309f, 314–315, 314f–316f
 screening, 307–309, 308f, 309f
 semilunar valves in, 309, 314
 sensitivity of, 310
 three-dimensional, 307, 309–310, 316–317, 317f–319f
 umbilical cord in, 310, 310f
 venous drainage in, 311–312, 312f
 ventricles in, 313, 313f
 ventricular septum in, 309, 313–314, 314f
 visceroatrial situs in, 307, 310–311, 311f
 embryologic development of, 279
 etiology of, 28, 29, 279, 306t
 hypoplastic left heart syndrome as, 328–330, 329f
 invasive fetal therapy for, 277t, 434t, 445, 446t
 pulmonary atresia with intact ventricular septum as, 328, 328f
 risk factors for, 305–306, 306t
 screening for, 306–310
 background of, 306–307
 technique of, 307–309, 307f–309f
 with three-dimensional imaging, 307, 309–310
 tetralogy of Fallot as, 324, 324f, 331–333, 332f, 333f
 transposition of the great arteries as, 333–334, 333f, 334f
- Congenital heart disease (CHD) (*Continued*)
 tricuspid atresia as, 327–328, 327f
 tricuspid valve dysplasia as, 326–327, 326f, 327f
 truncus arteriosus as, 334–335, 335f
 venous anomalies as
 pulmonary, 321–322, 321f
 systemic, 318–320, 319f–321f
 ventricular septal defect as, 313–314, 322–324, 323f, 324f
 hydrops fetalis due to, 507
 hypoplastic left heart syndrome as, fetal, 328–330, 329f
 incidence of, 28, 278, 305
 and intrauterine growth restriction, 638
 left-to-right shunt as, maternal, 800–804, 802f–804f
 anesthesia with, 1156–1157
 maternal, 800–810
 aortic stenosis as, 805–806, 806f
 anesthesia with, 1155
 atrial septal defects as, 800–802, 802f
 anesthesia with, 1157
 atrioventricular block as, 810
 coarctation of the aorta as, 808–809
 Ebstein anomaly as, 810, 810f
 Eisenmenger syndrome as, 804–805, 804f
 anesthesia with, 1157
 left-to-right shunt as, 800–804, 802f–804f
 mitral stenosis as, 805
 anesthesia with, 1154–1155
 obstructive, 805–809, 806f–809f
 patent ductus arteriosus as, 803–804, 804f
 anesthesia with, 1157
 primary pulmonary hypertension as, 805
 pulmonic stenosis as, 806–807, 806f, 807f
 tetralogy of Fallot as, 807–808, 807f–809f
 anesthesia with, 1157–1158
 ventricular septal defect as, 802–803, 803f
 anesthesia with, 1156–1157
 mitral stenosis as, maternal, 805, 811–812, 811f
 anesthesia with, 1154–1155
 nuchal translucency and, 237, 237t
 obstructive, maternal, 805–809, 806f–809f
 patent ductus arteriosus as, maternal, 803–804, 804f
 anesthesia with, 1157
 primary pulmonary hypertension as, maternal, 805
 pulmonary atresia with intact ventricular septum as, fetal, 328, 328f
 pulmonic stenosis as, maternal, 806–807, 806f, 807f
 recurrence risk of, 28–29, 28t, 278–279, 278t
 right-to-left shunts as, anesthesia with, 1157–1158
 risk factors for, 305–306, 306t
 tetralogy of Fallot as
 fetal, 324, 324f, 331–333, 332f, 333f
 maternal, 807–808, 807f–809f
 anesthesia with, 1157–1158
 transposition of the great arteries as, fetal, 333–334, 333f, 334f
 tricuspid atresia as, fetal, 327–328, 327f
 tricuspid valve dysplasia as, fetal, 326–327, 326f, 327f
 truncus arteriosus as, fetal, 334–335, 335f
 venous anomalies as
 pulmonary, 321–322, 321f
 systemic, 318–320, 319f–321f
 ventricular septal defect as
 fetal, 313–314, 322–324, 323f, 324f
 maternal, 802–803, 803f
 anesthesia with, 1156–1157
- Congenital Minimata disease, 354
 Congenital nephrosis, 235
 Congenital rubella syndrome (CRS), 775–776, 1219
 Congenital uterine anomalies. *See* Uterine anomalies.
 Congenital varicella syndrome, 933
 Congestive cardiomyopathy, in infants of diabetic mothers, 967
 Congestive heart failure (CHF), fetal, 315–316, 316t
 Conization, cervical cerclage after, 592–593
 Conjoined twins, 57, 60, 468–469, 468f
 Connective tissue changes, in pregnancy, 1124
 Connective tissue disease, neonatal outcomes with, 1198
 Consanguinity, 24, 24f
 Consensus Development Statement of Cesarean Childbirth, 711
 Consent, informed, for carrier screening, 238
 CONSORT statement, 208
 Constipation, 1052, 1052t
 Continuous ambulatory peritoneal dialysis (CAPD), 917–918
 Continuous positive airway pressure (CPAP), for respiratory distress syndrome, 1204
 Continuous subcutaneous insulin infusion (CSII), 977f, 979, 979t
 Contraception
 breastfeeding and, 134–135
 with renal transplantation, 921
 Contractile phase, of myometrial remodeling, 522
 Contractility, fetal, 162
 Contraction(s), 76–82
 defined, 522
 in diagnosis, 70
 effectiveness of, 522
 fetal heart rate with, 410f, 411t
 hormonal regulation of, 79–81, 79f, 80t
 during labor, 522–523
 measurement of, 399
 mechanics of, 76–79, 78f
 in pregnancy, 691
 and preterm birth, 558, 560
 regulation of electrical activity in, 76, 77f
 Contraction monitoring, after trauma, 1185
 Contraction stress test (CST), 381–382, 381f
 in diabetic pregnancy, 983t
 Contraction-associated proteins (CAPs), 79
 Contractures, 522
 Contrast venography, of deep venous thrombosis, 857
 Cool Cap Study Group, 1211
 Cooley anemia, 877
 Coombs test, direct, in anemia, 870, 870t, 872
 COP (colloid osmotic pressure)
 abnormalities of, 1174
 nonpregnant, 1171t
 during pregnancy, 103t, 1171t, 1174
 Copper supplementation, during pregnancy, 146t
 Copy number variations (CNVs), 3, 14, 31, 32
 Cordocentesis, 383–386
 biophysical profile score and, 383–384, 384f
 complications of, 385–386, 385t, 386f
 fetal respiratory status by, 386, 386t
 for idiopathic thrombocytopenic purpura, 839
 indications for, 383–384, 384t
 to monitor Rh-immunized pregnancies, 484
 monitoring after, 385
 for neonatal alloimmune thrombocytopenia, 841
 procedure for, 384–385, 384f, 385f
 technique of, 259

- Coronary artery disease (CAD), maternal, 816–817
 anesthesia with, 1158–1159
- Coronary heart disease, and diabetes, 961–962
- Coronary sinus, fetal echocardiography of, 311, 312f, 313f
- Corpus luteum cyst, 1143
- Corpus mammae, 129
- Cortical blindness, biophysical profile score and, 389t
- Corticosteroid(s)
 for asthma
 with acute exacerbations, 944t
 inhaled, 940–941, 940t, 941t
 during labor and delivery, 943
 oral, 940t, 942
 in breastfeeding, 131
 for cervical ripening, 702t
 developmental effects of, 153–154
 for hemolytic disease of the fetus and newborn, 494
 for idiopathic thrombocytopenic purpura, 838
 for induction of fetal pulmonary maturity, 423–428
 dosage of, 423, 423t
 experimental models of, 203, 203f
 maternal consequences of, 426
 mechanism of action of, 423
 neonatal outcomes of, 424–425, 424f–426f
 NIH Consensus Panel guidelines for, 427t, 428
 other fetal and neonatal effects of, 425–426
 repeated courses of, 426–428
 for inflammatory bowel disease, 1049
 long-term therapy with, 1030
 for neonatal alloimmune thrombocytopenia, 841–842
 for preterm labor, 561
 for preterm premature rupture of the membranes, 604, 605
 for rheumatic disease, 1081, 1082t
 for septic shock, 1178–1179
 for skin conditions, 1125
 as teratogens, 351t, 352
- Corticosteroid-binding globulin, during pregnancy, 1025, 1026f
- Corticotropin-releasing hormone (CRH)
 in control of labor, 72
 and fetal lung development, 203
 in neurohormonal control, 1015
 during pregnancy, 120, 1016, 1025
 in preterm labor, 529, 530f
 secretion of, 1025
- Corticotropin-releasing hormone (CRH) testing, for Cushing syndrome, 1022
- Corticotropin-releasing hormone-binding protein (CRH-BP)
 in control of labor, 72
 during pregnancy, 120
- Cortisol
 for Addison disease, 1027
 control of, 1025, 1025f
 in control of labor, 72
 excessive secretion of, 1021–1022
 and fetal lung development, 203
 for hypopituitarism, 1023
 during pregnancy, 120, 1016, 1025, 1026f
 and progesterone, 73–74
- Cortisone, for induction of fetal pulmonary maturity, 423t
- Coumadin. *See* Warfarin (Coumadin).
- Coupled behaviors, fetal, 362, 362f
- COX (cyclooxygenase) inhibitors, for preterm labor, 563–564
- COX-2 (cyclooxygenase-2), in control of labor, 74
- CP. *See* Cerebral palsy (CP).
- CPAP (continuous positive airway pressure), for respiratory distress syndrome, 1204
- CPD (cephalopelvic disproportion)
 arrest disorders due to, 695
 brow presentation due to, 707
- CPR (cardiopulmonary resuscitation), 1188–1189
- Craniofacial anomalies, 284–285, 285f
- Craniopagus, 468
- Craniopharyngiomas, 1016, 1093
- Craniosynostosis, 284, 299
- Creatinine, serum, during pregnancy, 910
- Creatinine clearance, in preeclampsia, 657
- Creatinine concentration, in preeclampsia, 657
- Cretninism, endemic, 1006
- CRH. *See* Corticotropin-releasing hormone (CRH).
- Crigler-Najjar syndrome, jaundice due to, 1060t
- Crista dividens, fetal, 160
- Crista interveniens, fetal, 160
- Critical oxygen delivery, 929, 929f
- Crixivan (indinavir), for HIV infection, 772t
- Crohn disease, 1047–1049
 clinical characteristics of, 1047–1048, 1048f, 1048t
 diagnostic testing for, 1048, 1049f
 effect of pregnancy on, 1048
 effect on pregnancy of, 1048
 genetics of, 28
 treatment of, 1048–1049, 1049t
- Cromolyn, for asthma, 940t, 941t, 942
- Crossing over, 8f, 9, 9f
- CRS (congenital rubella syndrome), 775–776, 1219
- Cryoprecipitate
 for abruptio placentae, 733t
 for hemorrhagic shock, 1181, 1181t
- Crystalloid solutions, for hemorrhagic shock, 1180
- CSII (continuous subcutaneous insulin infusion), 977f, 979, 979t
- CST (contraction stress test), 381–382, 381f
 in diabetic pregnancy, 983t
- CT (computed tomography)
 of appendicitis, 1047, 1047t
 of perinatal stroke, 1213, 1213f
- CTG (cardiotocogram)
 of abruptio placentae, 732
 in biophysical profile score, 365t, 366, 367f, 368f
 computerized, 370–371, 371f
- CTPA (computed tomography pulmonary angiography), for pulmonary embolus, 859, 860, 861, 861f, 862
- Cushing disease, 1021
- Cushing syndrome
 adrenal, 1027
 pituitary, 1021–1022
- Cutoff values, 221, 222t
- CVP (central venous pressure)
 nonpregnant, 1171t
 during pregnancy, 103t, 1171t
 and pulmonary capillary wedge pressure, 1170, 1170f
- CVR (CCAM volume ratio), 444
- CVS. *See* Chorionic villus sampling (CVS).
- Cyanotic congenital heart disease, neonatal management of, 1198t
- Cyclooxygenase (COX) inhibitors, for preterm labor, 563–564
- Cyclooxygenase-2 (COX-2), in control of labor, 74
- Cyclophosphamide
 for rheumatic disease, 1081, 1082t
 as teratogen, 352
- Cyclopia, 285
- Cycloserine, for tuberculosis, 937t
- Cyclosporine
 for renal transplantation, 918, 919
 for rheumatic disease, 1082t
- Cymbalta (duloxetine), dosage of, 1117t
- Cyst(s)
 bronchogenic, 285, 286f
 choledochal, 293
 choroid plexus, 284, 284f
 and aneuploidy, 227, 227t
 corpus luteum, 1143
 Dandy-Walker, 280–281, 281f
 milk-retention, 138
 ovarian, 1139–1143
 complications of, 1141–1142
 diagnosis of, 1140–1142, 1140t, 1141f, 1142f
 MRI for, 1141
 serologic markers for, 1140–1141
 ultrasonic characteristics in, 1140, 1140t, 1141f, 1142f
 epidemiology of, 886, 1139
 management of, 886, 1142–1143
 pathogenesis of, 1139, 1139t
 posterior fossa, and aneuploidy, 227t
- Cystic adenomatoid malformation, congenital, 286–287, 287f
 hydrops fetalis due to, 444, 509
 invasive fetal therapy for, 277t, 444
- Cystic fibrosis (CF), 31f, 946–948
 anesthesia with, 1151–1152
 carrier screening for, 238–240, 238t–240t, 242t
 effect of pregnancy on, 946–947
 epidemiology of, 946
 fetal risks with, 948
 labor and delivery with, 948
 management of, 948
 preconception counseling on, 947
 pregnancy outcome with, 947
 prenatal diagnosis of, 248t
- Cystic hygroma, 289–290, 289f
 and aneuploidy, 227t
 hydrops fetalis due to, 509
- Cystic lymphangioma, 289–290, 289f
- Cystitis, 753–754, 906
- Cytochrome P450 oxidoreductase (PORD)
 deficiency, 1031
- Cytogenetic abnormalities, fetal loss due to, 619–620
- Cytogenetics, molecular, 12–14, 13f, 14f
- Cytokines
 and immune response, 88
 in placental tissues, 117t
 in pregnancy, 88–89, 89f
 in preterm labor and birth, 526–527, 526f, 556
- Cytokinesis, 8
- Cytomegalovirus (CMV), 764–766
 breastfeeding with, 136t
 clinical manifestations of, 765
 congenital
 clinical manifestations of, 765, 1217–1218
 diagnosis of, 765
 pathogenesis of, 765
 treatment of, 765–766, 1218
 diagnosis of, 765
 epidemiology and pathogenesis of, 764–765
 fetal infection with, 1101
 fetal loss due to, 624
 hepatitis due to, 1069

- Cytomegalovirus (CMV) (*Continued*)
 hydrops fetalis due to, 510–511
 intrauterine growth restriction due to, 638
 intrauterine transfusion with, 492
 in newborn period, 1217–1218
 prevention of, 766
 risk factors for, 765
 treatment of, 765–766
- Cytosine, deamination of, 6, 6f
 Cytotec. *See* Misoprostol (Cytotec).
 Cytotoxic drugs, while breastfeeding, 139t, 140
 Cytotrophoblast, 41, 42, 42f, 43f
- D
- d4T (stavudine), for HIV infection, 772t
 Dairy products, in diet, 147
 Dalteparin, for venous thromboembolism, 863
 prevention of, 836
 Damage-associated molecular patterns (DAMPs), 92
 Dandy-Walker malformation, 280–281, 281f
 Dapsone, for *Pneumocystis jiroveci* pneumonia, 934
 Darunavir (Prezista), for HIV infection, 772t
 Database cohorts, on safety of exposures, 349–350
 Daughter cells, 7
 DDAVP (1-deamino,8-D-arginine vasopressin)
 for diabetes insipidus, 1024–1025
 for von Willebrand disease, 843–844, 845t
 ddC (zalcitabine), for HIV infection, 772t
 DDi (didanosine), for HIV infection, 772t
 D-dimer assays
 for deep venous thrombosis, 857–858, 858f
 for pulmonary embolus, 861, 861f, 862
 Deafness, congenital, carrier screening for, 242t
 Deamination, of cytosine, 6, 6f
 L-Deamino,8-D-arginine vasopressin (DDAVP, desmopressin acetate)
 for diabetes insipidus, 1024–1025
 for von Willebrand disease, 843–844, 845t
 Decelerations, in fetal heart rate
 early, 406, 411t
 late, 406, 408–409, 409f, 410f, 411t
 prolonged, 406
 variable, 406, 409–410, 410f, 411t
 Decidua, 37
 basalis, 37
 capsularis, 37, 38
 vera, 37, 38
 Decidual hemorrhage, preterm labor due to, 527–529, 529f
 Decidual/membrane activation, in labor and delivery, 523
 Decision analysis, 210
 Deep venous thrombosis (DVT)
 clinical presentation of, 856, 856t
 diagnosis and evaluation of, 856–858, 856t, 858f, 861
 epidemiology of, 855
 postcesarean, 709
 prevention of, 835–837, 864–865
 risk factors for, 855–856, 856t
 treatment of, 862–864, 862t
 Deflection abnormalities, 706–707
 Dehydroepiandrosterone sulfate (DHEAS)
 in control of labor, 70, 72
 in pregnancy, 115
 Deiodinases, during pregnancy, 996
 Deiodination
 in normal thyroid physiology, 995, 996f
 during pregnancy, 996
 Delavirdine (Rescriptor), for HIV infection, 772t
 Delayed interval delivery, 463
 Deletions, 15, 16f, 16t
 in linkage analysis, 33
 Delivery. *See* Labor and delivery.
 Delta base, 400, 401t
 Delta infection (hepatitis D virus), 786, 787t, 1065t, 1068
 Delta storage pool disease, 846–847
 Delta virus infection, 786
 Δ OD₁₅₀, of amniotic fluid, 483, 484f
 Dengue virus, breastfeeding with, 135
 Deoxyribonucleic acid. *See* DNA (deoxyribonucleic acid).
 Depakote (valproic acid)
 dosage of, 1116t
 as teratogen, 348, 351t, 352, 1117
 Dependent edema, 104
 Depression
 diagnostic criteria for, 1113, 1114t, 1115t
 epidemiology of, 1113
 identification of, 1114
 impact on pregnancy outcomes of, 1114, 1116
 postpartum, and thyroiditis, 1010
 and preterm birth, 555
 symptoms of, 1113, 1114t, 1115t
 treatment of
 clinical approach to, 1118–1119
 dosage for, 1117t
 during lactation, 1119–1120
 perinatal complications of, 1119
 risks of, 1117–1118
 Depression headaches, 1092
 Depression screening scales, 1114
 Depressive episode, 1113, 1114t, 1115t
 Dermatitis
 atopic, 1131
 autoimmune progesterone, 1125
 estrogen, 1130
 papular, of pregnancy, 1127
 Dermatomyositis, 1109
 Dermatos(es), 1124–1130, 1125t
 atopic eruption of pregnancy (prurigo gestationis) as, 1125t, 1126–1127, 1127f
 autoimmune progesterone dermatitis as, 1125t, 1130
 general treatment of, 1125
 impetigo herpeticiformis as, 1125t, 1129–1130, 1130f
 pemphigoid gestationis (herpes gestationis) as, 1125t, 1127–1129, 1128f, 1129f
 pruritic urticarial papules and plaques of pregnancy as, 1125t, 1126, 1126f
 pruritus gravidarum as, 1125–1126, 1125t
 DES (diethylstilbestrol), as teratogen, 351t
 Descent, during labor, 691–692, 692t, 693
 abnormalities of, 696–697, 696f, 696t
 Descriptive studies, 207–208
 Desensitization, for penicillin allergy, 780, 781t
 Desipramine (Norpramin), dosage of, 1117t
 Desmopressin acetate (L-deamino,8-D-arginine vasopressin)
 for diabetes insipidus, 1024–1025
 for von Willebrand disease, 843–844, 845t
 Development, 37–44
 fetal, 175–177, 176t
 in diabetic pregnancy, 982–984, 985
 in multiple gestation, 456–457, 461
 with post-term pregnancy, 614
 rate of, 636, 636f, 636t, 637f
 macroscopic, 37–41, 38f–40f
 microscopic, 41–44, 42f–44f
 postfertilization, 37, 38f, 39f
 with post-term pregnancy, 616–617
 Developmental delay, after intrauterine transfusion, 492
 Developmental effects, of post-term pregnancy, 616–617
 Developmental origins, of health and disease, 151–156
 animal models of, 154
 antenatal glucocorticoids in, 153–154
 breastfeeding in, 153
 childhood growth in, 153
 for diabetes, 152–156
 interventions based on, 154–155
 low birth weight in, 151–152, 152f
 and maternal body composition, 154–155
 maternal weight in, 152–154, 155
 mechanistic insights into, 154
 and neonatal feeding regimens, 155
 and nutrient supplementation, 154
 thrifty phenotype hypothesis in, 155
 Dexamethasone
 developmental effects of, 153
 fetal biophysical effects of, 425–426
 for hemolytic disease of the fetus and newborn, 494
 for 21-hydroxylase deficiency, 1028–1029, 1029f
 for induction of fetal pulmonary maturity
 dosage of, 423, 423t
 neonatal outcomes of, 424–425, 424f, 425f
 for neonatal alloimmune thrombocytopenia, 841
 after preterm premature rupture of the membranes, 605
 for rheumatic disease, 1081, 1082t
 for thyroid storm, 1003, 1003t
 Dexamethasone suppression test, for Cushing syndrome, 1021–1022
 Dextran solution, for hemorrhagic shock, 1180–1181, 1180t
 Dextrose, for diabetic ketoacidosis, 962t
 Dextro-transposition of the great arteries (D-TGA), 333–334, 333f
 DGI (disseminated gonococcal infection), 744, 746
 DHEAS (dehydroepiandrosterone sulfate)
 in control of labor, 70, 72
 in pregnancy, 115
 Diabetes, 953–986
 antenatal corticosteroids with, 426
 antihypertensive medications for, 973–982
 breastfeeding with, 986
 childhood neurologic abnormalities with, 968–969
 classification and pathobiology of, 953–955, 954t
 diagnosis of, 970–973, 971t–973t
 diagnostic criteria for, 955, 955t
 epidemiology of, 953, 954f
 fetal loss due to, 624–625
 fetal lung development with, 421
 fetal morbidity and mortality with, 963–967
 birth injury as, 966–967, 966f
 congenital anomalies as, 963–964, 963t
 fetal obesity as, 964–966, 965t, 966t
 miscarriage as, 963
 perinatal mortality as, 963, 963t
 and fetal pulmonary maturity, 421
 fetal surveillance with, 982, 982t, 983f, 983t
 genetic and other causes of, 955
 gestational, 955
 defined, 955
 developmental effect of, 152–153
 diagnosis of, 971–973, 971t–973t
 epidemiology of, 955
 glyburide for, 981
 insulin for, 979–980

- Diabetes (*Continued*)
 maternal-fetal metabolism in, 956–958, 957f
 pathophysiology of, 955
 risk factor screening for, 971, 971t, 973, 973t
 hydrops fetalis due to, 512
 intrapartum glycemic management with, 985–986, 985t
 intrauterine growth restriction due to, 641
 maternal morbidity with, 958–963
 due to cardiovascular complications, 961–962, 961f
 due to diabetic ketoacidosis, 962–963, 962t
 nephropathy as, 959–961, 959f, 959t, 960f
 retinopathy as, 958
 maternal obesity and, 144
 maternal-fetal metabolism in, 956–958, 957f
 maturity-onset, of young, 955
 metabolic management of, 973–982
 avoiding ketosis in, 974
 avoiding nocturnal hypoglycemia in, 974
 dietary therapy in, 973–974
 glucose monitoring in, 974–976
 pregestational, 970
 target levels in, 975–976, 975f, 976f, 976t
 timing of, 974–975, 975t
 insulin therapy in, 976–980, 977f, 977t, 979t
 low glycemic foods in, 974
 oral hypoglycemic agents in, 970, 980–982
 postpartum, 986
 preconceptional, 970
 principles of, 973–974
 neonatal morbidity and mortality with, 967–968, 968f, 986, 1197
 neonatal transitional management with, 986
 obesity and, 955
 overt, 970–971
 preconceptional management of, 969–970, 969t
 and preeclampsia, 654
 pregestational, 973–982
 antihypertensive medications for, 973–982
 dietary therapy for, 973–974
 glucose monitoring for, 970, 974–976, 975f, 975t, 976f, 976t
 insulin therapy for, 976–980, 977f, 977t, 979t
 oral hypoglycemic agents for, 970, 980–982
 preconceptional management of, 969–970, 969t
 with renal transplantation, 920
 timing and route of delivery with, 982–985, 984t, 985t
 type 1, 954, 970–971
 type 2, 954–955, 971
- Diabetes in Early Pregnancy (DIEP) study, 961, 964, 974
- Diabetes insipidus, 1024–1025
- Diabetic ketoacidosis (DKA), 962–963, 962t
- Diabetic mothers, infants of
 hyperbilirubinemia in, 1208
 morbidity and mortality in, 967–968, 968f, 986
- Diabetic nephropathy, 913–914, 959–961
 categories of, 959, 959t
 course during pregnancy of, 916t, 959–960, 960f
 effect of pregnancy on progression of, 959, 959f
 epidemiology of, 959
 pathophysiology of, 959
 renal dialysis for, 960
 renal transplantation for, 960–961
- Diabetic retinopathy, 958
- Diagnosis, prenatal. *See* Prenatal diagnosis.

 application of, 378–379, 379f
 fetal, 371–377
 and frequency of biophysical profile scoring, 371, 372t
 with intrauterine growth restriction, 644–645
 of middle cerebral artery, 374–375, 375f
 in Rh-immunized pregnancy, 485–488, 485f, 486f, 490
 of umbilical artery, 175, 372–374, 373f, 374f, 374t
 venous studies in, 375–377, 376f, 377f
 maternal, 377–378, 378f, 379f
 patterns of deterioration in, 378–379, 379f, 380f
- Doppler ultrasound transducer, for fetal heart rate monitoring, 399
- Dose response, to teratogens, 348

- Double-balloon enteroscopy, 1053
 “Double-bubble” sign, 291, 291f
 Double-outlet right ventricle (DORV), 333
 Douching, and preterm birth, 555
 Down syndrome
 prenatal screening for, 222–233
 ADAM 12 in, 230
 combined first- and second-trimester, 232
 cutoff values in, 222t
 ductus venosus wave form in, 231
 first-trimester
 impact of spontaneous miscarriages on, 231–232
 serum markers in, 229–230, 230t
 ultrasound markers in, 227–229, 230–231, 230t, 231f
 human chorionic gonadotropin in, 229–230
 integrated aneuploidy screening as, 232
 likelihood ratios in, 221–222, 222t, 225, 226, 226t
 maternal age in, 222, 222t, 232–233, 233t
 with multiple gestation, 458–459
 nasal bone in, 225, 230–231, 231f, 232
 nuchal translucency in, 228, 230
 PAPP-A in, 229
 in twins, 257, 459
 receiver operating curve in, 222f
 second-trimester
 serum markers in, 222–225, 224t, 226
 ultrasound markers in, 225–226, 225t, 226t
 sequential testing as, 232
 serum markers in
 first-trimester, 229–230, 230t
 second-trimester, 222–225, 224t, 226
 tricuspid regurgitation in, 231
 ultrasound markers in
 first-trimester, 227–229, 230–231, 230t, 231f
 second-trimester, 225–226, 225t, 226t
 recurrence risk for, 246–247
 due to robertsonian translocation, 247, 247t
 in twins, 256, 256t, 257, 257t, 458–459, 458t
 due to uniparental disomy, 247
 Doxepin (Sinequan), dosage of, 1117t
 Doxylamine, for nausea and vomiting, 1042
 Doxylamine succinate and pyridoxine hydrochloride with or without dicyclomine hydrochloride (Bendectin)
 for nausea and vomiting, 1042, 1042t
 as teratogen, 347
 Drug(s)
 and biophysical profile score, 369t
 and breastfeeding, 126, 139–141, 139t, 140f, 140t
 hydrops fetalis due to, 512
 and neonatal outcomes, 1199
 and thyroid function, 1000, 1000t
 Drug abuse. *See* Substance abuse.
 Drug-induced hypothyroidism, 1007
 Drug-induced thrombocytopenia, 843
 Drug-induced valvular heart disease, 814
 DTDST (diastrophic dysplasia sulfate transporter), in skeletal growth, 297
 D-TGA (dextro-transposition of the great arteries), 333–334, 333f
 Duchenne muscular dystrophy, prenatal diagnosis of, 248t
 Ductal arches, fetal echocardiography of, 314–315, 314f
 Ductus arteriosus
 fetal, 160f, 167
 echocardiography of, 314f, 315
 patent, prematurity and, 1201t
 premature closure or narrowing of, hydrops fetalis due to, 509
 maternal, patent, 803–804, 804f
 anesthesia with, 1157
 Ductus venosus, fetal, 159–160, 160f
 Doppler studies of, 376–377, 376f
 Ductus venosus wave form, prenatal screening for, 231
 Duffy antigen, 478f, 495t, 497t, 498–499
 Duloxetine (Cymbalta), dosage of, 1117t
 Dumping syndrome, 1051
 Duodenal atresia, 291–292, 291f
 and aneuploidy, 227t
 Duplications, 15
 Dural vascular anomalies
 intracranial, 1098–1099
 spinal, 1099
 DVT. *See* Deep venous thrombosis (DVT).
 Dwarfism, achondroplastic, anesthesia with, 1161
 Dynamic mutations, 29–30
 Dynamic ultrasound, of fetal anomalies, 275–276, 276f
 Dysautonomia, familial, carrier screening for, 242t
 Dysgerminoma, ovarian, 886, 1141
 Dyslipidemia, in preeclampsia, 658
 Dysmature offspring, 616–617
 Dyspnea, during pregnancy, 103
 Dysrhythmias. *See* Arrhythmias.
 Dysthymic disorder, diagnostic criteria for, 1113, 1115t
 Dystocia
 due to adnexal masses, 1142
 cesarean delivery for, 711
 shoulder, 697–698
 diabetes and, 966–967, 966f, 984
 umbilical cord acid-base balance with, 405
 Dystonia, 1102
 Dystrophy, myotonic, 1109
 DZ twins. *See* Dizygotic (DZ) twins.
 E
 E₁ (estrone), in pregnancy, 114f, 116f
 E₂ (estradiol)
 in implantation, 111
 in pregnancy, 114f, 116f
 Early decelerations, in fetal heart rate, 406, 411t
 Early goal-directed therapy (EGDT), for septic shock, 1176–1178
 EB(s) (elementary bodies), of *Chlamydia*, 93f, 95f, 747
 Ebola virus, breastfeeding with, 135
 Ebstein anomaly
 fetal, 326–327, 327f
 maternal, 810, 810f
 ECG (electrocardiography)
 fetal, ST analysis of, 415
 for pulmonary embolus, 859
 ECG (electrocardiographic) changes, during pregnancy, 799
 Echocardiography
 fetal. *See* Fetal echocardiography.
 for pulmonary embolus, 859
 transesophageal, 1173
 Echogenic bowel, 292–293, 292f
 Eclampsia
 defined, 651
 postpartum, 674
 risk factors for, 654
 Eclampsia (*Continued*)
 seizure prophylaxis and treatment in, 671–673, 671t, 672t
 symptoms preceding, 671, 671t
 ECoG (electrocorticogram), fetal, 171, 172f, 173, 174, 174f
 Economic status, and preterm birth, 554
 Ectoderm, 39f
 Ectopic ACTH syndrome, 1022
 Ectopic pregnancy
 after cesarean delivery, 710
 with renal transplantation, 918
 with uterine anomalies, 1144t
 Edema
 cerebral
 in acute liver failure, 1072
 in preeclampsia, 658
 dependent, 104
 labial, 1124
 due to preeclampsia, 651, 652f
 anesthetic considerations with, 1148
 cerebral, 658
 pulmonary, 674, 1175
 anesthetic considerations with, 1148
 pulmonary, 1174–1175
 colloid osmotic pressure abnormalities and, 1174
 hydrostatic or cardiogenic, 1174–1175
 in preeclampsia, 674, 1175
 anesthetic considerations with, 1148
 tocolytic-induced, 1175
 skin, due to nonimmune hydrops, 507, 507f
 Edinburgh Postnatal Depression Scale (EPDS), 1114
 EDNO (endothelium-derived nitric oxide), in fetal cardiovascular regulation, 166
 Educational status, and preterm birth, 554, 554t
 Efavirenz (Sustiva), for HIV infection, 772t
 Efavirenz + emtricitabine + tenofovir (Atripla), for HIV infection, 772t
 Effexor (venlafaxine), dosage of, 1117t
 EFM. *See* Electronic fetal monitoring (EFM).
 EFW (estimation of fetal weight), in diabetic pregnancy, 982–984, 985
 EGD (esophagogastroduodenoscopy), 1045, 1045f, 1046, 1053
 EGDT (early goal-directed therapy), for septic shock, 1176–1178
 EGF (epidermal growth factor)
 in implantation, 113, 113t
 in pregnancy, 118
 as uterine stimulant, 80
 Ehlers-Danlos syndrome, anesthesia with, 1160
 Eicosanoid cascade, 74–75, 75f
 Eisenmenger syndrome
 hemodynamics of, 1171
 maternal, 804–805, 804f
 anesthesia with, 1157
 Ejection reflex, 131, 132f, 133, 133f
 Elavil (amitriptyline), dosage of, 1117t
 ELBW (extremely low birth weight)
 and cerebral palsy, 1125
 defined, 545
 and survival and morbidity with preterm birth, 550–551, 551f
 Electrocardiographic (ECG) changes, during pregnancy, 799
 Electrocardiography (ECG)
 fetal, ST analysis of, 415
 for pulmonary embolus, 859
 Electrocorticogram (ECoG), fetal, 171, 172f, 173, 174, 174f
 Electromechanical coupling, 76
 Electromyography, 1104

- Electronic fetal monitor (EFM), 399
 adjuncts to, 414–415
 vs. auscultation, 413
 with multiple gestation, 462
- Electro-oculogram (EOG), fetal, 171, 172f
- Electrophysiologic evaluation, of nerve lesions, 1104–1105, 1106f
- Elementary bodies (EBs), of *Chlamydia*, 93f, 95f, 747
- Elliptocytosis, hereditary, 874
- Ellis–van Creveld syndrome, 298
- Embolus
 amniotic fluid, hemodynamics of, 1171–1172
 pulmonary. *See* Pulmonary embolus (PE).
- Embryonic demise
 due to endocrine disorders, 620–621
 due to genetic abnormalities, 619–620
 management of, 627–629, 627t, 628t
 peri-implantation, 619
 recurrent
 immunologic causes of, 621–622
 management of, 628–629, 628t
 due to uterine abnormalities, 622, 622t
- Embryonic development, 37–44
 of breast, 127–128, 127f, 128f
 macroscopic, 37–41, 38f–40f
 microscopic, 41–44, 42f–44f
 postfertilization, 37, 38f, 39f
- Embryonic stage, of fetal lung development, 193, 194f, 194t
- Employment, and preterm birth, 555
- Emsam (selegiline), dosage of, 1117t
- Emtricitabine (Emtriva), for HIV infection, 772t
- Enalapril, for chronic hypertension, 678, 678t
- Encephalitis, measles, 776–777
- Encephalocele, 281, 282f
- Encephalopathy
 hepatic, 1071
 neonatal, 1210
 hypoxic-ischemic, 1210–1211
 Wernicke, 1107
- End-diastolic velocities
 in middle cerebral artery
 absent, 375
 reverse, 375
 in umbilical artery
 absent, 372–373, 373f, 374t
 reverse, 372, 373–374, 374f
- Endemic cretinism, 1006
- Endocarditis, infective, prophylaxis against, 798, 821
- Endocervical curettage, 887
- Endocrine changes, in pregnancy, 119–122
- Endocrine disorders, fetal loss due to, 620–621
- Endocrine organ, fetoplacental unit as, 115–119
 estrogens in, 115–117, 116f
 growth factors as, 117–119, 117t, 118f, 119f
 progesterone in, 115
- Endocrine system, relationships and feedback mechanisms of, 1015, 1017f
- Endocrinology
 of fetoplacental unit, 115–119
 of implantation, 111–114, 112f, 113t
 of pregnancy, 111–122
 corticotropin-releasing hormone and corticotropin-releasing hormone-binding protein system in, 120
 early, 114
 estrogens in, 115–117, 116f
 growth factors in, 117–119, 118t, 119f, 120f
 human chorionic gonadotropin in, 113–114, 114f
 inhibin-related proteins in, 120
 insulin as, 118–120, 118f–120f, 120t
- Endocrinology (*Continued*)
 luteal-phase shift in, 114–115, 115f
 metabolic changes in, 119–122
 oxytocin in, 121
 progesterone in, 115
 prolactin in, 121–122, 121f
 prostaglandins in, 122
 relaxin in, 118f, 121
- Endoderm, 38
- Endodermal sinus tumors, 886, 1141
- Endogenous pressors, sensitivity to, in preeclampsia, 661–662, 662f
- Endometritis, puerperal, 760–761
 breastfeeding with, 136t
Chlamydia trachomatis and, 747

diagnosis of, 797
- Heart disease (*Continued*)
drug-induced valvular, 814
general guidelines for management of, 799–
800, 800t, 801t
heart failure as, 817
in Marfan syndrome, 818, 818f, 819f
mitral regurgitation as, 812, 812f, 813
anesthesia with, 1155–1156
mitral stenosis as, 805, 811–812, 811f
anesthesia with, 1154–1155
mitral valve prolapse as, 812, 812f
anesthesia with, 1156
pre-conception counseling for, 797–799,
798t
prophylactic antibiotics with, 821
rheumatic, 810–812, 811f
- Heart failure, maternal, 817
- Heart murmurs, during pregnancy, 104
- Heart rate
fetal, 172, 173f, 175
nonpregnant, 1171t
during pregnancy, 102, 102f, 103t, 1171t
with multiple gestation, 455
- Heart sounds, during pregnancy, 104
- Heart surgery, during pregnancy, 820–821
- Heart transplantation, pregnancy after, 817
- Heart valves, artificial, pregnancy with, 819–820,
820t, 864
- Heartburn, 1043
- Helicobacter pylori*, 1044t, 1045, 1045f, 1046
- HELLP syndrome, 653
anemia in, 872
diabetes in, 961
differential diagnosis of, 843, 843t
liver disease in, 1062, 1063
- Hemabate (prostaglandin 15-methyl F_{2α}), for
uterine atony, 1183t
- Hematocrit (Hct)
in anemia, 871, 871f
during pregnancy, 101
- Hematologic causes, of hydrops fetalis, 508t, 510
- Hematologic complications, of prematurity, 1199t
- Hematologic events, in pregnancy, 799, 870–872,
871f, 871t
- Hematologic malignancies, during pregnancy,
896–899, 897t
- Hematoma(s)
after cordocentesis, 386, 386f
postcesarean wound, 709
- Hemodialysis, 915–917, 916t
for diabetic nephropathy, 960
- Hemodilution, acute normovolemic, 1182
- Hemodynamic assessment, noninvasive, 1173,
1173t
- Hemodynamic monitoring, invasive central,
1168–1173
for anaphylactoid syndrome of pregnancy,
1171–1172
for aortic stenosis, 1171
background and insertion technique for,
1168–1169
complications of, 1169–1170, 1169t
hemodynamic considerations in, 1170, 1170t,
1171t
for hypertensive disorders of pregnancy, 1172,
1172f
indications for, 1169
for mitral valve stenosis, 1170–1171
and pulmonary capillary wedge pressure, 1170,
1170f
for pulmonary hypertension, 1171
for septic shock, 1172–1173
- Hemodynamic parameters, 1170, 1171t
- Hemodynamic variables, 1170, 1170t

- Hemodynamics
of anaphylactoid syndrome of pregnancy, 1171–1172
anteartum, 103, 103t
of aortic stenosis, 1171
of hypertensive disorders of pregnancy, 1172, 1172f
intrapartum, 104
of mitral valve stenosis, 1170–1171
postpartum, 104
of pulmonary hypertension, 1171
of septic shock, 1172–1173
- Hemoglobin (Hb), glycosylated, 974
- Hemoglobin A_{1c} (Hb A_{1c}), with diabetes, 970, 971, 972, 974
- Hemoglobin C (Hb C), carrier screening for, 243
- Hemoglobin C (Hb C) disease, 878t, 881
- Hemoglobin C (Hb C) trait, 878t, 881
- Hemoglobin (Hb) concentration, and stillbirth, 623
- Hemoglobin D (Hb D), carrier screening for, 243
- Hemoglobin E (Hb E), carrier screening for, 243
- Hemoglobin E (Hb E) disease, 881, 881t
- Hemoglobin (Hb) electrophoresis, 243, 870t
- Hemoglobin H (Hb H) disease, 245, 877, 877f, 878t
- Hemoglobin (Hb) level
in anemia, 869, 870t
normal, 869
- Hemoglobin (Hb) oxygen saturation, fetal, 160, 161, 161f
- Hemoglobin S (Hb S), carrier screening for, 243
- Hemoglobin S (Hb S)– β thalassemia, 878t, 881
- Hemoglobin S (Hb S)–high F, 878t
- Hemoglobin sickle C (Hb SC) disease, 878t, 880–881
- Hemoglobinopathies, 877–881
carrier screening for, 238t, 243–245, 244t
prenatal diagnosis of, 248t
structural, 878–881, 878t, 880t, 881t
thalassemia syndromes as, 877–878, 877f, 878t, 879f
- Hemoglobinuria, paroxysmal nocturnal, 876–877
- Hemolysis, jaundice due to, 1060t
- Hemolytic anemia, autoimmune, 874–875
- Hemolytic disease of the fetus and newborn (HDFN), 477–499
clinical management of, 486–495
chemotherapeutic agents for, 494–495
in first affected pregnancy, 486–488, 487f
intrauterine transfusion for, 488–493
access site for, 488
adjunctive measures with, 491
amount of, 490, 490t
method of, 488–490, 490f
outcome of, 492–493
with severely anemic early-second-trimester fetus, 491
source of red blood cells in, 491–492
timing of, 492
intravenous immune globulin for, 493–494
nasal tolerance for, 495
oral tolerance for, 494
plasmapheresis for, 493, 494
with previously affected fetus or infant, 488, 489f
sensitization to paternal leukocyte antigens for, 495
diagnosis of, 481–483
fetal blood typing through genetics for, 481–483, 482f–484f, 482t
in vitro tests for, 481
maternal antibody determination for, 481
- Hemolytic disease of the fetus and newborn (HDFN) (*Continued*)
genetics of, 479, 479f
historical perspectives on, 477
incidence of, 478, 478f
monitoring of, 483–486
amniocentesis for, 483–484, 484f
fetal blood sampling for, 484
ultrasound for, 484–486, 484f, 485f
due to non-RhD antibodies, 495–499, 495t, 497t
pathophysiology of, 478–479
prevention of, 479–481
terminology for, 477
- Hemolytic disease of the newborn (HDN). *See* Hemolytic disease of the fetus and newborn (HDFN).
- Hemolytic uremic syndrome (HUS), 842–843, 843t
acute renal failure due to, 908
- Hemophilia A, 24, 844t–846t, 847
prenatal diagnosis of, 248t
- Hemophilia B, 844t–846t, 847
- Hemorrhage. *See also* Bleeding.
anteartum, 725–734
due to abruptio placentae, 730f, 731–734, 733t
epidemiology of, 725
due to placenta accreta, 728–728, 728f
due to placenta previa, 725–729, 726f, 726t, 727t, 728f
due to vasa previa, 729–730, 730f
- fetomaternal, 478, 480–481
fetal loss due to, 624
hydrops fetalis due to, 510
due to trauma, 1185, 1185f
- intracranial (subarachnoid)
fetal
due to idiopathic thrombocytopenic purpura, 839
due to neonatal alloimmune thrombocytopenia, 840, 841–842
maternal, 1096–1098, 1097f, 1098f
anesthesia with, 1150
intraventricular, 1211–1212
prematurity and, 1201t
- obstetric, 1179–1184
clinical staging of, 1180, 1180t
defined, 1179–1180
incidence and etiology of, 1179–1180
management of, 1180–1184
additional supportive measures in, 1182
hemostasis in, 1182–1184, 1183t, 1184f
volume replacement in, 1180–1182, 1180t–1182t
protocol for, 727, 727t
postpartum, 698–699
uterine myomas and, 1137
- Hemorrhagic fevers, breastfeeding with, 135
- Hemorrhagic shock, 1179–1184
clinical staging of, 1180, 1180t
incidence and etiology of, 1179–1180
management of, 1180–1184
additional supportive measures in, 1182
hemostasis in, 1182–1184, 1183t, 1184f
volume replacement in, 1180–1182, 1180t–1182t
- Hemorrhoids, 1052–1053
- Hemostasis, for hemorrhagic shock, 1182–1184, 1183t, 1184f
- Hemostatic system, 825–829
anticoagulant system in, 826–828, 828f
disorders of. *See* Coagulation disorder(s).
effect of pregnancy on, 829
fibrin plug formation in, 826, 827f
fibrinolysis in, 828–829, 828f
platelet plug formation in, 825–826, 826f
- Heparin
for antiphospholipid antibody syndrome, 830–831, 1084, 1084t
for preeclampsia, 674
during pregnancy, 801t
with prosthetic heart valves, 819, 820, 820t
for recurrent pregnancy loss due to inherited thrombophilia, 628
for rheumatic disease, 1082t
for septic pelvic vein thrombophlebitis, 764
for venous thromboembolism, 862–863, 862t
prevention of, 836
- Heparin-induced thrombocytopenia (HIT), 863–864
- Hepatic complications, of prematurity, 1199t
- Hepatic encephalopathy, 1071
- Hepatic length, in Rh-immunized pregnancy, 485
- Hepatic lesions, in preeclampsia, 658, 658f
- Hepatic masses, fetal, 293, 293f
- Hepatic rupture, 1064
- Hepatic venous return, fetal, 159–160, 159f
- Hepatitis, 785–786, 787t
autoimmune, 1069
breastfeeding with, 135–137, 136t
chronic nonviral, 1069
viral, 1064–1069, 1065t, 1066t, 1068t
- Hepatitis A vaccine (Vaqta, Havrix), 785
- Hepatitis A virus (HAV), 785, 787t, 1065–1066, 1065t
breastfeeding with, 135, 136t
- Hepatitis B immune globulin (HBIG), 786, 1066t, 1067, 1218
- Hepatitis B surface antigen (HBsAg), in newborn period, 1218
- Hepatitis B vaccination, 1066t, 1067, 1218
- Hepatitis B virus (HBV), 786, 787t, 1065t, 1066–1067
acute, 1066
breastfeeding with, 135, 136t
chronic carrier state of, 1066
coinfection with hepatitis D virus, 1068
diagnosis of, 1065t, 1066
epidemiology of, 1066
medical personnel concerns with, 1067
in newborn period, 1218
perinatal aspects of, 1066–1067
prevention and treatment of, 1067
transfusion-related, 1182t
- Hepatitis C virus (HCV), 786, 787t, 1065t, 1067–1068
breastfeeding with, 135–137, 136t
chronic, 1068t
active, 1068t
diagnosis of, 1067–1068, 1068t
epidemiology of, 1067
and intrahepatic cholestasis of pregnancy, 1061
pregnancy concerns with, 1068
pregnancy management with, 1068
transfusion-related, 1182t
transmission of, 1067
- Hepatitis D virus (HDV, delta infection), 786, 787t, 1065t, 1068
- Hepatitis E virus (HEV), 786, 787t, 1065t, 1068–1069
- Hepatitis G virus (HGV), 786, 787t, 1069
- Hepatocellular carcinoma, jaundice due to, 1060t

- Hepatomegaly
 fetal, 293
 maternal, 1059
- Hereditary elliptocytosis, 874
- Hereditary nephritis, 912
- Hereditary spherocytosis, 874
- Heritability, 25, 26
- Hermansky-Pudlak syndrome, 846, 846t, 847
- Hernia, congenital diaphragmatic. *See* Congenital diaphragmatic hernia (CDH).
- Herpes gestationis, 1125t, 1127–1129, 1128f, 1129f
- Herpes simplex virus (HSV), 769–770
 breastfeeding with, 136t
 hepatitis due to, 1069
 in neonate, 1101, 1218
 after premature rupture of the membranes, 607
- Herpes zoster, 783–784
- Hespan (hydroxymethyl starch), for hemorrhagic shock, 1180t, 1181
- Hetastarch (hydroxymethyl starch), for hemorrhagic shock, 1180t, 1181
- Heteroplasmy, 29
- Heteroploidy, 14
- HEV (hepatitis E virus), 786, 787t, 1065t, 1068–1069
- Hexosaminidase A deficiency, carrier screening for, 238t, 240–241, 241t
- Hextend (hydroxymethyl starch), for hemorrhagic shock, 1180t, 1181
- HGV (hepatitis G virus), 786, 787t, 1069
- Hiccups, fetal, 361, 366
- HIFs (hypoxia-inducing factors), in preeclampsia, 665
- HIG (hyperimmune globulin), for cytomegalovirus, 624, 765
- Highly active antiretroviral therapy (HAART), for HIV infection, 771–772
- High-resolution comparative genomic hybridization (hCGH), 14
- Hirschsprung disease, 28
- Hirsutism, 1031–1032, 1031t, 1124
- Histamine type 2 (H₂) receptor antagonists
 for GERD, 1044, 1044t, 1045f
 for peptic ulcer disease, 1046
- Histones, 7
- HIT (heparin-induced thrombocytopenia), 863–864
- HIV. *See* Human immunodeficiency virus (HIV).
- Hivid (zalcitabine), for HIV infection, 772t
- HLA. *See* Human leukocyte antigen (HLA).
- HLHS (hypoplastic left heart syndrome), 328–330, 329f
 invasive fetal therapy for, 445
- HOEM (hypertrophic obstructive cardiomyopathy), anesthesia with, 1159
- Hodgkin lymphoma (HL), in pregnancy, 896–898, 897t
- Hofbauer cells, 41, 43
- Holoprosencephaly, 282–283, 283f
 and aneuploidy, 227t
- Homan sign, 856
- Homeobox (*HOX*) genes, in skeletal growth, 297
- Homoplasmy, 29
- Hormonal adaptations, to multiple gestation, 455
- Hormonal contraceptives, with breastfeeding, 134–135
- Hormonal control
 of labor, 70–76
 cascade of events in, 70–72, 71f
 estrogens in, 74
 fetal hypothalamic-pituitary-adrenal axis in, 72–73
- Hormonal control (*Continued*)
 oxytocin in, 75–76
 progesterone in, 73–74
 prostaglandins in, 74–75, 75f
 of myometrial contractions, 79–81, 79f, 80t
- Hormonal disorders, preterm labor due to, 531–532
- Hormonal regulation, of fetal heart rate, 398
- Hormones, maternal and fetal, and intrauterine growth restriction, 641
- HOX* (homeobox) genes, in skeletal growth, 297
- HPA(s) (human platelet antigens), in neonatal alloimmune thrombocytopenia, 840, 840t
- HPA (hypothalamic-pituitary-adrenal) axis, of fetus, in control of labor, 72–73
- HPV (human papillomavirus), 748–750, 749f
 and cervical intraepithelial neoplasia, 887
- 11 β -HSD (11 β -hydroxysteroid dehydrogenase), in control of labor, 72–73
- 3 β -HSD (3 β -hydroxysteroid dehydrogenase) deficiency, 1030
- HSV. *See* Herpes simplex virus (HSV).
- HTLV-1 (human T-cell leukemia virus type 1),
 breastfeeding with, 136t, 138
- Humalog (insulin lispro), 977f, 977t, 978, 979
- Human chorionic gonadotropin (hCG)
 and abruptio placentae, 732
 and choriocarcinoma, 1141
 and gestational trophoblastic neoplasia, 891
 hyperthyroidism related to, 1004–1005
 and maternal thyroid physiology, 996, 997f
 and nausea and vomiting, 1042
 in pregnancy, 113–114, 114f
 prenatal screening for, 223, 224, 229–230
 in twins, 257, 257t, 458, 459
- Human chorionic somatomammotropin (hCS),
 in pregnancy, 118–119, 118f, 120f
- Human Genome Project, 3, 34
- Human immunodeficiency virus (HIV), 770–773
 acute phase of, 771
 breastfeeding with, 136t, 137–138
 diagnosis of, 771
 epidemiology of, 770–771
 fetal blood sampling with, 386
 latent phase of, 771
 liver disease with, 1069
 myocarditis or cardiomyopathy with, 816
 in newborn period, 1218–1219
 pathogenesis of, 771
 perinatal transmission of, 771, 1101
 pneumonia with, 771, 929–930, 933–934, 934f
 symptomatic phase of, 771
 transfusion-related, 1182t
 treatment of, 771–773, 772t, 1101
- Human immunodeficiency virus (HIV)-
 associated nephropathy, 915
- Human leukocyte antigen (HLA)
 lack of expression of, 89–90
 sensitization to paternal, for hemolytic disease of the fetus and newborn, 495
- Human leukocyte antigen C (HLA-C), in preeclampsia, 661
- Human leukocyte antigen G (HLA-G), and early pregnancy loss, 619
- Human papillomavirus (HPV), 748–750, 749f
 and cervical intraepithelial neoplasia, 887
- Human placental growth hormone, in pregnancy, 119
- Human platelet antigens (HPAs), in neonatal alloimmune thrombocytopenia, 840, 840t
- Human T-cell leukemia virus type I (HTLV-1),
 breastfeeding with, 136t, 138
- Humerus, in Down syndrome, 225–226
- Humoral immunity, 87
- Huntington disease, prenatal diagnosis of, 248t
- HUS (hemolytic uremic syndrome), 842–843, 843t
 acute renal failure due to, 908
- Hyaluronidase, for cervical ripening, 702t
- Hybridization-based methods, 31–32, 31f
- Hydatidiform mole, 42, 891
 hyperthyroidism due to, 1005
 and preeclampsia, 654
- Hydralazine
 for chronic hypertension, 678, 678t
 for preeclampsia, 673, 673t
 during pregnancy, 801t
- Hydramnios
 due to nonimmune hydrops, 507
 in twin-to-twin transfusion syndrome, 62
- Hydrencephaly, 283–284
- Hydrocephalus, 279–280
 and aneuploidy, 227t
 diagnosis of, 279–280, 279f, 280f
 invasive fetal therapy for, 277t, 280
 post-hemorrhagic, 1212
 prognosis for, 280
- Hydrocortisone
 for Addison disease, 1027
 for asthma, 943
 for hyperemesis gravidarum, 1043
 for hypopituitarism, 1023
 for induction of fetal pulmonary maturity, 423t
 for septic shock, 763, 1179
- Hydronephrosis
 and aneuploidy, 227t
 during pregnancy, 105
- Hydrops fetalis, 505–513
 defined, 478, 505
 delivery considerations with, 513
 diagnostic approach to, 512–513
 echocardiography of, 310
 epidemiology of, 505
 etiology of, 507–512, 508t
 cardiovascular, 507–509, 508t
 chondrodysplasia as, 508t, 511–512
 chromosomal, 508t, 509
 congenital cystic adenomatoid malformation as, 444, 509
 diabetes in, 512
 gastrointestinal, 508t, 512
 hematologic, 508t, 510
 hemolytic disease of the fetus and newborn as, 478–479
 infectious, 508t, 510–511
 malformation sequence in, 508t
 medications in, 512
 metabolic, 508t, 511
 parvovirus as, 511, 774
 thoracic, 508t, 509–510
 twin pregnancy in, 508t, 510
 urinary, 508t, 512
- experimental management of idiopathic, 512
- fetal fluid accumulation in, 444, 506–507, 506f, 507f
- homozygous, 877f
 management of, 513
 mirror syndrome due to, 505–506
 presenting signs and symptoms of, 505–506
 recurrence risks for, 513
 scoring system for, 506
 ultrasonography of, 506, 506f, 507f
- Hydroquinone cream, for melasma, 1124
- Hydrostatic pulmonary edema, 1174–1175
- Hydrothorax
 hydrops fetalis due to, 509–510
 invasive fetal therapy for, 444
 neonatal management of, 1198t

- Hydroureter, during pregnancy, 105
 Hydroxychloroquine, for rheumatic disease, 1082t
 25-Hydroxycholecalciferol [25(OH)D, vitamin D₃], 1032
 2-Hydroxyestradiol, in pregnancy, 115
 2-Hydroxyestriol, in pregnancy, 115
 2-Hydroxyestrone, in pregnancy, 115–116
 11-Hydroxylase deficiency, 1029–1030
 17-Hydroxylase deficiency, 1030
 21-Hydroxylase deficiency, 1028–1029, 1029f
 Hydroxymethyl starch (hetastarch, Hespan, Hextend), for hemorrhagic shock, 1180t, 1181
 17 α -Hydroxyprogesterone (17-OHP), in pregnancy, 114f, 115
 17 α -Hydroxyprogesterone caproate (17P), for preterm labor, 532, 570–571, 570t, 571f
 3 β -Hydroxysteroid dehydrogenase (3 β -HSD) deficiency, 1030
 11 β -Hydroxysteroid dehydrogenase (11 β -HSD), in control of labor, 72–73
 Hygroma, cystic, 289–290, 289f
 and aneuploidy, 227t
 hydrops fetalis due to, 509
 Hyperaldosteronism, primary, 1027–1028, 1028f
 Hyperandrogenism, gestational, 1031–1032, 1031t
 Hyperbilirubinemia
 in infants of diabetic mothers, 967
 after intrauterine transfusion, 493
 in neonatal period, 1208–1209, 1209t
 Hypercalcemia, 1033–1035, 1033t, 1034t
 familial hypocalciuric, 1034
 Hypercoagulability, in pregnancy, 1153
 Hypercortisolism, 1021–1022
 Hypercholeic bowel, and aneuploidy, 226, 227t
 Hyperemesis gravidarum, 1004–1005, 1042–1043
 Hyperglycemia
 and biophysical profile score, 369t
 transient maternal, due to antenatal corticosteroids, 426
 Hyperhomocysteinemia, 833–834
 and fetal loss, 625t, 834
 Hyperimmune globulin (HIG), for cytomegalovirus, 624, 765
 Hyperinsulinemic-euglycemic clamp, 956, 956f
 Hyperlipidemia, in preeclampsia, 658
 Hypermastia, 128
 Hypermetabolism, due to burns, 1187
 Hypermorphic allele, 6
 Hyperosmolar laxatives, for constipation, 1052, 1052t
 Hyperoxia, maternal, for intrauterine growth restriction, 645
 Hyperparathyroidism, primary, 1033–1035, 1033t, 1034t
 Hyperpigmentation, in pregnancy, 1124
 Hyperreactio luteinalis, 1031
 Hyperreflexia, in preeclampsia, 657
 HyperRHO, 479–480
 Hypertension
 benign intracranial, 1094–1095
 chronic, 676–679
 defined, 651
 with diabetes, 961
 diagnosis of, 652–653, 676
 effects on fetus of, 676
 effects on mother of, 676
 epidemiology of, 676
 obstetric management of, 679
 pathogenesis of, 676
 pharmacologic management of, 676–679, 678t
 preeclampsia superimposed on, 651–652
 Hypertension (*Continued*)
 with chronic kidney disease, 912
 classification of, 651–653, 652f, 653f, 653t
 with diabetes, 970
 in diabetic nephropathy, 913–914
 with dialysis, 917
 in eclampsia, 651
 fetal loss due to, 624
 gestational, 652
 excessive weight gain and, 145
 maternal obesity and, 144
 in HELLP syndrome, 652
 hemodynamics of, 1172, 1172f
 portal, 1071
 in preeclampsia. *See* Preeclampsia.
 pulmonary
 fetal, congenital diaphragmatic hernia and, 441–442
 maternal, 805
 anesthesia with, 1158
 hemodynamics of, 1171
 in neonatal period, 1207
 with renal transplantation, 919
 Hypertensive emergencies, in preeclampsia, 673, 673t
 Hyperthyroidism
 diagnosis of, 1001
 differential diagnosis of, 1001–1002
 fetal and neonatal, 1003–1004, 1004f
 in pregnancy, 1001–1003, 1001t, 1003t
 recurrent gestational, 1005
 related to human chorionic gonadotropin, 1004–1005
 signs and symptoms of, 1001
 subclinical, 1003
 thyroid storm due to, 1003, 1003t
 treatment of, 1002–1003
 in women, 1000
 Hypertrophic cardiomyopathy
 idiopathic, 815–816, 815f
 in infants of diabetic mothers, 967
 Hypertrophic obstructive cardiomyopathy (HOCM), anesthesia with, 1159
 Hyperventilation
 during pregnancy, 104, 927
 for subarachnoid hemorrhage, 1150
 Hyperviscosity, in infants of diabetic mothers, 967
 Hypocalcemia
 in infants of diabetic mothers, 967
 maternal, 1035
 Hypofibrinogenemia, 844t, 845t, 848
 Hypogastric artery ligation, for obstetric hemorrhage, 1183, 1184f
 Hypoglycemia
 in acute liver failure, 1072
 avoidance of nocturnal, for diabetes, 974
 and biophysical profile score, 369t
 in infants of diabetic mothers, 967
 prematurity and, 1201t
 Hypoglycemic agents, oral, 970, 980–982
 Hypomorph allele, 6
 Hypoparathyroidism, 1035, 1035t
 Hypophysial arteries, 1015
 Hypophysitis-pituitary-adrenal-placental axis, fetal, in preterm labor, 529, 530f
 Hypopituitarism, 1022–1024, 1023t
 Hypoplastic anemia, 875–876
 Hypoplastic left heart syndrome (HLHS), 328–330, 329f
 invasive fetal therapy for, 445
 Hypotension
 fetal heart rate with, 409f, 411t
 maternal, due to cesarean delivery, 710
 Hypotension (*Continued*)
 noninvasive assessment of, 1173, 1173f
 for subarachnoid hemorrhage, 1150
 Hypothalamic-pituitary-adrenal (HPA) axis, of fetus, in control of labor, 72–73
 Hypothalamus
 anatomy and physiology of, 1015, 1016f, 1017f
 disorders of, 1016
 fetal development of, 1016
 during pregnancy, 1015–1016, 1016f, 1017f
 Hypothermia
 for hypoxic-ischemic encephalopathy, 1211
 for subarachnoid hemorrhage, 1150
 Hypothesis generation, 208
 Hypothesis testing, 208, 211–212, 212t
 Hypothyroidism
 differential diagnosis of, 1007
 drug-induced, 1007
 fetal and neonatal, 1008
 idiopathic, 1007
 iodine deficiency and, 1005–1006, 1005f
 mental retardation due to, 1007
 and postpartum thyroiditis, 1010
 in pregnancy, 1005–1008
 screening for, 1008
 signs and symptoms of, 1006–1007
 subclinical, 1007–1008
 treatment of, 1007
 in women, 1000–1001
 Hypothyroxinemia, 1005f
 subclinical, 1008
 Hypotonic fluids, for preeclampsia, 674
 Hypoventilation, maternal, and fetal respiratory acidosis, 401
 Hypoxemia
 defined, 401, 401t
 fetal responses to, 362–364, 363f, 364f
 Hypoxia
 and cerebral palsy, 1216
 defined, 401, 401t
 fetal, and behavioral state activity, 174, 174f
 fetal responses to, 399–400
 maternal, and fetal respiratory acidosis, 401
 physiologic, 188
 saltatory fetal heart rate due to, 413, 413f
 Hypoxia-inducing factors (HIFs), in preeclampsia, 665
 Hypoxic-ischemic encephalopathy, in neonatal period, 1210–1211
 Hyrtl anastomosis, 40
 Hysterectomy
 for cervical cancer, 888, 889
 cesarean, 713
 for obstetric hemorrhage, 1183
 for placenta accreta, 729
 Hysteroscopic myomectomy, 1039
 I
 IAP (intrapartum antibiotic prophylaxis), for group B *Streptococcus* infection, 766, 767–768, 768f
 IBD. *See* Inflammatory bowel disease (IBD).
 IBS (irritable bowel syndrome), 1049–1050, 1050t
 Ibuprofen, for rheumatic disease, 1082t
 ICH. *See* Intracranial hemorrhage (ICH).
 Ichthyosiform erythroderma, 1132
 Ichthyosis, 1132
 ICP (intrahepatic cholestasis of pregnancy), 1060–1061, 1125
 ICSI (intracytoplasmic sperm injection), perinatal risks of, 260–261
 Ideogram, 12, 12f
 Idiopathic hypertrophic cardiomyopathy, 815–816, 815f

- Idiopathic hypertrophic subaortic stenosis (IHSS), anesthesia with, 1159
- Idiopathic thrombocytopenic purpura (ITP), 837–840
- IDMs (infants of diabetic mothers)
 - hyperbilirubinemia in, 1208
 - morbidity and mortality in, 967–968, 968f, 986
- IDO (indolamine 2,3-dioxygenase), 90, 94, 95f
- IDS (Inventory of Depressive Symptomatology), 1114
- IE (infective endocarditis), prophylaxis against, 798, 821
- IFG (impaired fasting glucose), 955, 971
- IFN- α (interferon- α), for hepatitis C virus, 1068
- IgA nephropathy, 916f
- IGFs. *See* Insulin-like growth factors (IGFs).
- IGT (impaired glucose tolerance), 955, 971
- IL. *See* Interleukin (IL) *entries*.
- Ileus, adynamic, postcesarean, 709
- Illicit drugs, as teratogens, 356
- IM (intramembranous) pathway, 49, 50–51
- Imipenem-cilastin
 - for pelvic abscess, 762
 - for puerperal endometritis, 760
 - for septic shock, 763
- Imipramine (Tofranil), dosage of, 1117t
- Immune globulin
 - hepatitis A, 785
 - hepatitis B, 786, 1066t, 1067, 1218
 - intravenous. *See* Intravenous immune globulin (IVIG).
 - rhesus, 478, 479–481
 - for idiopathic thrombocytopenic purpura, 839
 - varicella zoster, 783
- Immune privileged site, pregnant uterus as, 88–90, 89f, 90f
- Immune response(s)
 - cytokines and, 88
 - to trophoblast, 88–90, 89f–91f, 91–92
 - types of, 87–88
- Immune suppression
 - local, 90, 90f
 - systemic, 88
- Immunity
 - adaptive, 87–88
 - cellular, 87
 - humoral, 87
 - natural or innate, 87
 - in pregnancy, 90–92, 91f
- Immunologic causes, of pregnancy loss, 621–622, 628
- Immunologic changes, in preeclampsia, 666, 667
- Immunologic complications, of prematurity, 1199t
- Immunology
 - general concept of, 87–88
 - of pregnancy, 87–96
 - defining, 87
 - infection in, 92–96, 93f–95f
 - innate immune system in, 90–92, 91f
 - maternal immune response to trophoblast in, 88–90, 89f, 90f
 - and rheumatic diseases, 1079–1080
 - and thyroid system, 998–999
- Immunomodulators, for inflammatory bowel disease, 1049
- Immunosuppressive agents
 - for renal transplantation, 918, 919, 920, 921
 - as teratogens, 351t, 352
- Imodium (loperamide), for inflammatory bowel disease, 1049
- Impaired fasting glucose (IFG), 955, 971
- Impaired glucose tolerance (IGT), 955, 971
- Impetigo herpeticiformis, 1125t, 1129–1130, 1130f
- Implantation, 37, 38f, 40
 - endocrinology of, 111–114, 112f, 113t
 - site of, 112
 - steps in, 111, 112f, 619
 - timing of, 619
 - window for, 111
- Imprinting, 30
- In vitro fertilization (IVF)
 - antiphospholipid antibodies and, 1083–1084
 - implantation with, 111
 - perinatal risks of, 260–261
 - and preterm birth, 558
- Incidental thrombocytopenia of pregnancy, 838
- Incontinence, cesarean delivery to prevent, 708, 711
- Independent assortment, 22, 23f
- Indinavir (Crixivan), for HIV infection, 772t
- Indirect assays, 30
- Indirect obstetric deaths, 1167
- Indolamine 2,3-dioxygenase (IDO), 90, 94, 95f
- Indomethacin
 - for cervical insufficiency, 589
 - and necrotizing enterocolitis, 1207–1208
 - for preterm labor, 563–564
 - for rheumatic disease, 1082t
- Induction of labor, 700–703
 - for breech presentation, 705
 - and cesarean delivery, 700
 - contraindications for, 701
 - in diabetic pregnancy, 985
 - elective, 700–701, 700t
 - for fetal demise, 627–628
 - incidence of, 700, 700f
 - indicated, 701–703, 702t, 703t
 - for post-term pregnancy, 615–616
 - after premature rupture of the membranes, 604
- Infant mortality rate
 - defined, 548
 - with preterm birth, 548–551, 549f–552f, 553t
- Infantile polycystic kidney, 295, 296f
- Infants of diabetic mothers (IDMs)
 - hyperbilirubinemia in, 1208
 - morbidity and mortality in, 967–968, 968f, 986
- Infection(s), 739–787
 - with bacterial vaginosis, 741–742, 742f, 742t, 743t
 - and premature rupture of the membranes, 599
 - and preterm birth, 556, 568, 570, 741, 742, 742t
 - during breastfeeding, 135–138, 136t–137t
 - with candidiasis, 739–741, 740t
 - breastfeeding with, 135, 136t, 137t, 138–139
 - due to central venous catheters, 1170
 - and cerebral palsy, 1215–1216
 - with *Chlamydia trachomatis*, 746–748
 - breastfeeding with, 136t
 - diagnosis of, 747
 - epidemiology of, 746
 - and gonorrhoea, 745, 746
 - life cycle of, 93f
 - pathogenesis of, 746–747
 - and postpartum endometritis, 747
 - and pregnancy outcome, 93–96, 93f–95f, 747
 - and preterm birth, 556
 - prevention of, 748
 - treatment of, 747–748, 748t
 - chorioamnionitis as, 757–759, 758t
 - and bronchopulmonary dysplasia, 1205
 - and cerebral palsy, 1216
 - due to cervical cerclage, 594
- Infection(s) (*Continued*)
 - clinical, 757
 - in neonatal period, 1197–1198, 1217
 - after premature rupture of the membranes, 600, 604, 605, 606
 - umbilical cord acid-base balance with, 404, 404t

- Levothyroxine (L-thyroxine)
 for hypopituitarism, 1023
 for prevention of postpartum thyroiditis, 1010–1011
- Levo-transposition of the great arteries (L-TGA), 334, 334f
- Lexapro (escitalopram), dosage of, 1117t
- LGA (large-for-gestation-age) infants
 health and disease in, 153
 maternal diabetes and, 964–966, 965t, 966t
 maternal obesity and, 144
- LH (luteinizing hormone), in pregnancy, 114f
- LHR (lung area to head circumference ratio), in congenital diaphragmatic hernia, 288, 441, 442t, 443f
- Lidocaine, during pregnancy, 801t
- Lifestyle modifications, for GERD, 1044, 1045, 1045f
- Likelihood ratios, 215–216
 in Down syndrome, 221–222, 222t, 225, 226, 226t
- Liley, William, 477
- Limb reduction defects (LRD), after chorionic villus sampling, 256
- Limits of viability, 1200–1202
- Linea nigra, 1124
- Linezolid, for mastitis, 764
- Linkage analysis, 30–31, 30f, 33–34
- Linkage disequilibrium, 34
- Lipid(s)
 in surfactant, 197, 197f
 total plasma, during pregnancy, 119
- Lipoproteins, during pregnancy, 119
- Listeriosis, 773, 1100
 fetal loss due to, 623
- Lithium
 during lactation, 1119–1120
 perinatal complications of, 1119
 as teratogen, 351t, 353, 1116–1117
 for thyroid storm, 1003, 1003t
- Little, William John, 1214
- Livedo reticularis, 1080
- Liver
 acute fatty, 1062–1063, 1063t
 acute renal failure due to, 909
 imaging of, 1059–1060
- Liver disease, 1059–1073
 acute fatty liver of pregnancy as, 1062–1063, 1063t
 acute liver failure as, 1071–1072, 1071t, 1072t
 Budd-Chiari syndrome as, 1070
 chronic, 1069–1071
- Liver disease (*Continued*)
 cirrhosis as, 1070–1071
 primary biliary, 1069
 coincidental to pregnancy, 1064–1069, 1065t, 1066t, 1068t
 diagnosis of, 1059–1060, 1059t
 in HELLP syndrome, 1063
 hepatitis as
 nonviral, 1069
 viral, 1064–1069, 1065t, 1066t, 1068t
 due to herpes simplex virus, 1069
 due to HIV infection, 1069
 intrahepatic cholestasis of pregnancy as, 1060–1061
 liver infarction as, 1064
 liver rupture as, 1064
 liver transplantation for, 1072–1073
 overlap syndromes with, 1062–1064, 1063t
 portal hypertension as, 1071
 in preeclampsia, 1063
 primary sclerosing cholangitis as, 1070
 unique to pregnancy, 1060–1064, 1063t
 Wilson disease as, 1070
- Liver failure, acute, 1071–1072, 1071t, 1072t
- Liver function, in pregnancy, 1059, 1060t
- Liver function tests
 in acute fatty liver of pregnancy, 1062, 1063t
 in acute liver failure, 1071
 in preeclampsia, 658
 in pregnancy, 1059, 1060t
- Liver infarction, 1064
- Liver rupture, 1064
- Liver transplantation, 1072–1073
- Liver tumors, fetal, 293
- LMP (last menstrual period), and gestational age, 613
- LMWH. *See* Low molecular weight heparin (LMWH).
- Local immune suppression, 90, 90f
- Locus heterogeneity, 25
- Long arm, 12, 12f
- Long limb gastric bypass, 1051, 1051t
- Long-chain 3-hydroxyacyl-coenzyme A dehydrogenase (LCHAD) deficiency, 1062
- Loop electrosurgical excision procedure (LEEP), 887, 888
 cervical cerclage after, 592–593
 cervical insufficiency due to, 586–587
 and preterm birth, 557–558
- Loperamide (Imodium), for inflammatory bowel disease, 1049
- Lopinavir/ritonavir (Kaletra), for HIV infection, 772, 772t
- Lorazepam, for status epilepticus, 1090
- Low birth weight (LBW)
 and adult disease, 151–152, 152f, 153
 antidepressants and, 1118
 defined, 545
 extremely. *See* Extremely low birth weight (ELBW).
 incidence of, 545–546, 546f
 and preterm labor and birth, 545–546
 prevention of, 154
 very. *See* Very low birth weight (VLBW).
- Low molecular weight heparin (LMWH)
 for antiphospholipid antibody syndrome, 830–831, 1084, 1084t
 with prosthetic heart valves, 819, 820t, 864
 for recurrent pregnancy loss due to inherited thrombophilia, 628
 for rheumatic disease, 1082t
 for venous thromboembolism, 863
 prevention of, 836, 865

- Low spinal anesthesia, for labor and delivery, 716
- Low-dose aspirin (LDA), for antiphospholipid antibody syndrome, 830–831
- Lower esophageal sphincter (LES), in pregnancy, 1041, 1043
- Lower urinary tract obstruction (LUTO)
invasive fetal therapy for, 277t, 434t, 444–445, 445t
pathophysiology of, 444
- Low-glycemic foods, for diabetes, 974
- Low-lying placenta, 725, 726f
- LRD (limb reduction defects), after chorionic villus sampling, 256
- L/S ratio. *See* Lecithin/sphingomyelin (L/S) ratio.
- LSVC (left-sided vena cava), persistent, 318–320, 319f, 320f
- L-TGA (levo-transposition of the great arteries), 334, 334f
- L-thyroxine (levothyroxine)
for hypopituitarism, 1023
for prevention of postpartum thyroiditis, 1010–1011
- Lumbar disk protrusion, 1104
- Lumbosacral plexus lesion, 1105
- Lumbosacral root lesions, 1104
- Lung(s), wet, 1202–1203, 1203f
- Lung anomalies, 285–289, 286f–289f
- Lung area to head circumference ratio (LHR), in congenital diaphragmatic hernia, 288, 441, 442t, 443f
- Lung bud, 193, 194f
- Lung development, fetal, 193–204, 194t
alveolar stage of, 194f, 194t, 195–196, 195t, 196f
canalicular stage of, 194, 194f, 194t
embryonic stage of, 193, 194f, 194t
fetal breathing movements and, 176–177
fetal lung fluid in, 197
induced maturation in, 202–204, 203f, 203t
pseudoglandular stage of, 193, 194f, 194t
and pulmonary hypoplasia, 196–197, 196t
saccular stage of, 194–195, 194f, 194t, 195f
surfactant in, 197–202
composition of, 197–198, 197f
metabolism of, 198–200, 199f, 201f
physiologic effects of, 200–202, 201f
for respiratory distress syndrome, 202, 202f
- Lung fluid, fetal, 49, 197
- Lung maturation, induced. *See* Fetal pulmonary maturity, induction of.
- Lung profile, fetal, 419
- Lupus erythematosus, systemic. *See* Systemic lupus erythematosus (SLE).
- Lupus flare, 914, 1081
- Lupus nephritis, 914, 916t
- Luteal phase defect, fetal loss due to, 620
- Luteal-placental shift, timing of, 114–115, 115f
- Luteinizing hormone (LH), in pregnancy, 114f
- Luteomas, 1031
- Lutheran antigen, 478f
- LUTO (lower urinary tract obstruction)
invasive fetal therapy for, 277t, 434t, 444–445, 445t
pathophysiology of, 444
- Luvox (fluvoxamine), dosage of, 1117t
- Lyme disease, breastfeeding with, 136t
- Lymphadenectomy, for cervical cancer, 888, 889
- Lymphangioma, cystic, 289–290, 289f
- Lymphatic hamartoma, 289–290, 289f
- Lymphocytic adenohypophysitis (LAH), 1023–1024, 1023t
- Lymphocytic thyroiditis, chronic, 1007
- Lymphoma
Burkitt, 899
diffuse, large B-cell, 898–899
Hodgkin, 896–898, 897t
non-Hodgkin, 897t, 898–899
- Lysosomal storage diseases, hydrops fetalis due to, 511
- M
- M antigen, 497–498
- MacLayne, Eufame, 715
- Macroadenoma, 1019, 1020t
- Macrobid (nitrofurantoin monohydrate macrocrystals), for asymptomatic bacteriuria and acute cystitis, 752t, 906
- Macrocytic anemia, 869, 872
- Macronutrient intake, 147
- Macrophages, during pregnancy, 90
- Macrosomia
excessive weight gain and, 145
maternal diabetes and, 964–966, 965t, 966t, 982–984
maternal obesity and, 144
with post-term pregnancy, 614
- Magma reticulare, 38
- Magnesium
for preterm labor, 561
as uterine relaxant, 80–81
- Magnesium sulfate (MgSO₄)
anesthesia with, 1148
for preeclampsia, 671–672, 672t
for preterm labor, 565–566
and cerebral palsy, 1216
- Magnetic resonance arteriography (MRA), for pulmonary embolus, 860, 861f, 862
- Magnetic resonance imaging (MRI)
of adnexal masses, 1141
of appendicitis, 1047, 1047t
of breast cancer, 892
of hypoxic-ischemic encephalopathy, 1211
of perinatal stroke, 1213f, 1214
- Magnetic resonance (MR) venography, of deep venous thrombosis, 857
- Major depressive disorder
diagnostic criteria for, 1113, 1115t
epidemiology of, 1113
identification of, 1114
impact on pregnancy outcomes of, 1116
treatment of
clinical approach to, 1118–1119
dosage for, 1117t
during lactation, 1119–1120
perinatal complications of, 1119
risks of, 1117–1118
- Malalignment ventricular septal defects, 324, 324f

 anesthesia with, 1154–1155
 hemodynamics of, 1170–1171
- Mitral valve, fetal echocardiography of, 313
- Mitral valve prolapse (MVP), maternal, 812, 812f
 anesthesia with, 1156
- Mixed acidemia, 401, 401t
- Mixed venous oxygen saturation (SVO₂), 929
- Mixed venous oxygen tension, 929
- Mixed venous oxygenation, 929
- MLCK (myosin light-chain kinase)
 in myometrial contraction, 78
 in tocolysis, 562
- MMC (myelomeningocele), invasive fetal therapy
 for, 277t, 445–447, 447t
- MMIHS (megacystis-microcolon-intestinal
 hypoperistalsis syndrome), 296
- M-mode analysis, of fetal arrhythmias, 337, 337f
- MMPs (matrix metalloproteinases)
 in implantation, 113t
 in membrane rupture, 599
 in preterm labor, 523, 528
- MNS antigens, 478f, 495t, 497–498, 497t
- MODY (maturity-onset diabetes of the young),
 955
- Molar pregnancy, 42, 891
 hyperthyroidism due to, 1005
 and preeclampsia, 654
- Molecular cytogenetics, 12–14, 13f, 14f
- Molluscum fibrosum gravidarum, 1124
- Mometasone, for asthma, 941t
- MOMS (Management of Myelomeningocele
 study), 446
- Monilial vaginitis, 739–741, 740t
- Monoamine oxidase, in fetal heart, 163
- Monoamine oxidase inhibitors (MAOIs), dosage
 of, 1117t
- Monoamniotic twins, 57, 58, 59f, 60, 61, 466–
 467, 466f
- Monochorionic twins, 57, 57f, 58, 60
 acardiac, 65f
 antenatal diagnosis of, 455–456, 456t
 diamniotic, 58, 58f, 60–61, 61f, 62f
- Monochorionic twins (*Continued*)
 intrauterine demise of one fetus with, 469
 invasive fetal therapy with, 436–440, 436f, 438f,
 439t
 monoamniotic, 60
 selective termination with, 470
 twin-to-twin transfusion syndrome with, 62f,
 63f
- Monocyte(s), during pregnancy, 90
- Monocyte chemiluminescence test, for RhD
 antibody, 481
- Monocyte chemoattractant protein-1 (MCP-1),
 73
- Monocyte monolayer assay, for RhD antibody,
 481
- 5'-Monodeiodination, in normal thyroid
 physiology, 995, 996f
- Monogenic disorders, preimplantation genetic
 screening for, 160
- Monoiodotyrosine, in normal thyroid physiology,
 995
- Mononeuropathies
 peripheral, 1104–1107, 1106f
 traumatic, 1106
- Monosomy, 15, 17, 18f
- Monozygotic (MZ) twins, 55
 causes of, 56, 57f
 frequency of, 55–56
 heterokaryotic, 66
 identification of, 66–67
 placentation of, 57, 58, 58f
- Montelukast (Singulair), for asthma, 940t, 942
- Montgomery glands, 129, 129f
- Mood disorders, 1113–1120
 diagnostic criteria for, 1113, 1114t, 1115t
 epidemiology of, 1113
 identification of, 1113–1114
 impact on pregnancy outcomes of, 1114,
 1115–1116
 symptoms of, 1114t
 treatment of, 1116–1120
 clinical approach to, 1118–1119
 dosage for, 1116t, 1117t
 during lactation, 1119–1120
 perinatal complications of, 1119
 risks of, 1116–1118
- Mood stabilizers
 clinical approach to, 1119
 dosage of, 1116t
 during lactation, 1119–1120
 perinatal complications of, 1119
 risks of, 1116–1117
- Morning sickness, 1042
- Morphine sulfate, for prolonged latent phase, 694
- Mortality Prediction Model (MPM), 1167
- Morula, 37, 38f
- Mosaic results
 of amniocentesis, 249
 of chorionic villus sampling, 254–255
- Mosaicism
 in amniocentesis, 249
 confined placental, 254–255
- Motor vehicle accidents, 1184–1186, 1185f
- Movement(s), fetal, 172, 173f, 175, 177, 361
 in biophysical profile score, 365t, 366
 counting of, 383, 383t
- Movement disorders, 1102
- MPM (Mortality Prediction Model), 1167
- MR (magnetic resonance) venography, of deep
 venous thrombosis, 857
- MRA (magnetic resonance arteriography), for
 pulmonary embolus, 860, 861f, 862
- MRI. *See* Magnetic resonance imaging (MRI).
- mRNA (messenger RNA), 5, 5f
- MSAFP. *See* Maternal serum α -fetoprotein
 (MSAFP).
- MTD (*Mycobacterium tuberculosis* Direct) Test,
 935
- mtDNA (mitochondrial DNA), in developmental
 origins of health and disease, 154
- MTHFR (methylene tetrahydrofolate reductase)
 gene mutations, 833–834
- MTP (mitochondrial trifunctional protein), 1062
- Mucopolidiosis type IV, carrier screening for, 242t
- Mueller-Hillis maneuver, 697
- Müllerian duct fusion anomalies
 cervical insufficiency due to, 586
 pregnancy loss due to, 622, 622t
 and preterm birth, 557
- Multicolor karyotyping, 13–14, 14f
- Multicystic dysplastic kidney (MDK), 295, 295f
- Multifactorial inheritance, 25–29, 27t, 28t
- Multifetal gestation. *See* Multiple gestation.
- Multifetal pregnancy reduction (MFPR), 470–
 471, 471t
- Multiorgan injury, due to hypoxic-ischemic
 encephalopathy, 1210
- Multiple gestation, 55–67, 453–471
 abnormalities of, 64–66, 64f–66f
 acardiac twin in, 64–65, 65f, 66f, 467–468
 invasive fetal therapy for, 434t, 468
 amniocentesis in, 257–258, 258t, 459
 aneuploidy in, 256, 256t, 458–459, 458t
 antepartum management of, 459–461
 birth weight with, 454
 breastfeeding after, 134
 causes of, 56, 57f
 and cerebral palsy, 1215
 cervical length in, 457, 460
 chimeras in, 66
 chorionic villus sampling with, 258, 258t, 459
 chorionicity of, 57, 57f–60f, 58, 455f, 454–456
 conjoined, 57, 60, 468–469, 468f
 diagnosis of, 455
 diamniotic, 57, 57f, 58
 acardiac, 65f
 dichorionic, 57–58, 58f, 59f
 monochorionic, 58, 58f, 60–61, 61f, 62f
 twin-to-twin transfusion syndrome with, 63f
 dichorionic, 57, 57f–59f, 58
 diagnosis of, 455–456, 456f
 selective termination with, 470
 disappearance of twin in, 66
 dizygotic, 55
 causes of, 56
 frequency of, 56
 identification of, 66–67
 placentation of, 57–58, 58f, 59f
 Down syndrome in, 256, 256t, 257, 257t, 458–
 459, 458t
 fetal anomalies in, 456, 457–459, 458t
 fetal growth in, 456–457
 fetal loss with, 625
 fetal pulmonary maturity in, 421, 461
 fetal surveillance in, 457, 461
 fetal well-being in, 457
 fraternal, 55
 higher-order
 labor and delivery with, 463
 pregnancy reduction with, 470–471, 471t
 identical, 55
 incidence of, 55, 453, 454t
 intrapartum management of, 461–463
 intrauterine demise of one fetus in, 469
 intrauterine growth restriction due to, 639
 maternal adaptations to, 454–455
 maternal complications of, 461
 maternal mortality and morbidity with, 454

- Multiple gestation (*Continued*)
 membranous, 64, 64f, 65f
 monoamniotic, 57, 58, 59f, 60, 61, 466–467, 466f
 monochorionic, 57, 57f, 58, 60f
 acardiac, 65f
 antenatal diagnosis of, 455–456, 456t
 diamniotic, 58, 58f, 60–61, 61f, 62f
 intrauterine demise of one fetus with, 469
 invasive fetal therapy with, 436–440, 436t, 438f, 439t
 monoamniotic, 60
 selective termination with, 470
 twin-to-twin transfusion syndrome with, 62f, 63f
- monozygotic, 55
 causes of, 56, 57f
 frequency of, 55–56
 heterokaryotic, 66
 identification of, 66–67
 placentation of, 57, 58, 58f
 neonatal outcomes with, 1198
 neural tube defects with, 459
 nutrition with, 148
 perinatal mortality and morbidity with, 453–454, 454f, 461
 placentation in, 57–61, 57f–60f
 preeclampsia with, 460–461, 654
 pregnancy reduction with, 470–471, 471t
 prenatal diagnosis with, 256–258, 256t–258t
 preterm labor and birth with
 interventions for, 460
 pathogenesis of, 529–531, 531f, 558
 rates of, 460, 546, 547f, 558, 559f, 559t
 selective termination of anomalous fetus in, 469–470
 twin reversed arterial perfusion sequence in, 64–65, 65f, 66f, 467–468
 twin-to-twin transfusion syndrome in, 61–64, 61f–63f, 463–466, 463f
 types of, 55–56
 ultrasonography of, 455–457, 456f, 456t
 velamentous insertion of umbilical cord and vasa praevia in, 59, 60f
 zygosity in, 66–67, 67f
- Multiple sclerosis, 1102–1103
 anesthesia with, 1149
- Multivariable analysis, 213
- Multivitamins
 for nausea and vomiting, 1042
 during pregnancy, 146, 146t
- Mumps, 773–774
 Mumps vaccine, 774
- Muscle biopsy, fetal, 259
- Muscle disorders, 1109
- Muscular dystrophy, prenatal diagnosis of, 248t
- Muscular ventricular septal defects, 323, 323f
- Musculoskeletal development, fetal, 177
- Mutation(s), 5–6, 6f, 6t
 dynamic, 29–30
 new, 24
 silent, 5f
- MVP (mitral valve prolapse), maternal, 812, 812f
 anesthesia with, 1156
- Myasthenia gravis, 1108–1109
 neonatal outcomes with, 1198
- Mycobacterium avium-intracellulare*, with HIV infection, 771
- Mycobacterium tuberculosis*. See Tuberculosis.
- Mycobacterium tuberculosis* Direct (MTD) Test, 935
- Mycoplasma hominis*
 breastfeeding with, 136t
 and bronchopulmonary dysplasia, 1205
- Mycoplasma pneumoniae*, pneumonia due to, 931
- Myelomeningocele (MMC), invasive fetal therapy for, 277t, 445–447, 447t
- Myocardial function, fetal, 162–164
- Myocardial infarction (MI), 817
- Myocardial ischemia, 816–817
- Myocarditis
 with HIV infection, 816
 hydrops fetalis due to, 509
- Myocardium, fetal, 163
- Myomas. See Uterine leiomyomas.
- Myomectomy
 cesarean, 1039
 hysteroscopic, 1039
 laparoscopic, 1039
 laparotomic, 1039
 during pregnancy, 1138–1139
 pregnancy after, 1039
- Myometrial contractions, 76–82
 defined, 522
 in diagnosis, 70
 effectiveness of, 522
 fetal heart rate with, 410f, 411t
 hormonal regulation of, 79–81, 79f, 80t
 during labor, 522–523
 measurement of, 399
 mechanics of, 76–79, 78f
 in pregnancy, 691
 and preterm birth, 558, 560
 regulation of electrical activity in, 76, 77f
- Myometrial differentiation, 79
- Myometrial hyperplasia, 69
- Myometrial remodeling, in pregnancy, 522
- Myometrial stretch, preterm labor due to, 529–531, 531f
- Myometrium, regulation of electrical activity within, 76, 77f
- Myonecrosis, at episiotomy incision site, 760
- Myosin, in myometrial contraction, 76
- Myosin head, in myometrial contraction, 76–78, 78f
- Myosin light-chain kinase (MLCK)
 in myometrial contraction, 78
 in tocolysis, 562
- Myosin-actin crossbridge, in myometrial contraction, 78f
- Myotonia congenita, 1109
- Myotonic dystrophy, 1109
 autosomal dominant, 30
 prenatal diagnosis of, 248t
- MZ twins. See Monozygotic (MZ) twins.
- N
- N antigen, 498
- NAATs (nucleic acid amplification tests)
 for *Chlamydia trachomatis*, 747
 for gonorrhea, 744, 745
- Nabumetone, for rheumatic disease, 1082t
- NAEPP (National Asthma Education and Prevention Program), 938, 941, 942, 943
- Nafcillin
 for mastitis, 764
 for wound infection, 761
- Nail changes, in pregnancy, 1124
- NAIT (neonatal alloimmune thrombocytopenia), 840–842, 840t
- Naproxen, for rheumatic disease, 1082t
- Narcosis, therapeutic, for prolonged latent phase, 694
- Narcotic analgesics, for labor and delivery, 715
- Nasal anomalies, 285
- Nasal bone (NB), in Down syndrome, 225, 230–231, 231f, 232
- Nasal bone (NB) contingency screening, for Down syndrome, 232
- Nasal tolerance, to RhD antigen, 495
- National Asthma Education and Prevention Program (NAEPP), 938, 941, 942, 943

- Natural immunity, 87
 in pregnancy, 90–92, 91f
- Natural killer (NK) cells
 during pregnancy, 90
 and pregnancy loss, 621
- Nausea and vomiting, 1041–1042, 1042t
 nutrition with, 148
- Navane (thiothixene), dosage of, 1116t
- NB (nasal bone), in Down syndrome, 225, 230–231, 231f, 232
- NB (nasal bone) contingency screening, for Down syndrome, 232
- Necrotizing enterocolitis (NEC), 1207–1208, 1208f
 feeding problems due to, 1210
 prematurity and, 1201t
- Necrotizing fasciitis
 due to abdominal wound infection, 761–762
 at episiotomy incision site, 760
- Negative predictive value (NPV), 214–215, 215t, 221
- Neisseria gonorrhoeae*. See Gonorrhea.
- Nelfinavir (Viracept), for HIV infection, 772t
- Nelson syndrome, 1022
- Neomorphic allele, 6
- Neonatal abstinence syndrome, 1199
- Neonatal alloimmune thrombocytopenia (NAIT), 840–842, 840t
- Neonatal behavior, transition from fetal to, 362
- Neonatal complications
 of cesarean delivery, 710
 of diabetes, 967–968, 968f, 986
 of intrauterine growth restriction, 646
 of placenta previa, 729
 after premature rupture of the membranes, 601
 of renal transplantation, 920
- Neonatal encephalopathy, 1210
- Neonatal gonococcal ophthalmia, 744
- Neonatal lupus syndrome, 1081
- Neonatal management decisions, 1197
- Neonatal morbidity and mortality
 with alloimmune hemolytic disorders, 1199
 with chorioamnionitis, 1197–1198
 with congenital malformations, 1198–1199
 with diabetes, 967–968, 968f, 986, 1197
 excessive weight gain and, 145
 with maternal autoimmune disease, 1198
 with maternal malnutrition, 1198
 with maternal medications, 1199
 with multifetal gestation, 1198
 with preeclampsia, 1198
 with substance abuse, 1199
- Neonatal outcomes, common morbidities of pregnancy and, 1197–1199, 1198t
- Neonatal period
 gastrointestinal problem(s) in, 1207–1210
 feeding problems as, 1209–1210
 hyperbilirubinemia as, 1208–1209, 1209t
 necrotizing enterocolitis as, 1207–1208, 1208f

- Neonatal period (*Continued*)
infectious disease(s) in, 1217–1220
 chorioamnionitis as, 1217
 with group B β -hemolytic streptococci, 1217
 sexually transmitted, 1219–1220
 viral, 1217–1219
neurologic problem(s) in, 1210–1217
 cerebral palsy as, 1214–1217, 1214t
 hypoxic-ischemic encephalopathy as, 1210–1211
 intraventricular hemorrhage as, 1211–1212
 perinatal stroke as, 1213–1214, 1213f
 periventricular leukomalacia as, 1212
respiratory problem(s) in, 1202–1207
 bronchopulmonary dysplasia as, 1205–1206, 1206f, 1206t
 meconium aspiration syndrome as, 1206–1207
 pulmonary hypertension as, 1207
 pulmonary hypoplasia as, 1203–1204
 respiratory distress syndrome as, 1203f, 1204–1205
 transient tachypnea of the newborn as, 1202–1203, 1203f
- Neonatal resuscitation, at limits of viability, 1202
- Nephritis
 hereditary, 912
 lupus, 914, 916t
- Nephropathy
 diabetic, 913–914, 959–961
 categories of, 959, 959t
 course during pregnancy of, 916t, 959–960, 960f
 effect of pregnancy on progression of, 959, 959f
 epidemiology of, 959
 pathophysiology of, 959
 renal dialysis for, 960
 renal transplantation for, 960–961
 HIV-associated, 915
 IgA, 916t
 reflux, 913, 916t

 with preterm birth, 548–551, 549f–552f, 553t, 1199, 1200f
 uterine myomas and, 1137
 Perinatal stroke, 1213–1214, 1213f
 Periodic fetal heart rate patterns, 405, 407, 408–410, 409f–411f
 Peridontal disease, and preterm birth, 556, 568
 Peripartum cardiomyopathy, 814–815
 Peripheral entrapment neuropathies, 1104–1107, 1106f
 Peripheral mononeuropathies, 1104–1107, 1106f
 Peritoneal dialysis, 917–918
 Periventricular leukomalacia (PVL), 1212
 chorioamnionitis and, 758–759, 758t
 Peroneal nerve palsy, 1105, 1106
 Persistent left-sided superior vena cava, 318–320, 319f, 320f
 Persistent umbilical vein, 318, 319f
 Persistent vegetative state, 1189–1190, 1189t
 Pessaries, for cervical insufficiency, 589
 PET (positron emission tomography), of Hodgkin lymphoma, 897
 PG. *See* Phosphatidylglycerol (PG).
 PGD₂ (prostaglandin D₂), in control of labor, 74
 PGDH (prostaglandin dehydrogenase), in control of labor, 72
 PGE₁. *See* Prostaglandin E₁ (PGE₁).
 PGE₂. *See* Prostaglandin E₂ (PGE₂).
 PGF_{2α} (prostaglandin F_{2α})
 in control of labor, 74
 for postpartum hemorrhage, 698–699
 PGH (placental growth hormone), in pregnancy, 120f
 PGH₂ (prostaglandin H₂), in control of labor, 74
 PGHS (prostaglandin H synthase), in control of labor, 72
 PGHS (prostaglandin H₂ synthase), in control of labor, 74–75
 PGL₂ (prostaglandin I₂)
 in control of labor, 74
 in fetal cardiovascular regulation, 166
 PGM (prothrombin gene mutation), 831t, 833
 and venous thromboembolism, 856t
 PGS (preimplantation genetic screening), 259–261
 pH
 defined, 401t
 fetal blood, 162, 162t, 386, 386t
 determination of, 400–401
 in labor, 402t
 during pregnancy, 1173, 1173t
 umbilical cord, 402–403, 403t
 Phagocytic cells, in immune response, 87
 Phalen maneuver, 1105
 Pharyngeal gonorrhoea, 744
 Phenobarbital
 for hemolytic disease of the fetus and newborn, 494–495
 for preterm labor, 561
 Phenocopy, 25
 Phenolsulfophthalein, excretion of, in preeclampsia, 664
 Phenothiazines, for nausea and vomiting, 1042, 1042t
 Phenotype, 22
 Phenoxybenzamine, for pheochromocytoma, 1030
 Phentolamine, for pheochromocytoma, 1030
 Phenylephrine, for septic shock, 1178t
 Phenylketonuria (PKU), 1101–1102
 prenatal diagnosis of, 248t
 Phenytoin
 for preeclampsia, 672
 as teratogen, 348, 351t, 352, 1091
 Pheochromocytoma, 679, 1030–1031, 1031t
 Phosphates, for hypercalcemia, 1034, 1034t
 Phosphatidylcholine, in surfactant, 197, 197f
 metabolism of, 199f, 200
 Phosphatidylglycerol (PG)
 in amniotic fluid, 419
 in diabetic pregnancy, 421, 967, 968f
 impact of contaminants on, 422, 422t
 in surfactant, 197, 197f
 metabolism of, 199f, 200
 in vaginal fluid specimens, 423
 Phosphatidylinositol (PI)
 in amniotic fluid, 419
 in diabetic pregnancy, 421
 in vaginal fluid specimens, 423
 Phosphatidylinositol glycan class A (PIGA) gene, 876
 Phospholipase A₂ (PLA₂), in control of labor, 74
 Phospholipids
 in amniotic fluid, 419
 in surfactant, 197, 197f
 metabolism of, 199–200, 199f
 Phospho-soda, for hypercalcemia, 1034t
 Physical activity, and preterm birth, 555, 569
 Phytohemagglutinin, 11
 PI (phosphatidylinositol)
 in amniotic fluid, 419
 in diabetic pregnancy, 421
 in vaginal fluid specimens, 423
 Pica, due to iron deficiency anemia, 873
 Pierre Robin syndrome, 285
 PIGA (phosphatidylinositol glycan class A) gene, 876
 Pigmentary changes, in pregnancy, 1123
 Pinopodes, 619
 PIOPED (Prospective Investigation of Pulmonary Embolism Diagnosis), 860
 Piperacillin-tazobactam
 for acute pyelonephritis, 756t
 for puerperal endometritis, 760
 for septic shock, 763
 Pitocin. *See* Oxytocin (Pitocin).

 - laboratory considerations for, 249–250
 - with multiple gestation, 257–258, 258t, 459
 - pregnancy lost after, 250–251, 250t
 - technique of, 247–249, 248f
 - biopsies for, 259
 - chorionic villus sampling for, 251–256

- Prenatal diagnosis (*Continued*)
 accuracy of, 253–255
 amniocentesis vs., 258–259
 complications of, 255–256
 history of, 251–252
 laboratory aspects of, 253
 with multiple gestation, 258, 258t
 pregnancy loss after, 255
 risk of fetal abnormality after, 256
 transabdominal, 252–253, 253f
 transcervical, 252, 252f, 253
 of fragile X syndrome, 246
 indication(s) for, 246–247, 247t, 248t
 maternal age as, 232–233, 233t
 with multiple gestation, 256–258, 256t–258t
 of neural tube defects, 235, 236f
 noninvasive, 261–263
 percutaneous umbilical blood sampling for, 259
 for Tay-Sachs disease, 241
 for β -thalassemia, 244–245
- Prenatal screening, 221–246
 for acetylcholinesterase, 234–235, 234t
 cutoff values in, 221, 222t
 for Down syndrome, 222–233
 ADAM 12 in, 230
 combined first- and second-trimester, 232
 cutoff values in, 222t
 ductus venosus wave form in, 231
 first-trimester
 impact of spontaneous miscarriages on, 231–232
 serum markers in, 229–230, 230t
 ultrasound markers in, 227–229, 230–231, 230t, 231f
 human chorionic gonadotropin in, 229–230
 likelihood ratios in, 221–222, 222t, 225, 226, 226t
 maternal age in, 222, 222t, 232–233, 233t
 nasal bone in, 225, 230–231, 231f, 232
 nuchal translucency in, 228, 230
 PAPP-A in, 229
 in twins, 257, 459
 receiver operating curve in, 222f
 second-trimester
 serum markers in, 222–225, 224t, 226
 ultrasound markers in, 225–226, 225t, 226t
 serum markers in
 first-trimester, 229–230, 230t
 second-trimester, 222–225, 224t, 226
 tricuspid regurgitation in, 231
 ultrasound markers in
 first-trimester, 227–229, 230–231, 230t, 231f
 second-trimester, 225–226, 225t, 226t
 first-trimester
 impact of spontaneous miscarriages on, 231–232
 serum markers in, 229–230, 230t
 with twins, 257, 459
 ultrasound markers in, 227–229, 228f, 228t, 229f, 230–231, 231f
 for gene mutations, 238–246
 in cystic fibrosis, 238–240, 238t–240t, 242t
 in fragile X syndrome, 245–246, 246t
 in hemoglobinopathies, 238t, 243–245, 244t
 informed consent for, 238
 in Jewish population, 238t, 240–243, 241t, 242t
 recommendations on, 238, 238t
 goal of, 238
 for human chorionic gonadotropin, 223, 224, 229–230
 in twins, 257, 257t, 458, 459
- Prenatal screening (*Continued*)
 ideal test for, 221
 likelihood ratios in, 221–222, 222t, 225, 226, 226t
 maternal age as indication for, 222, 222t, 232–233, 233t
 for maternal serum α -fetoprotein, 223, 224, 224t, 233–235, 234t
 in twins, 257, 257t, 458, 459
 with multiple gestation, 256–257, 256t, 257t, 458, 459
 for neural tube defects, 233–235, 234t, 236f
 in twins, 257, 459
 for pregnancy-associated plasma protein A, 229
 receiver operating curve in, 221, 222f
 second-trimester
 serum markers in, 223–224, 224t, 226
 with twins, 256–257, 257t, 458–459
 ultrasound markers in, 225–227, 225t–228t
 value of, 236–237, 237t
 sensitivity and specificity of, 221
 serum markers in
 first-trimester, 229–230, 230t
 with twins, 257, 459
 second-trimester, 223–224, 224t, 226
 with twins, 256–257, 257t, 458
 for twins, 256–257, 256t, 257t, 458–459
 ultrasound markers in
 first-trimester, 227–229, 228f, 228t, 229f, 230–231, 231f
 second-trimester, 225–227, 225t–228t
 value of, 236–237, 237t
- Prepidil (dinoprostone)
 for cervical ripening, 702t, 703t
 for post-term pregnancy, 615, 616
 for uterine atony, 1183t
- Preprandial glucose levels, 975t, 978–979
- Presentation(s), abnormal, 703–707
 breech as, 703–706, 705t
 compound, 707
 deflection abnormalities as, 706–707
 transverse lie as, 706
 uterine anomalies and, 1144
 uterine myomas and, 1137
- Preterm and growth-restricted neonates, defined, 635
- Preterm labor and birth, 545–573. *See also* Prematurity.
 antidepressants and, 1118
 body mass index and, 144
 and cerebral palsy, 552, 1214–1215, 1216–1217
 cigarette smoking and, 356, 356f
 clinical presentations of, 547–548
 in common pathway of parturition, 521–524, 522f, 524f
 complications of, 1199–1200, 1199t, 1201f, 1201t
 consequence(s) of, 548–552, 549f–554f, 553t
 long-term, 551–552, 553f, 554f
 perinatal and infant mortality as, 548–551, 549f–552f, 1199, 1200f
 perinatal morbidity as, 551, 552f, 553t
 defined, 521, 545
 diagnosis of, 560–561
 incidence of, 521, 545–546, 546f, 547f
 indicated, 521, 545, 548, 548f, 569
 infant morbidity and mortality with, 1199, 1200f
 interventional strategy(ies) for, 560–567
 after acute treatment, 567
 antenatal corticosteroids as, 561
 antibiotics as, 561
 neuroprotectants as, 561
- Preterm labor and birth (*Continued*)
 primary, 560
 to reduce morbidity and mortality, 561
 regionalization of care as, 561
 secondary, 560
 tertiary, 560
 tocolytic therapy as, 561–567
 calcium channel blockers for, 562–563
 choice of agent for, 562
 clinical uses of, 566–567
 contraindications to, 561
 cyclooxygenase inhibitors for, 563–564
 goals of, 561–562
 magnesium sulfate for, 565–566
 nitric oxide donors for, 564–565
 oxytocin antagonists for, 564
 β -sympathomimetic drugs as, 566
 and low birth weight, 545–546
 with multiple gestation
 interventions for, 460
 pathogenesis of, 529–531, 531f, 558
 rates of, 460, 546, 547f, 558, 559f, 559t
 pathogenesis of, 521–532
 allergic phenomena in, 531
 cervical disorders in, 531
 genetic factors in, 70
 hormonal disorders in, 531–532
 infection and inflammation in, 524–527, 525f, 526f, 528f
 maternal and fetal stress in, 529, 530f
 mechanisms of, 521–524, 522f, 524f
 uterine overdistention in, 529–531, 531f
 uteroplacental vascular disease and decidual hemorrhage in, 527–529, 529f
 prevention of, 567–573
 antibiotics for, 570
 cervical cerclage for, 568–569, 571–572
 cervical examination for, 568–569
 with clinical risk factors, 569–573, 570t, 571f
 modification of maternal activity for, 569
 nutritional supplements for, 567–568, 569, 570t, 572
 periodontal care for, 568
 before pregnancy, 572–573
 progestational agents for, 570–571, 570t, 571f
 in routine prenatal care, 567–569
 screening for, 568–569
 smoking cessation for, 568, 572
 recurrence of, 556–557, 557t, 572
 risk factor(s) for, 552–560
 assisted reproductive technologies as, 558
 asymptomatic bacteriuria as, 568, 751
 bleeding as, 558
 cervical length as, 558–560, 559f, 560f
 cervical surgery as, 557–558
 current pregnancy characteristics as, 558–560, 559f, 559t, 560f
 educational and economic status as, 554, 554t
 familial, 553
 infections as, 556
 maternal behaviors and environment as, 554–555
 maternal characteristics as, 553–556, 554t, 555f
 multiple gestation as, 558, 559f, 559t
 nutritional status as, 555–556, 555f
 physical activity as, 555, 569
 pregnancy termination as, 557
 prior preterm birth as, 556–557, 557t
 psychological, 555
 race and ethnic background as, 551, 552f, 554, 554t, 555f, 557

- Preterm labor and birth (*Continued*)
 reproductive history as, 556–558, 557t
 scoring of, 568
 uterine anomalies as, 557
 uterine contractions as, 558
 uterine volume as, 558
 spontaneous, 521, 545, 548, 548f
 prevention of, 569–572, 570t, 571f
 as syndrome, 524, 525f
 with uterine anomalies, 1144t
 uterine myomas and, 1136, 1136t
 and viability, 521
- Preterm lung, physiologic effects of surfactant on, 200–202, 201f
- Preterm neonates, defined, 635
- Preterm premature rupture of the membranes (pPROM)
 with cervical cerclage, 594, 606–607
 early, 601, 603f, 604–607
 epidemiology of, 600
 due to fetal inflammatory response syndrome, 527, 528f
 and fetal pulmonary maturity, 423, 601
 after fetoscopic procedures, 435, 435t
 late, 603f, 604
 management of, 602–607, 603f
 antibiotics for, 209, 209f, 210f, 604, 605–606
 corticosteroids for, 604, 605
 initial evaluation in, 602
 tocolysis for, 606
 due to maternal herpes infection, 607
 due to microbial invasion of the amniotic cavity, 525
 prediction and prevention of, 600
 previsible, 601, 603f, 607
 risk factors for, 599–600
 due to uteroplacental vascular disease or decidual hemorrhage, 527–529, 529f
- Pretest odds, 215
- Previsible premature rupture of the membranes, 601, 603f, 607
- Prezista (darunavir), for HIV infection, 772t
- Primary biliary cirrhosis, 1069
- Primary Care Evaluation of Mental Disorders (PRIME-MD), 1114
- Primary immune thrombocytopenic purpura, 837–840
- Primary pulmonary hypertension, maternal, 805
 anesthesia with, 1158
- Primary sclerosing cholangitis (PSC), 1070
- Probability value, 212
- Probenecid, for gonorrhea, 745
- Procainamide, during pregnancy, 801t
- Procaine penicillin, for syphilis, 781t
- Professional policies, for preterm birth prevention, 572
- Progestational agents, for preterm birth prevention, 570–571, 570t, 571f
- Progesterone
 as anti-inflammatory agent, 73
 in cervical remodeling, 523
 constipation due to, 1052
 in control of labor, 73–74
 and cortisol, 73–74
 and fetal loss, 620–621, 628, 628t
 and fetoplacental unit, 115
 and hyperventilation of pregnancy, 927
 in implantation, 111
 in pregnancy, 114–115, 114f, 115f, 117
 for prevention of preterm labor and birth, 570–571, 570t, 571f
 with multiple gestation, 460
 suspension of action of, preterm labor due to, 531–532
- Progesterone blockade, 73
- Progesterone dermatitis, autoimmune, 1125
- Progesterone receptor A (PR-A), 73
- Progesterone receptor (PR) antagonist, 73
- Progesterone receptor B (PR-B), 73
- Progesterone receptor (PR) cofactors, 73
- Progestins
 during pregnancy, 117
 for preterm labor, 532
- Proinflammatory cytokines, in preterm labor and birth, 526–527, 526f, 556
- Prolactin
 in breastfeeding, 131, 132f
 and fetal loss, 621
 neurohormonal control of, 1015
 during pregnancy, 121–122, 121f, 1015, 1017f
- Prolactinoma, 1018–1020, 1019f, 1020f, 1020t
- Proapsed intervertebral disk, 1104
- Proliferative phase, of myometrial remodeling, 522
- Prolonged deceleration, in fetal heart rate, 406
- Prolonged latent phase, 694–695
- Prolonged pregnancy. *See* Post-term pregnancy.
- PROM. *See* Premature rupture of the membranes (PROM).
- Promethazine
 for hemolytic disease of the fetus and newborn, 494
 for hyperemesis gravidarum, 1043
- Promoter sequences, 5
- Promotility drugs, for GERD, 1044, 1045f
- Prone ventilation, for acute respiratory distress syndrome, 1174
- Pronucleus, 11f
- Pro-opiomelanocortin (POMC), 1025
- Propafenone, during pregnancy, 801t
- Prophase, 7–8, 7f
- Propranolol
 for chronic hypertension, 678t
 for thyroid storm, 1003, 1003t
- Propylthiouracil (PTU), for thyroid storm, 1003, 1003t
- Prospective cohort study, 208
- Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED), 860
- Prostacyclin, in preeclampsia, 663
- Prostaglandin(s)
 for cervical ripening, 702t
 in control of labor, 74–75, 75f
 in fetal cardiovascular regulation, 166
 in fetal heart rate, 398
 for induction, with multiple gestation, 461
 in labor and delivery, 523–524, 524f
 and patent ductus arteriosus, 167
 during pregnancy, 122
 in preterm labor and birth, 526f, 556
 as uterine stimulants, 80
- Prostaglandin 15-methyl F_{2α} (Hemabate), for uterine atony, 1183t
- Prostaglandin D₂ (PGD₂), in control of labor, 74
- Prostaglandin dehydrogenase (PGDH), in control of labor, 72
- Prostaglandin E₁ (PGE₁)
 for cervical ripening, 702–703, 702t, 703t
 for fetal demise, 627–628
 for postpartum hemorrhage, 699
 for post-term pregnancy, 616
 for uterine atony, 1183t
- Prostaglandin E₂ (PGE₂)
 for cervical ripening, 702t, 703t
 in control of labor, 74
 in fetal cardiovascular regulation, 166
 and nausea and vomiting, 1042
- Prostaglandin E₂ (PGE₂) (*Continued*)
 and patent ductus arteriosus, 167
 for post-term pregnancy, 615, 616
 for uterine atony, 1183t
- Prostaglandin F_{2α} (PGF_{2α})
 in control of labor, 74
 for postpartum hemorrhage, 698–699
- Prostaglandin H synthase (PGHS), in control of labor, 72
- Prostaglandin H₂ (PGH₂), in control of labor, 74
- Prostaglandin H₂ synthase (PGHS), in control of labor, 74–75
- Prostaglandin I₂ (PGI₂)
 in control of labor, 74
 in fetal cardiovascular regulation, 166
- Prostaglandin induction, after premature rupture of the membranes, 604
- Prostaglandin inhibitors, for cervical insufficiency, 589
- Prostaglandin synthesis inhibitors
 for preterm labor, 563–564
 as uterine relaxants, 81
- Prosthetic heart valve, pregnancy with, 819–820, 820t, 864
- Protease inhibitors, for HIV infection, 772t
- Protease-activated receptor type 1 (PAR-1), in preterm labor, 528
- Protein(s)
 in diet, 147
 serum, 1059
 in surfactant, 198
- Protein C (PC)
 activated
 in anticoagulant system, 828, 828f
 for septic shock, 763, 1179
 in anticoagulant system, 828, 828f
- Protein C (PC) deficiency, 831t, 834
 and fetal loss, 625, 625t, 626t, 834–835
 and venous thromboembolism, 856t
- Protein hormones, in placental tissues, 117t
- Protein S (PS) deficiency, 831t, 834–835
 and fetal loss, 625, 625t, 626t, 834–835
 and venous thromboembolism, 856t
- Protein synthesis, 5, 5f
- Protein Z (PZ), in anticoagulant system, 828, 828f
- Protein Z (PZ) antigen, and fetal loss, 625t
- Protein Z (PZ) deficiency, 835
- Protein Z–dependent protease inhibitor (ZPI), in anticoagulant system, 828, 828f
- Protein Z–dependent protease inhibitor (ZPI) deficiency, 835
- Proteinuria
 defined, 651
 in preeclampsia, 657, 664, 670
- Prothrombin G20201A, 833
 and fetal loss, 625, 625t, 626t, 833
- Prothrombin gene mutation (PGM), 831t, 833
 and venous thromboembolism, 856t
- Prothrombin time, in abruptio placentae, 733t
- Prothrombotic state, pregnancy as, 855
- Proton pump inhibitors
 for GERD, 1044–1045, 1044t, 1045f
 for peptic ulcer disease, 1046
- Protraction disorders, 695
- Protriptyline (Vivactil), dosage of, 1117t
- PROWESS (Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis) trial, 1179
- Prozac (fluoxetine), dosage of, 1117t
- PRRs (pattern recognition receptors), 87, 91, 92
 in preterm labor, 526
- Prurigo gestationis, 1125t, 1126–1127, 1127f
- Prurigo of pregnancy, 1125t, 1126–1127, 1127f

- Pruritic urticarial papules and plaques of pregnancy (PUPPP), 1125t, 1126, 1126f
- Pruritus
 gravidarum, 1125–1126, 1125t
 due to intrahepatic cholestasis of pregnancy, 1061, 1125
- PS (protein S) deficiency, 831t, 834–835
 and fetal loss, 625, 625t, 626t, 834–835
 and venous thromboembolism, 856t
- PSC (primary sclerosing cholangitis), 1070
- Pseudoglandular stage, of fetal lung development, 193, 194f, 194t
- Pseudohypoparathyroidism, 1035
- Pseudomosaicism, 249
- Pseudotumor cerebri, 1094–1095
- Pseudo–von Willebrand disease (pseudo–vWD), 843–845, 844t, 845t
- PSF (polypyrimidine tract binding protein–associated splicing factor), 73
- Psoriasis, 1132
 pustular, 1125t, 1129–1130, 1130f
- Psoriatic arthritis, 1085
- PSV (peak systolic velocity), in fetal middle cerebral artery, 374–375, 374f
- Psychiatric disorder(s), 1109–1110, 1113–1120
 diagnostic criteria for, 1113, 1114t, 1115t
 epidemiology of, 1113
 identification of, 1113–1114
 impact on pregnancy outcome of, 1114–1116
 treatment of, 1114–1120
 clinical approach to, 1118–1119
 dosage for, 1116t, 1117t
 during lactation, 1119–1120
 perinatal complications of, 1119
 risks of, 1116–1118
- Psychological factors, and preterm birth, 555
- Psychopharmacologic treatment
 clinical approach to, 1118–1119
 dosages for, 1116t, 1117t
 during lactation, 1119–1120
 perinatal complications of, 1119
 risks of, 1116–1118
 teratogenicity of, 351t, 353
- Psychosis
 diagnostic criteria for, 1113, 1114t, 1115t
 epidemiology of, 1113
 identification of, 1113–1114
 impact on pregnancy outcomes of, 1114–1115
 Korsakoff, 1107
 treatment of
 clinical approach to, 1118, 1119
 dosages for, 1116t
 during lactation, 1119–1120
 perinatal complications of, 1119
 risks of, 1116
- Psychotherapeutic medications
 clinical approach to, 1118–1119
 dosages for, 1116t, 1117t
 during lactation, 1119–1120
 perinatal complications of, 1119
 risks of, 1116–1118
 as teratogens, 351t, 353
- Psychotic symptoms, 1113, 1114t, 1115t
- Psychotropic medications
 clinical approach to, 1118–1119
 dosages for, 1116t, 1117t
 during lactation, 1119–1120
 perinatal complications of, 1119
 risks of, 1116–1118
 as teratogens, 351t, 353
- Psyllium, for constipation, 1052, 1052t
- PTH (parathyroid hormone), in calcium metabolism, 1032
- PTHrP (parathyroid hormone–related protein), 1032, 1032f, 1033f
 hypercalcemia due to increased production of, 1034
 as uterine relaxant, 80
- PTHrPR (parathyroid hormone–related protein receptor), in skeletal growth, 297
- PTU (propylthiouracil), for thyroid storm, 1003, 1003t
- Pubertal development, of breast, 127f, 128
- Public educational interventions, for preterm birth prevention, 572
- Public policies, for preterm birth prevention, 572
- PUBS (percutaneous umbilical blood sampling). *See* Cordocentesis.
- PUD (peptic ulcer disease), 1045–1046, 1045f
- Pudendal block, for labor and delivery, 716
- Puerperal endometritis, 760–761
 breastfeeding with, 136t
Chlamydia trachomatis and, 747
- Puerperal fever, 760–761
- PUFA (polyunsaturated fatty acids), for preterm birth prevention, 569, 570t
- Pulmonary arterial hypertension
 congenital diaphragmatic hernia and, 441–442
 hemodynamics of, 1171
- Pulmonary arteriography, for pulmonary embolus, 860–861, 862
- Pulmonary artery, fetal echocardiography of, 309, 309f, 314–315, 314f
- Pulmonary artery catheter (PAC), 1168
 complications of, 1169–1170, 1169t
 hemodynamic variables measured by, 1170, 1170t, 1171t
 indications for, 1169
 insertion of, 1168–1169
- Pulmonary atresia
 with intact ventricular septum, 328, 328f
 tetralogy of Fallot with, 332, 332f
- Pulmonary capillary wedge pressure (PCWP)
 central venous pressure and, 1170, 1170f
 with hypertension, 1172
 with mitral stenosis, 1171
 nonpregnant, 1171t
 during pregnancy, 103t, 1168, 1171t
- Pulmonary complications, of prematurity, 1199t
- Pulmonary edema, 1174–1175
 colloid osmotic pressure abnormalities and, 1174
 hydrostatic or cardiogenic, 1174–1175
 in preeclampsia, 674, 1175
 anesthetic considerations with, 1148
 tocolytic-induced, 1175
- Pulmonary embolus (PE)
 clinical findings with, 858–859
 diagnosis and evaluation of, 858–862, 859t, 861f
 epidemiology of, 855
 prevention of, 835–837, 864–865
 risk factors for, 855–856, 856t
 risk score for, 859, 859t
 treatment of, 862–864, 862t
- Pulmonary hypertension
 fetal, congenital diaphragmatic hernia and, 441–442
 maternal, 805
 anesthesia with, 1158
 hemodynamics of, 1171
 in neonatal period, 1207
- Pulmonary hypoplasia, 196–197, 196t, 1203–1204
 with preterm premature rupture of the membranes, 601
- Pulmonary stenosis
 fetal
 invasive fetal therapy for, 277t, 445, 446t
 tetralogy of Fallot with, 324f, 331–332, 332f
 maternal, 806–807, 806f, 807f
- Pulmonary valve
 absent, tetralogy of Fallot with, 332–333, 333f
 fetal echocardiography of, 309, 314
- Pulmonary valvuloplasty, fetal, 277t, 445, 446t
- Pulmonary vascular resistance (PVR)
 nonpregnant, 1171t
 during pregnancy, 103t, 1171t
- Pulmonary veins, fetal echocardiography of, 308f, 311, 312f
- Pulmonary venous anomalies, 321–322, 321f

- Venous occlusive disease, intracranial, 1096, 1096f, 1097f
- Venous return, fetal, 159–160, 160f, 161f
- Venous thromboembolism (VTE), 855–865
 diagnosis and evaluation of, 856–862
 for acute pulmonary embolus, 858–862, 859t, 861f
 for deep venous thrombosis, 856–858, 856t, 858f
 epidemiology of, 855
 pregnancy and risk of, 829
 prevention of, 835–837, 864–865
 risk factors for, 855–856, 856t
 due to thrombophilia. *See* Thrombophilia(s).
 treatment of, 862–864, 862t
- Venous thrombosis
 due to central venous catheters, 1170
 deep. *See* Deep venous thrombosis (DVT).
 intracranial, 1096, 1096f, 1097f
- Venous ultrasonography (VUS)
 of deep venous thrombosis, 856–858, 858f
 for pulmonary embolus, 861–862, 861f
- Venous vascular bed, during pregnancy, 103
- Ventilation-perfusion (V/Q) scanning, for pulmonary embolus, 859–860, 861f, 862
- Ventricles, fetal echocardiography of, 313, 313f
- Ventricular function, in pregnancy-induced hypertension, 1172, 1172f
- Ventricular septal defect (VSD)
 fetal, 313–314, 322–324, 323f, 324f
 epidemiology of, 278
 maternal, 802–803, 803f
 anesthesia with, 1156–1157
- Ventricular septum, fetal echocardiography of, 309, 313–314, 314f
- Ventricular tachycardia, in fetus, 340, 340f
- Ventriculomegaly, 279–280
 and aneuploidy, 227t
 diagnosis of, 279–280, 279f, 280f
 invasive fetal therapy for, 277t, 280
 prognosis for, 280
- Verapamil, during pregnancy, 801t
- Vernix caseosa, in amniotic fluid, 420
- Vertex-breech twins, 462
- Vertex-nonvertex twins, 462
- Vertex-transverse twins, 462
- Vertex-vertex twins, 462
- Very low birth weight (VLBW)
 defined, 545
 incidence of, 546
 and survival and morbidity with preterm birth, 550–551, 551f, 553t
- Viability, 521, 1200–1202
- Vibroacoustic stimulation (VAS), 382–383
- Videx (didanosine), for HIV infection, 772t
- Villous capillaries, 41–42
- Viracept (nelfinavir), for HIV infection, 772t

- Viral hepatitis, 785–786, 787t
 breastfeeding with, 135–137, 136t
 Viral infections, in neonatal period, 1217–1219
 Viral influenza, 784–785
 Viral pneumonias, 932–933
 Viramune (nevirapine), for HIV infection, 772t
 Viread (tenofovir), for HIV infection, 772t
 Virilization, in pregnancy, 1031–1032, 1031t
 Visceroatrial situs, fetal echocardiography of, 307, 310–311, 311f
 Visual complications, of prematurity, 1199t
 Vital capacity, during pregnancy, 105t
 Vitamin A, as teratogen, 353
 Vitamin B₆
 for nausea and vomiting, 1042, 1042t
 for tuberculosis, 936
 Vitamin B₁₂
 in anemia, 870, 870t
 in pregnancy, 872
 Vitamin B₁₂ deficiency, 1101
 megaloblastic anemia due to, 874
 Vitamin C, for prevention of preeclampsia, 675
 Vitamin D
 in calcium metabolism, 1032
 for hypoparathyroidism, 1035
 Vitamin D₂ (1 α ,25-dihydroxycholecalciferol), 1032
 Vitamin D₃ (25-hydroxycholecalciferol), 1032
 Vitamin deficiencies, after bariatric surgery, 1051, 1051t
 Vitamin E, for prevention of preeclampsia, 675
 Vitamin K antagonists, as teratogens, 348, 351–352, 351t
 Vitamin K₁, with anticonvulsants, 1091
 Vitamin supplementation, during pregnancy, 146, 146t
 Vitelline vessels, 40
 Vivactil (protriptyline), dosage of, 1117t
 VLBW (very low birth weight)
 defined, 545
 incidence of, 546
 and survival and morbidity with preterm birth, 550–551, 551f, 553t
 VO₂. *See* Oxygen consumption (VO₂).
 Volume depletion, intravascular, in preeclampsia, 1147
 Volume expansion, during pregnancy, 101, 107
 Volume homeostasis, during pregnancy, 107
 Volume regulation, during pregnancy, 1016, 1018f
 Volume replacement, for hemorrhagic shock, 1180–1182, 1180t–1182t
 Volume resuscitation, for septic shock, 1176
 Vomiting, 1041–1042, 1042t
 nutrition with, 148
 von Willebrand disease (vWD), 843–845, 844t–846t
 von Willebrand factor (vWF)
 deficiency in, 843
 in platelet plug formation, 825
 V/Q (ventilation-perfusion) scanning, for pulmonary embolus, 859–860, 861f, 862
 VSD (ventricular septal defect)
 fetal, 313–314, 322–324, 323f, 324f
 epidemiology of, 278
 maternal, 802–803, 803f
 anesthesia with, 1156–1157
 VTE. *See* Venous thromboembolism (VTE).
 Vulvovaginal candidiasis (VVC), 739–741, 740t
 VUS (venous ultrasonography)
 of deep venous thrombosis, 856–858, 858f
 for pulmonary embolus, 861–862, 861f
 vWD (von Willebrand disease), 843–845, 844t–846t
 vWF (von Willebrand factor)
 deficiency in, 843
 in platelet plug formation, 825
 VZIG (varicella zoster immune globulin), 783
 VZV (varicella-zoster virus), 783–784
 W
 Wakefulness, fetal, 171–174
 animal studies of, 171–172, 172f
 developmental changes in, 173–174, 173t
 effect of hypoxia and intrauterine growth restriction on, 174, 174f
 human studies of, 172–173, 173f
 Warfarin (Coumadin)
 during pregnancy, 801t
 with prosthetic heart valves, 819–820, 820t, 864
 for rheumatic disease, 1082t
 as teratogen, 351–352, 351t
 Warfarin embryopathy syndrome, 800
 Warts, genital, 748, 749, 750
 Water channels, 51
 Wegener granulomatosis, renal dysfunction in, 914
 Weight gain, during pregnancy, 143, 145–146, 145t, 146t
 inadequate, intrauterine growth restriction due to, 639
 with multiple gestation, 455
 Wellbutrin (bupropion), dosage of, 1117t
 Wernicke encephalopathy, 1107
 West Nile virus (WNV), breastfeeding with, 135
 Wet lungs, 1202–1203, 1203f
 WGAS (whole-genome association studies), 26
 White classification, of diabetes in pregnancy, 954, 954t
 White, Priscilla, 953
 Whole blood, for hemorrhagic shock, 1181
 Whole blood clotting time, in abruptio placentae, 733t
 Whole-genome association studies (WGAS), 26
 Williams syndrome, 13f
 Wilson disease, 1070, 1102
 Window of receptivity, 37
 WinRHO-SDF, 480
 Wireless capsule endoscopy, 1053
 Wiskott-Aldrich syndrome, 846, 846t
 WNV (West Nile virus), breastfeeding with, 135
 Woods maneuver, for shoulder dystocia, 697
 Work, and preterm birth, 555
 Wound hematomas, postcesarean, 709
 Wound infection, 761–762
 due to burns, 1187–1188
 Wurm cerclage, 593
 X
 X cells, 43, 43f
 X chromosome, 7, 19
 aneuploidies of, 19–20, 20t
 X inactivation, 19, 24
 Xiphopagus, 468
 XIST gene, 19
 X-linked dominant inheritance, 25, 25f
 X-linked inheritance, 24–25, 25f
 X-linked recessive inheritance, 24–25, 25f
 X-rays, during pregnancy, 889–890, 890t
 Y
 Y chromosome, 7, 19
 Yolk sac, 38–39, 39f
 Yolk sac tumors, 886
 Z
 Zafirlukast (Accolate), for asthma, 940t, 942
 Zalcitabine (ddC, Hivid), for HIV infection, 772t
 ZAM (zone of altered morphology), in decidual/membrane activation, 523
 Zanamivir, for influenza, 785
 Zavanelli maneuver, for shoulder dystocia, 697
 Zerit (stavudine), for HIV infection, 772t
 Ziagen (abacavir), for HIV infection, 772t
 Zidovudine (AZT, Retrovir), for HIV infection, 771, 772t, 773
 Zidovudine + lamivudine + abacavir (Trizivir), for HIV infection, 772t
 Zidovudine and lamivudine (Combivir), for HIV infection, 771–772, 772t
 Zinc, and intrauterine growth restriction, 639
 Zinc supplementation, during pregnancy, 146t
 Ziprasidone (Geodon), dosage of, 1116t
 Zolofit (sertraline), dosage of, 1117t
 Zona pellucida, 37
 Zone of altered morphology (ZAM), in decidual/membrane activation, 523
 ZPI (protein Z–dependent protease inhibitor), in anticoagulant system, 828, 828f
 ZPI (protein Z–dependent protease inhibitor) deficiency, 835
 Zygonema, 8f, 9
 Zygosity, identification of, 66–67, 67f
 Zygote, 8f
 Zyprexa (olanzapine)
 dosage of, 1116t
 risks of, 1116
