2/10	Acute fetal asphyxia, most likely with chronic decompensation.	125/1000	Deliver for fetal indications (usually cesarean section).
0/10	Severe, acute asphyxia virtually certain.	600/1000	If fetal status is viable, deliver immediately by cesarean section.

*Per test, within 1 week of the result shown, if no intervention. For scores of 0, 2, or 4, intervention should begin virtually immediately, provided the fetus is viable. For all interventions, lethal anomaly should be excluded as a potential cause of the abnormal behavior. AFV, amniotic fluid volume; PNM, perinatal mortality; ROM, rupture of membranes.

Equivocal or Abnormal Scores. The correlation between abnormal scores and high risk of poor outcome has been demonstrated in large population studies and produces a characteristically shaped outcome curve (Fig. 21-9).⁸⁵ Statistically, the most likely correlate of an equivocal score is coincidental absence of behavior in a normal

fetus. Even an abnormal score carries a differential diagnosis, including many obstetrical factors (Table 21-3). Extending the testing period, retesting after a brief interval, or adding ancillary tests can be done before moving to delivery for equivocal scores. When a score of 0 to 4/10 is found for a fetus whose screening in the first and second trimesters was normal, and especially when biophysical parameters and anatomic review were normal in the recent past, undue delay in delivery is usually not advisable.

The Monitoring Context. The *process* of obtaining the BPS can provide important information. Further investigation may be stimulated by, for example, the mother's observations, the uterine response to stimulation by the transducer, or observation of individual abnormal behavior. This interactive style of monitoring is preferable to the rigid application of a simple BPS.⁸⁶ Performance of BPS; routine ultrasound observation of the uterus, placenta, and membranes; measurement of fetal growth parameters; and comprehensive Doppler survey, as well as identification of subjective changes such as echogenic bowel or behavioral ones such as reduced tone, all constitute information gathering.

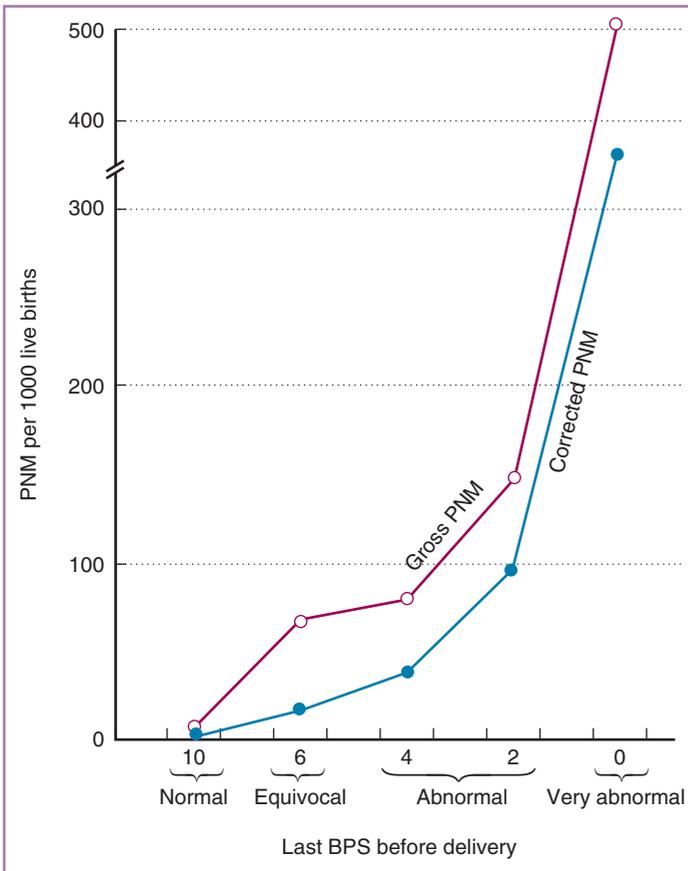

FIGURE 21-9 Perinatal mortality and BPS. Perinatal mortality (PNM) varies exponentially with declining biophysical profile score (BPS). The important contribution of lethal fetal anomalies accounts for the difference between the two curves.

Fetal Heart Rate Monitoring

Isolated use of FHR testing, whether by classic NST or by the introduction of contraction challenges (oxytocin challenge test or contraction stress test), is not considered standard of care for high-risk fetuses. There may be economic or logistic reasons why ultrasound is not available to women with no identifiable risks who are receiving routine prenatal care, but even in that population, it may not be appropriate to use the NST as the sole surveillance tool (Table 21-4). A valuable component of virtually all multivariable systems, the NST recognizes the unique coupling of fetal neurologic status to cardiovascular reflex responses.⁸⁷ It is one of the factors that tends to disappear earliest during progressive fetal compromise,^{39,88} and many studies have shown it to be the most sensitive of the four shorter-term variables that indicate worsening hypoxemia or acidosis.^{89,90} In modified BPS systems, a fully reactive NST may be used to infer fetal movement. Any abnormality in such test results, including the nonreactive NST, occasional decelerations, decreased variability, and persistent minor decelerations, calls for complete ultrasound evaluation.

TABLE 21-3 FACTORS THAT INFLUENCE BIOPHYSICAL PROFILE SCORING PERFORMANCE

Agent	Fetal Effect
Drugs	
Sedatives/sedative side effects (e.g., Aldomet)	Diminished activity of all varieties; abolition of none
Excitatory (e.g., theophylline)	Continuous, "picket fence" FBM
Street drugs (e.g., crack cocaine)	Rachitic, rigid, furious, bizarre FM
Indomethacin	Oligohydramnios
Maternal cigarette smoking	Various observations: FBM abolished or attenuated but some report no change; FM reduced
Maternal hyperglycemia (iatrogenic or unregulated)	Sustained FBM or acidosis, diminution or abolition of FM or FT or CTG-reactivity
Maternal hypoglycemia (e.g., poor nutrition, insulin excess)	Abnormal paucity of all behaviors, normal AFV
Single Parameter Removed by Perinatal Condition	
Persistent fetal arrhythmia	Uninterpretable CTG
Spontaneous premature rupture of membranes	Obligatory oligohydramnios
Periodic decelerations (e.g., in proteinuric preeclampsia)	CTG defined as non-reactive
Acute Disasters (eclampsia, abruptio placentae, ketoacidosis)	May invalidate predictive accuracy

AFV, amniotic fluid volume; CTG, cardiotocogram; FBM, fetal breathing movements; FM, fetal movement; FT, fetal tone.

Nonreactive Test

Poor specificity for compromise
 Poor specificity for fetal death

Reactive Test

Falsely reassuring rate, * 6/1000
 Unreliable as backup test*

*Falsely reassuring rate for post-term pregnancy, 20/1000. Falsely reassuring rate for decreased fetal movement, 24/1000.

The Nonstress Test

The coupled presence of palpable fetal movements and FHR acceleration is the essence of the NST. The classic criteria for a reactive NST are at least two FHR accelerations lasting at least 15 seconds and rising at least 15 beats/min above the established baseline heart rate.⁹¹ Most term fetuses have many of these accelerations in each 20- to 30-minute period of active sleep (behavioral state 2F), and the term fetus seldom goes more than 60 minutes, and certainly not more than 100 minutes, without meeting these criteria.⁴⁴ On the other hand, preterm fetuses, IUGR fetuses at similar gestations, or fetuses with maternal medication such as sedatives or magnesium sulfate frequently have paired accelerations—movements that do not meet these criteria.⁷⁹ Modification of these criteria in BPS (e.g., including accelerations of 10 beats/min lasting 10 seconds on a background of normal FHR variability, for fetuses less than 32 weeks) accepts the principle that earlier fetuses have smaller accelerations but that they should always demonstrate some degree of FHR acceleration with palpated fetal movements.

NST reactivity may be inferred. Experienced nurses listening to a heart rate monitor can detect accelerations and properly classify a reactive NST without looking at the paper record.⁹² Real-time ultrasound observation of concurrent FHR accelerations and movements also correlates perfectly with reactive NST.

Falsely reassuring NSTs do occur, at a rate of four to five per 1000 in the largest studies.^{46,93,94} These are most problematic in fetuses with asymmetrical IUGR, oligohydramnios, or metabolic problems associated with severe macrosomia, for whom false-reassuring rates may reach 15%. Thus, NST has significant liabilities in the groups at highest risk. Strong evidence, including data from randomized trials, shows that NST should not be used in isolation in determining the antenatal status of such fetuses.

The nonreactive NST is defined by an FHR monitoring interval that does not meet the criteria just described. However, there is a large variation in the total duration allowed, and it ranges from a minimum of 10 minutes of monitoring to 40 minutes or even 60 minutes according to some authors.^{95,96} In the context of BPS, 30 minutes is allowed for the NST to reach reactivity. About 10% to 12% of fetuses in the third trimester do not meet these criteria at 30 minutes. This number

falls below 6% by 40 minutes.⁴⁴ Clearly, the choice of time end point is critical in determining the false-alarm rate, its major clinical drawback. In fact, because most normal fetuses demonstrate normal ultrasound BPS (i.e., a score of 8/8) within 15 minutes, spending the additional time to perform NST is optional. By far the most common explanation for the nonreactive NST is the presence of a longer-than-average sleep cycle in a normal fetus.⁶ A nonreactive NST, especially if variability remains present and there are no decelerations, should not be assumed to indicate fetal compromise. The standard of care indicates that ultrasound evaluation (a full BPS) should be available as the backup test. Although fetal nonstress testing in isolation has frequently been the reference test for post-term pregnancies, decreased fetal movement on maternal movement counting programs, and other published protocols for first-line monitoring, the standard of care now indicates a much more comprehensive evaluation.⁹⁷

Ultrasound may resolve apparently abnormal NST as well. For example, repetitive nonreactive NST in a fetus with normal serial ultrasound variables may lead to a diagnosis of central nervous system abnormalities, drug ingestion, or prior fetal central nervous system injury. As well, late deceleration or variable decelerations may occur in the context of NST monitoring, with no deflection of the uterine pressure monitor. Uterine activity is probably responsible, but the situation (placental insufficiency in the case of late decelerations, umbilical cord compression in the case of variable decelerations) is so precarious that even minor changes in uterine tone may provoke them. Either pattern should call for immediate evaluation by real-time and Doppler ultrasound to exclude IUGR, direct fetal compromise, oligohydramnios, chronic placental insufficiency, or more acute events such as abruption. This should be done immediately, as the explanation may be imminent cord prolapse or evolving placental separation without significant maternal findings. Or it may be simpler: variable decelerations lasting up to 2 minutes may occur as the term fetus squeezes the cord with its hand.⁹⁸ In the context of modern fetal evaluation, all these issues suggest that FHR monitoring should be done in a unit capable of immediate ultrasound evaluation.

Computerized Cardiotocography

The binary reactive or nonreactive interpretation of FHR has been evaluated in many ways, but more detailed visual analysis has not proved superior.⁴⁶ Computerized storage and interpretation of FHR records obtained with conventional monitors has a clear advantage. Objective interpretation using digitized analysis of heart rate patterns can clarify the information available from the CTG.^{99,100} This is essentially a computerized extension of the National Institutes of Health workshop on electronic heart rate monitoring,¹⁰¹ which categorized heart rate variability as undetectable, minimal, moderate, marked, or sinusoidal. Computerized analysis can depict variability as a continuous output variable, analyzing beat-to-beat variability (short-term variation, which has a mean of 3 to 8 msec), or as overall variation, depicted as mean minute variability from the established baseline.¹⁰² Normal mean minute variation is correlated with gestational age. An example is shown in Figure 21-10. The interpretation algorithm is very complex and includes correlation of gestational age for the definitions of accelerations, variability, baseline heart rate, movement frequency, and the depiction of fetal state.⁷² Although the subtleties of states 3F and 4F are not depicted, states 1F (low variability, fetal movements) and 2F (high variability and significantly increased movement frequency) are correctly classified.¹⁰³ Finally, variations within periods of high episodes and low episodes are also analyzed and compared with gestational age-corrected means. Data stored on a hard disk are used to examine serial changes.

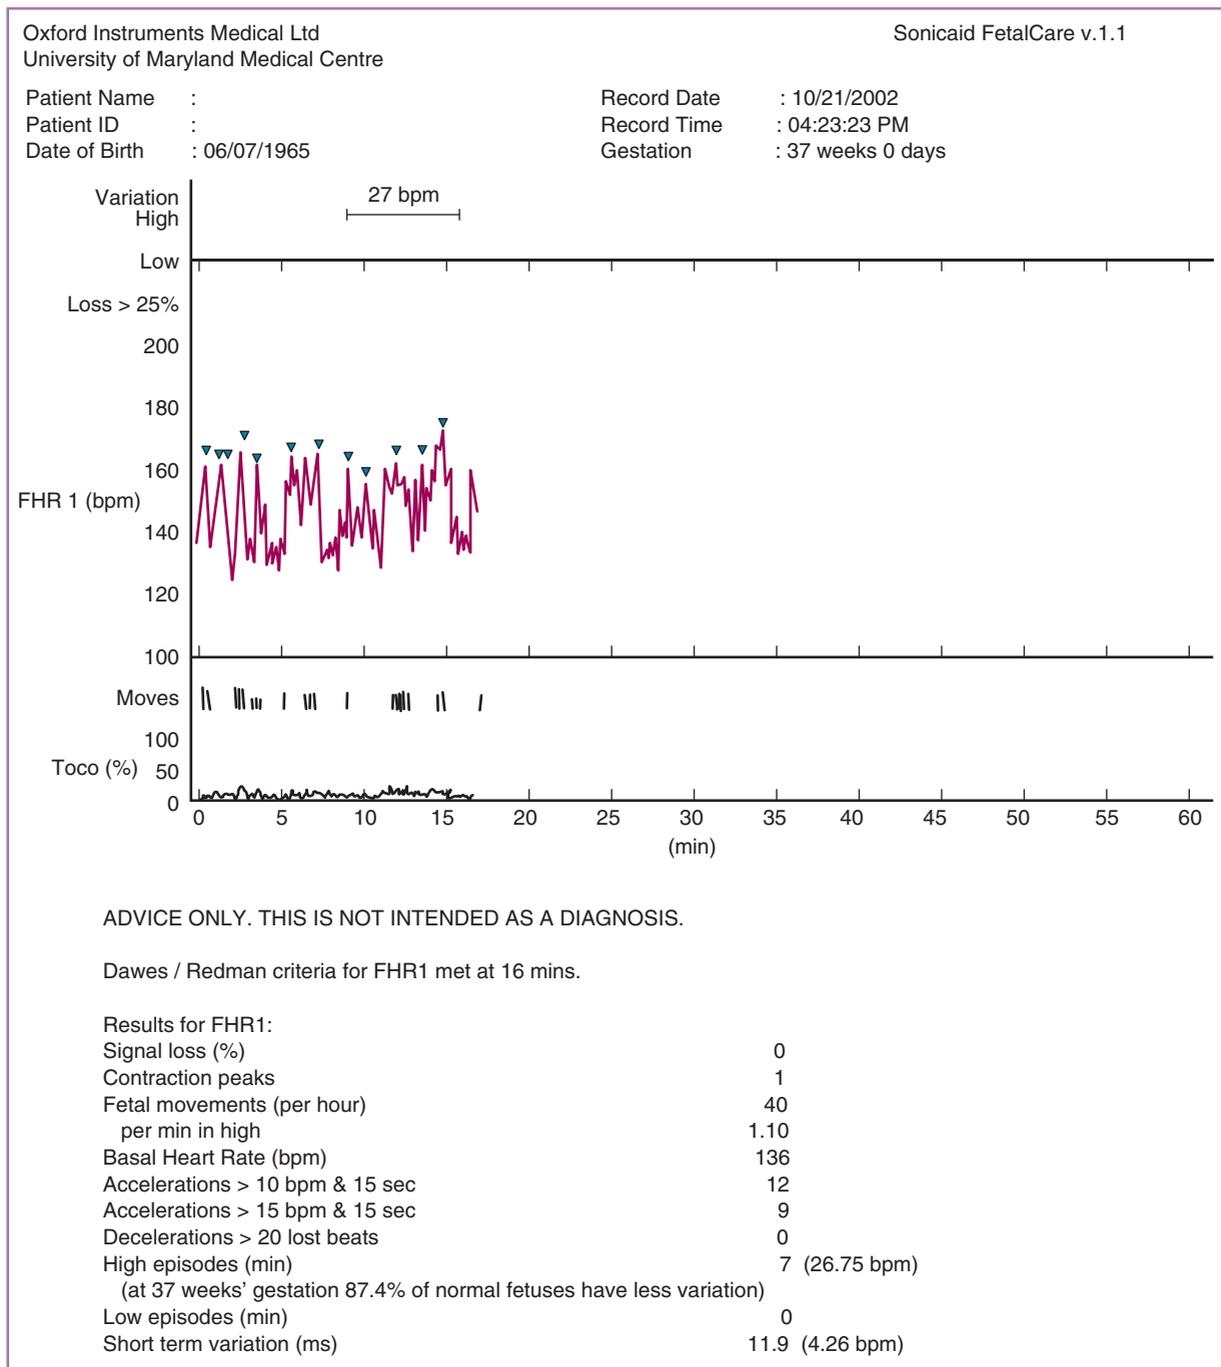

FIGURE 21-10 Output from Oxford Sonicaid System 8002 computerized cardiotocogram (CTG) interpretation algorithm. bpm, beats per minute; FHR, fetal heart rate.

Computerized cardiotocography (CCTG) outperforms NST by expanding the applicable gestational age and making objective interpretations. Statistically, this means better positive and negative predictive accuracy, fewer equivocal test results, and superior performance at less than 32 weeks' gestation. Although good evidence suggests CCTG, like the NST, should not be used as a solitary method of fetal surveillance, increasing evidence supports a central role in multivariable testing when maintaining fetal safety to gain critical time is the goal (e.g., with severe placenta-based IUGR at the lower limits of viability).¹⁰⁴ In more common populations undergoing fetal surveillance,

however, this degree of precision is generally not required, and the binary format of the NST suffices.

Doppler Ultrasound

In the overall context of fetal evaluation, Doppler velocimetry defines placental status and, therefore, the relative risk of sudden deterioration.^{34,105} For example, Doppler categories of risk mandate the frequency of biophysical profile scoring (Table 21-5).³⁹ Extreme Doppler abnormalities may indicate intervention, but Doppler is not used in

TABLE 21-5 DOPPLER ABNORMALITY DICTATES FREQUENCY OF BIOPHYSICAL PROFILE SCORING (BPS)*

Abnormality [†]	BPS Frequency [‡]	Decision to Deliver (Fetal) [§]
Elevated indices only	Weekly	Abnormal BPS [¶] or Term or >36 weeks with no fetal growth
AEDV	Twice weekly	Abnormal BPS [¶] or >34 weeks proven maturity of Conversion to REDV
REDV	Daily	Any BPS < 10/10 [¶] or >32 weeks dexamethasone given
REDV-UVP	Three times daily	Any BPS < 10/10 [¶] or >28 weeks dexamethasone given

*BPS determines management. Must be viable to enter: >25 weeks gestation, >500 g, normal anatomy, normal karyotype.

[†]Umbilical artery and complete venous-tree Doppler; cerebralization of blood flow confirms umbilical artery abnormality as serious, does not directly alter management.

[‡]Minimum testing frequency, increased on basis of severity: maternal condition(s), degree of IUGR, gestation.

[§]Neonatal consultation, maternal condition/instability, direct fetal parameter by cordocentesis, all will impact this decision.

[¶]Any BPS ≤ 4/10, or 8/10—Oligo, or repeated 6/10.

[¶]BPS 8/10 cyclic absence of FBM is the only exception, in which case, repeat BPS < 6 hr.

AEDV, absent end-diastolic velocity; FBM, fetal breathing movement; IUGR, intrauterine growth retardation; REDV, reversed end-diastolic velocity; UVP, umbilical venous pulsations.

isolation, and evaluation of fetal status using all available tools is imperative.

Fetal Doppler Velocimetry

Fetal Doppler studies have evolved from simple evaluation of the umbilical outflow to assess the placenta¹⁰⁶ to comprehensive multivessel evaluation of fetal circulatory status.¹⁰⁵ Although most literature is focused on umbilical artery velocimetry by itself, current standards of practice require both placental and fetal systemic Doppler studies to adequately assess the compromised fetus.¹⁰⁷⁻¹¹⁰

Umbilical Artery

Hemodynamics. The umbilical arteries arise from the common iliac arteries and represent the dominant outflow of the distal aortic circulation. Because there are no somatic branches after their origin, the umbilical arteries purely reflect the downstream resistance of the placental circulation. Normal umbilical artery resistance falls progressively through pregnancy, reflecting increased numbers of tertiary stem villous vessels (Fig. 21-11).¹¹¹ In a number of pathologic conditions, increased resistance in the umbilical arteries represents placental injury with loss of cross-sectional arterial outflow.¹¹² In the sheep model, infarction of multiple small vessels by infusing microspheres can be titrated to induce precise rises in umbilical artery resistance.^{113,114} As umbilical artery resistance rises (Fig. 21-12), diastolic velocities fall, and ultimately these are absent (absent end-diastolic velocities [AEDV]).¹¹³ As resistance rises even further, an elastic component is added, which will induce REDV, as the insufficient, rigid placental circulation recoils after being distended by pulse pressure.¹¹⁵ This latter condition is terminal and can exist for only a short period of time; our longest recorded healthy survivor had 13 days of REDV, whereas our longest survivor with AEDV had more than 14 weeks.³⁹

Measurement. As with all Doppler evaluations, the sample gate is enlarged to encompass the entire vessel, and transducer position is adjusted to eliminate aliasing, to minimize the Doppler angle, and to sample a single umbilical artery.¹¹⁶ In the initial Doppler evaluation of any compromised fetus, both umbilical arteries should be sampled, and information from the best umbilical artery should be used in clinical decisions.¹¹⁷ There is no established standard as to where along the course of the umbilical artery the definitive evaluation should be made. Especially for the compromised IUGR fetus, the length of the cord may represent substantial resistance in itself (Fig. 21-13). Although all these waveforms are abnormal, the mid-cord waveform may be most representative.

Clinical Significance. In isolation, elevated umbilical artery indices suggest placental liability but correlate with IUGR in less than 60% of cases.¹¹⁸ Monitoring of fetal growth, proportions, amniotic fluid volume, and well-being are indicated, but intervention is seldom justified by elevated umbilical artery resistance by itself. Markedly elevated umbilical artery resistance suggests placental injury, mandating increased fetal surveillance, including multivessel systemic Doppler assessment and BPS.^{119,120}

AEDV may exist in equilibrium, but in many fetuses, AEDV is not stable and will progress to REDV over time. Many fetuses with AEDV also have altered brain blood flow, with increased diastolic velocities—the brain-sparing phenomenon.³² Not all fetuses with this degree of placental resistance have functional evidence of placental insufficiency in the form of acidosis or hypoxemia, but AEDV is not usually compatible with term pregnancy. It is not surprising that the majority (80% to 100%) of such fetuses are delivered by cesarean section, often electively, or provoked by fetal distress in labor. Clearly, the combination of prematurity, IUGR, and potential placental respiratory insufficiency suggests that tertiary delivery is indicated for most of these fetuses.

AEDV is an indication to prepare for delivery, including appropriate referral, administration of antenatal steroids, and detailed maternal evaluation to exclude undiagnosed hypertension, renal disorders, connective tissue disorders, or thrombophilias. Furthermore, because up to 20% of such fetuses have malformations or overt aneuploidy, a diligent review of fetal anatomy, and in some cases invasive fetal testing for fetal karyotype, is indicated.¹²¹ Although the latter may seem unduly invasive considering the short intrauterine time remaining, avoidance of maternal morbidity (about 35% of those requiring cesarean delivery undergo classic cesarean sections) and exclusion of fetal karyotypic abnormality are important. Even in fetuses with no visible anomalies, the combination of IUGR, including fetal disproportion, and abnormal placental Doppler parameters may be associated with 5% to 8% aneuploidy.¹²²

Monitoring the fetus with AEDV requires multivariable assessment. Fetal heart rate monitoring alone is insufficient, as most of these fetuses have reduced heart rate variability and small accelerations. Relying on composite scoring of the BPS means a lower rate of false-positive tests but does require the observer to become attuned to the movement pattern of the individual fetus. In this precarious situation, subjectively reduced amniotic fluid volume, overall reductions in total fetal activity, long intervals between periods of fetal breathing, and spontaneous FHR decelerations observed on real-time ultrasound may

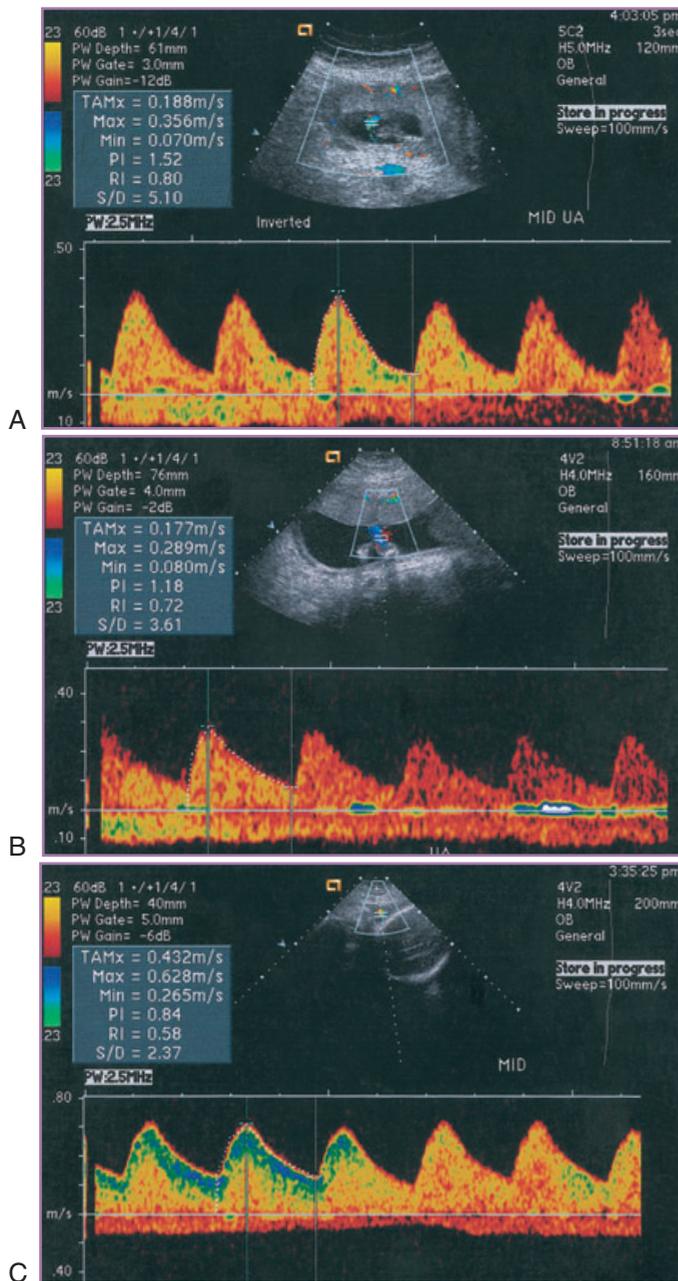

FIGURE 21-11 Evolution of normal umbilical artery resistance, measured in mid cord. Although there is an increase in diastolic velocities and a corresponding gradual decline in systolic-to-diastolic ratio from first trimester to third (A to C), there is already well-developed diastolic flow in the earlier waveform.

lie above the baseline threshold for BPS variables and yet indicate progressive deterioration in fetal status. This level of awareness required of the ultrasound observer may explain some authors' dissatisfaction with withholding delivery of these fetuses.^{123,124} Infants who had AEDV as fetuses are at risk for many neonatal complications because of placental insufficiency, asphyxial events surrounding delivery, and the significant impacts of prematurity (Table 21-6).¹²⁵⁻¹²⁷ Progression to AEDV, or from AEDV to REDV, calls for enhanced fetal assessment, with shorter intervals, BPS scored out of 10, and arterial and venous Doppler studies together. Monitoring such fetuses by simple NST and

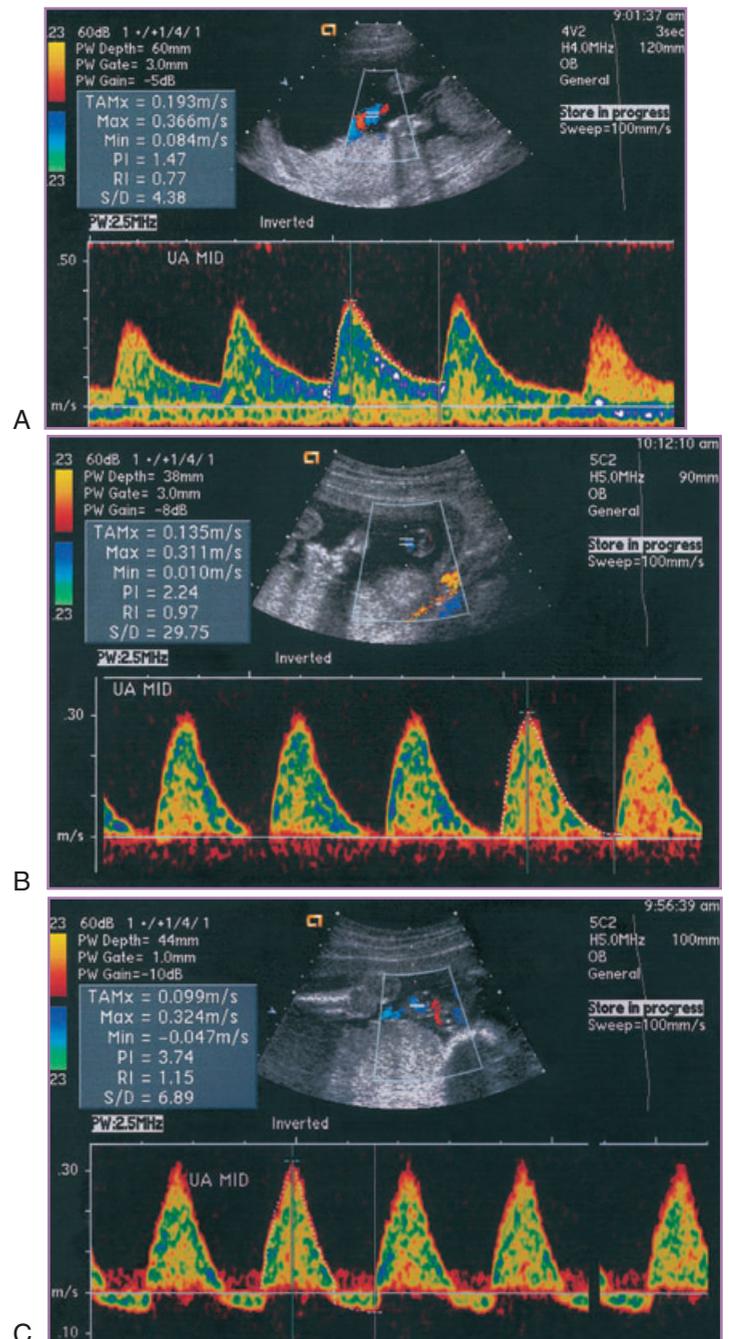

FIGURE 21-12 Progressive abnormality of umbilical artery resistance. Initially nearly normal at 18 weeks (pulsatility index, 1.47) (A), by 24 weeks (B) the umbilical artery shows absent end-diastolic velocities, which progressed to reversal of flow for 25% of the cardiac cycle (C). The infant had an umbilical venous pH of 7.18 after nonlabored cesarean section. All measurements in the mid cord.

repeated single umbilical artery Doppler does not satisfactorily ascertain fetal status.^{128,129}

REDV magnifies these dangers and risks. In almost every fetal situation, this is a very unstable, often rapidly changing fetal-placental process. Acute vascular accidents (abruption, intraplacental bleeding, or fetal maternal hemorrhage) are frequent end points. Thus, many authors have recommended delivery as soon as possible.¹³⁰⁻¹³² Because

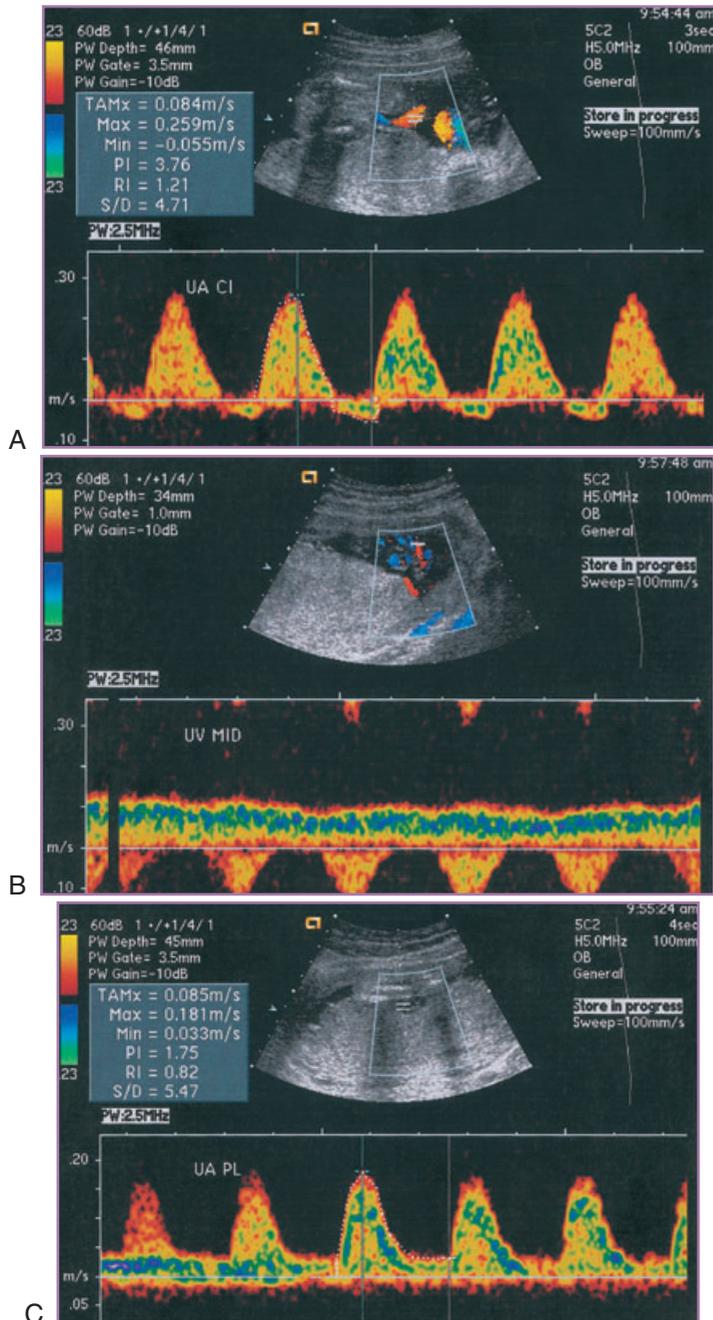

FIGURE 21-13 Umbilical artery resistance may vary extremely from one point on the umbilical cord to another. **A**, Abdominal cord insertion shows reverse end-diastolic velocities. **B**, At mid cord, end-diastolic velocities are absent (waveforms inverted in this image). **C**, At placental cord insertion, there is elevated resistance, but positive diastolic flow is demonstrated.

many cases of REDV are discovered on the first evaluation (e.g., on referral for evaluation of clinical IUGR), the progression for an individual fetus is difficult to determine. If the BPS is normal and amniotic fluid is adequate, there are no decelerations on the CTG, mean minute variation is greater than 3 msec, and most importantly if venous Doppler parameters are normal, time can be taken to administer antenatal steroids and to evaluate maternal condition before delivery. Because REDV is often associated with very significant abnormality of

TABLE 21-6 ABNORMAL UMBILICAL ARTERY DOPPLER PREDICTS ADVERSE OUTCOMES*

Cesarean section for fetal distress

cerebral and venous circulations, it is linked to the highest frequency of fetal compromise, neonatal complications, perinatal mortality, and perinatal morbidity. Reducing the superimposed impacts of prematurity on such infants is effective in achieving the highest rate of intact survival.^{105,119}

Middle Cerebral Artery

Hemodynamics. The middle cerebral artery (MCA) is short, straight, and uniformly positioned relative to the fetal skull and other intracranial landmarks. Doppler measurements taken from this vessel are more reproducible than those taken from other vascular beds and have few collateral circulatory influences, while representing a critical component of the fetal circulation, and the MCA is usually readily accessible throughout gestation.¹³³ Because the Doppler angle can be minimized, direct interpretation of the peak systolic velocity can be used to evaluate the absolute speed of blood flow, which has direct application in fetal anemia.^{134,135} As the blood becomes thinner, cardiac ejection fraction increases and transaortic velocities increase, and the MCA offers an ideal location for direct interpretation of this increase in velocity as a decline in fetal hematocrit (Fig. 21-14).¹³⁶

Placental insufficiency may alter peak systolic velocity, in some fetuses by anemia, transmitted hypertension, or both, but the key MCA abnormality expressed by the compromised fetus is centralization.^{137,138} This is an increase in diastolic velocities and represents increased brain blood flow (Fig. 21-15). A significant question is whether such changes are compensatory (parenchymal vasodilation by active mechanisms) or involuntary (increased shunting of blood away from somatic circulations, under the force of hypertension dictated by accelerating placental vascular resistance).¹³⁹ As fetal compromise progresses, it is likely that both mechanisms are operant. Cerebral blood flow as depicted by the MCA may be responsive to a number of stimuli, including maternal administration of oxygen (increased resistance),¹⁴⁰ carbon dioxide (decreased resistance),¹⁴¹ or nicotine (increased resistance, and lack of responsiveness).¹⁴² These changes may occur gradually, indicated by subtle changes in the cerebroplacental ratio,¹⁴³ which reflects the calculated ratio of resistance indices in the MCA and umbilical artery. This ratio changes in response to redistribution of blood flow, the first

stage of brain sparing.¹⁴⁴ The cerebroplacental ratio may therefore provide an early warning system to initiate more detailed fetal surveillance.

Measurement. The ideal location for Doppler assessment of the MCA is 2 mm after its origin from the internal carotid.¹⁴⁵ As demon-

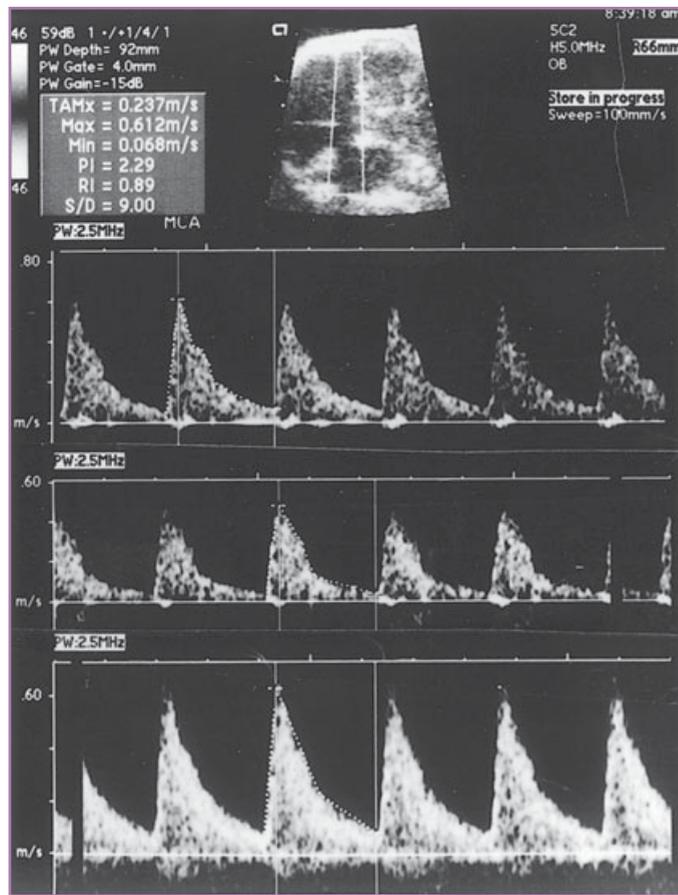

FIGURE 21-14 The peak systolic velocity (PSV) in the middle cerebral artery (MCA) reflects fetal hematocrit accurately. This fetus had serious anti-D isoimmune anemia. *Top*, Pretransfusion, MCA PSV of 60 cm/sec accurately predicted anemia (hematocrit, 19.0). After intrauterine transfusion, the MCA peak fell to 41 cm/sec as hematocrit rose to 44.0. Before the next transfusion (*bottom*), the MCA rose to 62 cm/sec and hematocrit had fallen to 20.0.

strated in Figures 21-14 and 2-15, the gate is opened to encompass the vessel, and short periods of insonation are used to minimize the amount of direct multifrequency ultrasound delivered to the fetal brain. Most authorities recommend fetal MCA velocimetry should not be studied in the first trimester.

Clinical Significance. As IUGR worsens and compensatory mechanisms take place, MCA diastolic velocities rise. This centralization continues to increase in most fetuses with AEDV, and in many with REDV.¹⁴⁶ At the point when REDV and fetal hypoxemia result in cardiac decompensation, MCA diastolic velocities may fall, returning to an apparently high-resistance pattern because cardiac output is no longer sufficient to force blood into the fetal circulation (fetal cerebrovascular tone and fetal brain edema are thought to contribute here). This reversion resulting from heart failure has been called normalization, and it is an ominous sign meriting consideration for delivery.¹⁴⁷ Separate information may come from individual parameters of the waveform. In some fetuses, the MCA peak systolic velocity may be a better indicator of poor outcome than the Doppler index itself.¹⁴⁸ This relationship is independent of fetal anemia, for which MCA peak systolic velocity is not a reliable tool in growth-restricted fetuses.¹⁴⁹ Other than these infrequent findings, the MCA indicates the need for further testing rather than dictating clinical management by itself.¹⁵⁰ Critical examination suggests that the value of MCA Doppler information is minor when umbilical artery, precordial veins, and BPS are combined. Shifts in the cerebroplacental ratio or overt centralization of the MCA indicates a need for comprehensive fetal examination, testing using multi-vessel Doppler, and BPS (scored out of 10), on a frequent basis.¹⁰⁵ An exception to this rule occurs close to term, where MCA centralization without abnormal umbilical arteries or precordial veins may be associated with acidosis and hypoxemia and poor perinatal outcome.¹⁵¹ The frequency of this finding in completely normal fetuses is unknown.

Fetal Venous Doppler Studies

Clinical Significance. There is evidence that venous Doppler studies are crucial in predicting severe compromise in fetal growth restriction (FGR) and other fetal-placental vascular abnormalities.¹⁵²⁻¹⁵⁴ Without the use of venous Doppler, prediction of outcome (including perinatal mortality, acid-base status, birth asphyxia, and requirement for intensive neonatal support) is incomplete. Ductus venosus deterioration precedes, but strongly predicts, changes in BPS that require delivery. Although MCA Doppler changes are not statistically predictive of increased adverse outcome, ductus venosus resistance elevation and depression of the a-wave correlate with a threefold

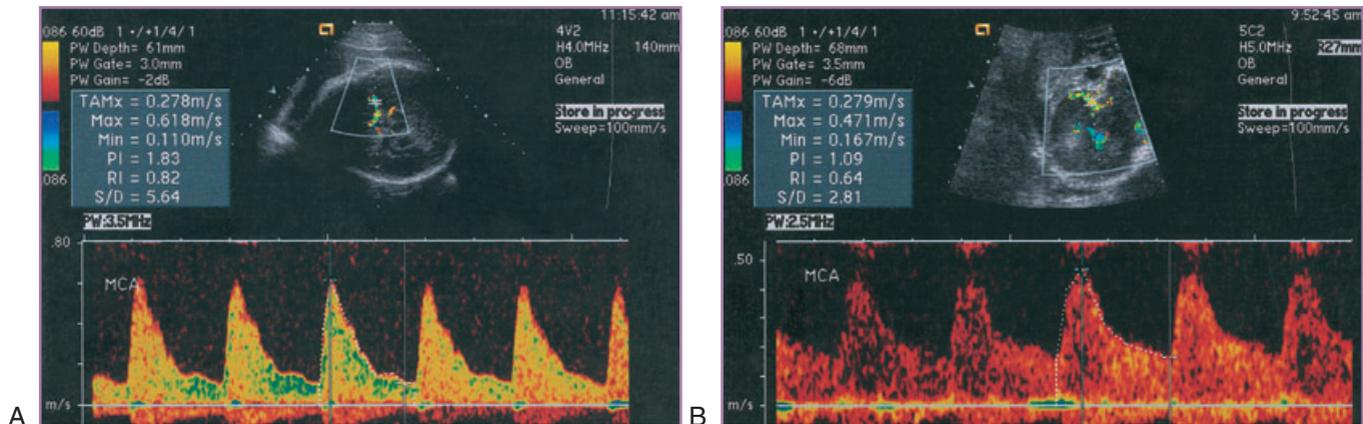

FIGURE 21-15 Centralization of blood flow. **A**, Normal middle cerebral artery (MCA) shows high resistance, low diastolic velocities. **B**, As placental resistance rises, brain blood flow increases, with falling resistance and increased diastolic velocities in the MCA.

rise in major neonatal complications. When both phases of the ductus venosus are abnormal and are also associated with umbilical venous pulsations, this relative risk exceeds 11.¹⁵⁵ Perhaps more important than the correlations of poor ductus venosus waveform with poor outcome is the reassurance of normal ductus venosus flow. Even in the presence of significant arterial abnormalities, the preservation of normal ductus venosus flow and normal biophysical variables is strongly correlated with normal fetal status, allowing successful extension of the pregnancy. There is strong agreement between abnormal venous Doppler parameters and an abnormal BPS in predicting fetuses who need delivery. However, venous Doppler studies and BPS are not strictly concordant: some fetuses who show deterioration manifest this primarily in umbilical and ductus venosus waveforms, with late decline in fetal behavior. Others demonstrate declining biophysical performance and yet maintain reasonably normal venous waveforms. These two systems are complementary—only with dual application is outcome optimized.¹⁵⁶

Ductus Venosus. The ductus venosus is a sharply tapered conduit from the proximal umbilical vein into the inferior vena cava, directly at its connection to the right atrium. Its hourglass shape regulates inflow to the central circulation through a narrow aperture that is constricted in the healthy near-term fetus, allowing only 20% of umbilical venous return into the right atrium. Because of the Venturi effect,

this narrow jet delivers highly oxygenated blood at high velocity directly to the foramen ovale, keeping it open and promoting right-to-left shunting of this nutrient-rich stream. In healthy fetuses, the ductus venosus regulates the distribution of oxygen and placental nutrients by restricting the centralization of flow. The high-velocity flow through the ductus venosus makes it easy to identify with color flow Doppler. When this short vessel is identified, Doppler insonation and depiction of the characteristic waveform (Fig. 21-16A) is relatively straightforward. The reflected wave seen in the ductus venosus waveform represents the impact of cardiac actions (directly analogous to the adult jugular venous waveform). The phases of the ductus venosus correspond to cardiac events as depicted in Figure 21-16B. During atrial systole, reduction in forward flow always occurs, producing the most notable characteristic of this waveform, the a-wave. The a-wave becomes progressively deeper as high afterload develops as a result of adverse placentation. It is further magnified as poor cardiac function superimposes (e.g., with hydrops, viral infection, endstage anemia) or as severe placental resistance results in respiratory dysfunction and direct hypoxemia. A retrograde a-wave (see Fig. 21-16C) signifies the onset of significant cardiac impairment. When cardiac function deteriorates toward preterminal pump failure, dramatic changes occur in both the atrial and ventricular phases of the ductus venosus (see Fig. 21-16D).

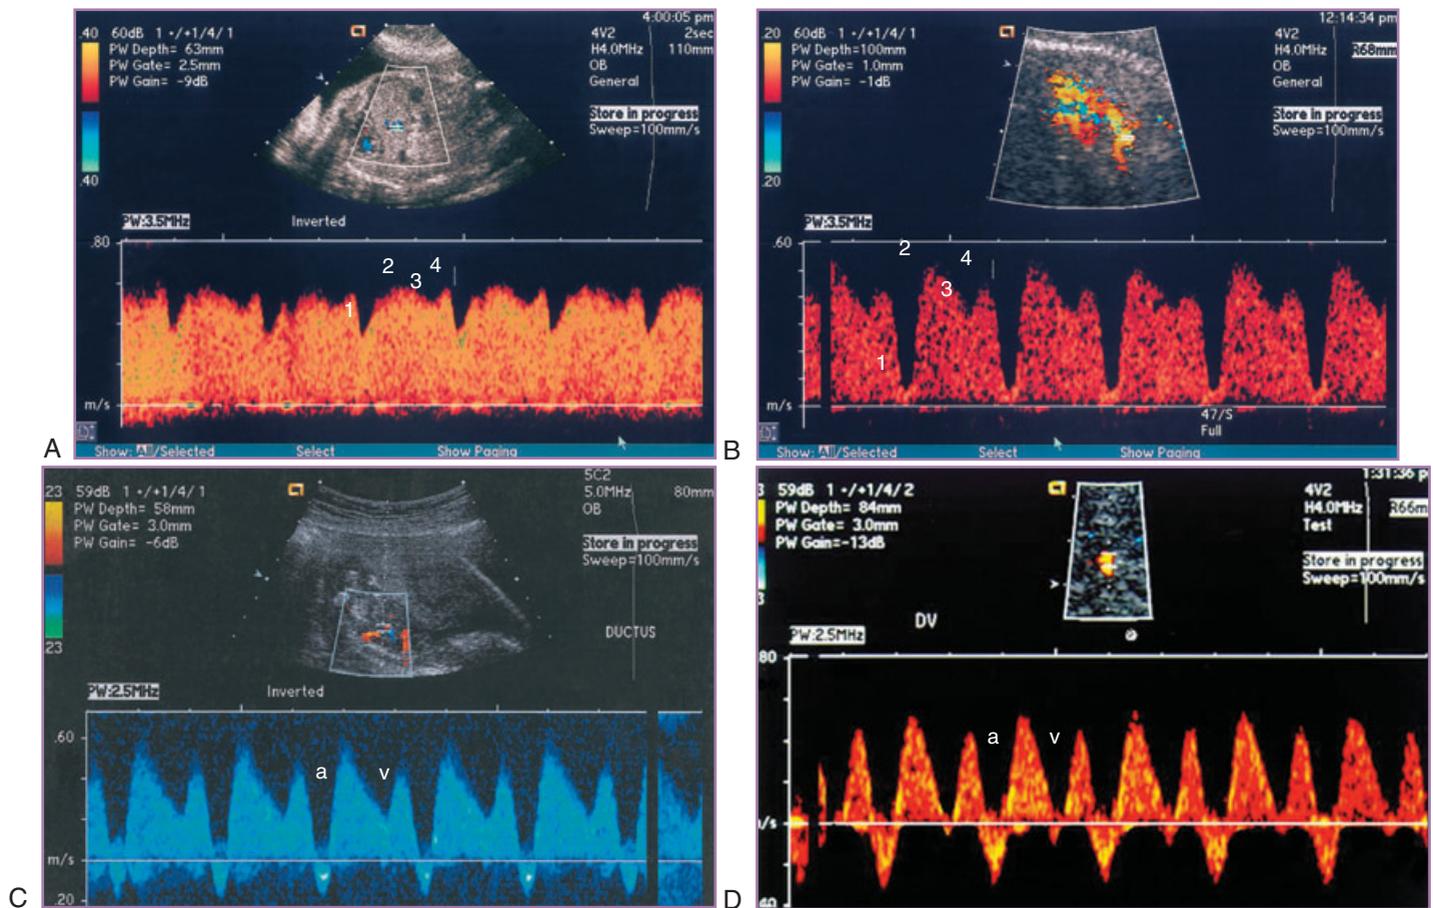

FIGURE 21-16 Ductus venosus waveforms. **A**, Normal four-phase waveform (1, atrial contraction, called an a-wave; 2, ventricular systole; 3, ascent of annulus; 4, diastole) with a-wave showing only modest normal reduction in forward flow. **B**, In fetuses with growth restriction, increased afterload (from placental resistance) is reflected through the heart as markedly abnormal forward cardiac function, with a nearly retrograde a-wave. **C**, Cardiac effects are also reflected distally. Note retrograde a-wave as well as cardiac function producing distortion of v-descent (compare to 3 in normal wave form). **D**, Severe cardiac decompensation results in both phases being negative.

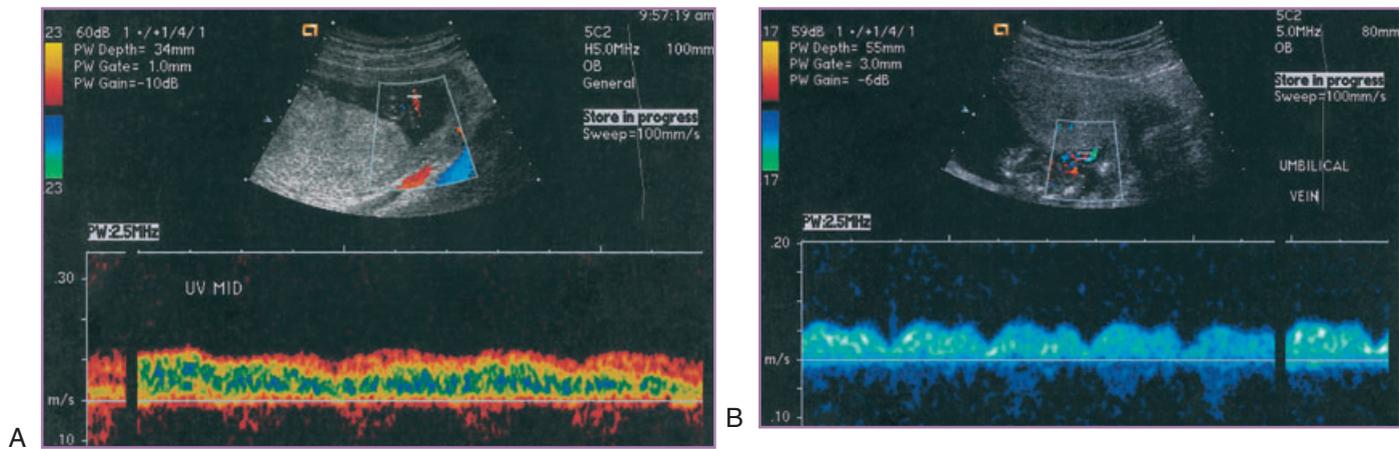

FIGURE 21-17 Umbilical venous pulsations. **A**, Moderate pulsatility, increased placental resistance in intrauterine growth restriction. **B**, Cardiac failure with tricuspid regurgitation reflected as retrograde flow all the way back to mid cord. Note timing relationship to arterial pulsations (*below line*).

The ductus venosus offers dual insights into oxygen-regulated flow and cardiovascular function. These factors, as well as the ease of identification throughout gestation, suggest that the ductus venosus is the precordial vein of choice. Multiple venous systems have been studied, and there is no statistical basis for choosing the inferior vena cava, umbilical vein within the free abdomen, or other venous index over the ductus venosus for accuracy in predicting fetal compromise. Furthermore, only the ductus venosus can actively dilate with hypoxemia, an added benefit that supports its superior application.

Functionally, the retrograde a-wave is frequently associated with umbilical venous pulsations (see Fig. 21-17). These pulsations reflect retrograde conduction of the a-wave impulse (facilitated by the dilated ductus venosus) and a distended column of blood extending directly back from the heart into the free portion of the umbilical vein. Umbilical venous pulsations are infrequent, so they are not a practical marker with a high rate of detection of the compromised fetus. When seen in association with ductus venosus abnormality, umbilical venous pulsations call for prompt referral to a tertiary center and preparation for delivery.

Umbilical Vein. Pulsations in the umbilical vein occur for a number of reasons.¹⁵⁷ During fetal heart rate accelerations, temporary pulsation may reflect increased cardiac dynamic action. If the cord is tightly coiled around the body or limb, or temporarily constricted by fetal position, umbilical venous pulsations may be documented. It is important to retain the context of these observations, because a series of umbilical vein pulsations in isolation, or umbilical venous pulsations with normal ductus venosus waveform, are of uncertain significance. There is also the possibility of specific vascular anomalies, including a partially occluded or even absent ductus venosus. Although the pulsation pattern has been suggested as a discriminator,¹⁵⁸ other investigators have not been able to duplicate these correlations (Fig. 21-17). Many groups have demonstrated that umbilical venous pulsations are an ominous finding and frequently lead to intrauterine demise or serious neonatal compromise.¹⁵⁹ The lack of standard definitions means that there are many false positives, and action based solely on umbilical venous pulsations appears unwarranted. Thus, umbilical venous pulsations are the best example of the warning that Doppler investigations are not to be taken in isolation, out of context with other fetal observations.¹⁶⁰

Other Veins. The inferior vena cava (IVC) shares some characteristics with the ductus venosus but is not easily interpreted. It is normal

to have a retrograde a-wave in the IVC, so meticulous measurement of the venous resistance index is required. Second, the IVC does not vary with hypoxemia, so reflection distally cannot be inferred as a marker for sequential fetal compromise. Similar observations can be obtained from cerebral veins, hepatic veins, or regional venous vessels. All the precordial veins are involved in the fetal responses to hypoxemia.¹⁶¹ The apparent ease of ductus venosus recognition seems to be the reason it is suggested as the standard for this information.

Maternal Doppler Studies

Uterine Artery

The uterine arteries normally demonstrate progressive reduction in resistance and increased diastolic velocities throughout gestation (Fig. 21-18).¹⁶² This depends on absence of maternal hypertension and presence of normal placental invasion.¹⁶³ Pre-pregnancy, high-impedance characteristics of uterine artery circulation, including high resistance, persistence of diastolic notching, and even absent end-systolic forward flow, can persist throughout pregnancy if placentation is inadequate.¹⁶⁴ Different components of uterine artery abnormality have different sensitivities and specificities for placental malfunction and for maternal hypertensive disorders, or both. These findings may be of diagnostic benefit in a hypertensive mother (to evaluate the possibility of preeclampsia) or for a small fetus (to assess the possibility of FGR based on placental insufficiency). Failure of complete development of a uterine artery pattern (Fig. 21-19), especially in patients with a history of prior severe preeclampsia or eclampsia, may be indicative of recurrent maternal disease or FGR. Prophylactic trials using first-trimester uterine artery Doppler screening to allocate low-dose aspirin offer promise.^{165,166} However, a monitoring role for uterine artery Doppler in the third trimester has not been established, because as many as two thirds of preeclamptic mothers have normal uterine artery Doppler tracings.

Maternal Cerebral Doppler Studies

Initial interest in maternal MCA Doppler in the monitoring and pharmacologic management of serious preeclampsia has not become standard of practice.^{167,168} The maternal MCA can be visualized through the thin temporal window just anterior to the temporal artery. Characteristics in normal and hypertensive pregnancies are shown in

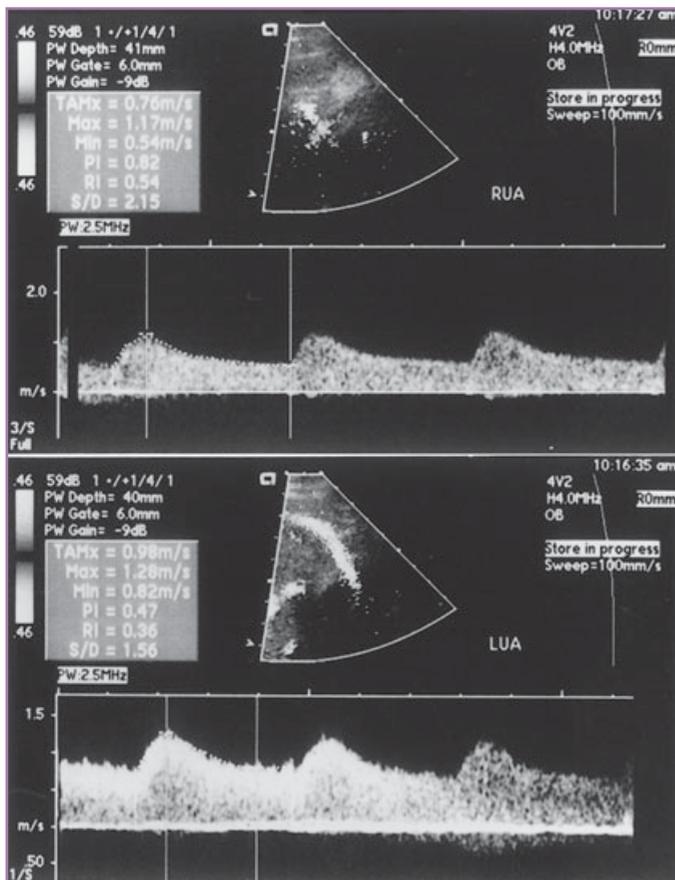

FIGURE 21-18 Normal maternal Doppler studies from right (RUA) and left (LUA) uterine arteries. Low resistance, high diastolic flow, and little difference from one side to the other characterize normal placentation.

Figure 21-20. Monitoring of maternal cerebral circulation, especially in women who were eclamptic and are being treated with multiple antihypertensive drugs including acute vasodilators such as nitroglycerin, may offer a role for serial monitoring of these vessels.¹⁶⁹ In general, however, the research demonstrating the powerful and almost immediate effect of magnesium sulfate in producing dilation of the cerebrovasculature, thus releasing arterial spasm, means that clinical application of maternal MCA Doppler is seldom mandatory.¹⁷⁰ More recent studies, with a better understanding of maternal MCA characteristics specific to pregnancy, have focused on monitoring changes.^{171,172}

Doppler Application

Important applications of Doppler technology exist from the first trimester to near term. Evaluation of placentation through uterine arteries can predict the frequency and severity of preeclampsia and placenta-based FGR. Umbilical artery Doppler provides insight into the fetal aspects of placentation, directly reflecting placental vascular resistance. These findings are strongly correlated with FGR and multiple critical fetal and neonatal outcome characteristics, progressively worsening as reduction, loss, and reversal of diastolic flow follow in deteriorating sequence. As umbilical artery abnormalities advance, direct assessment of the fetal circulation, using a combination of systemic arterial and venous Doppler waveforms (MCA and precordial

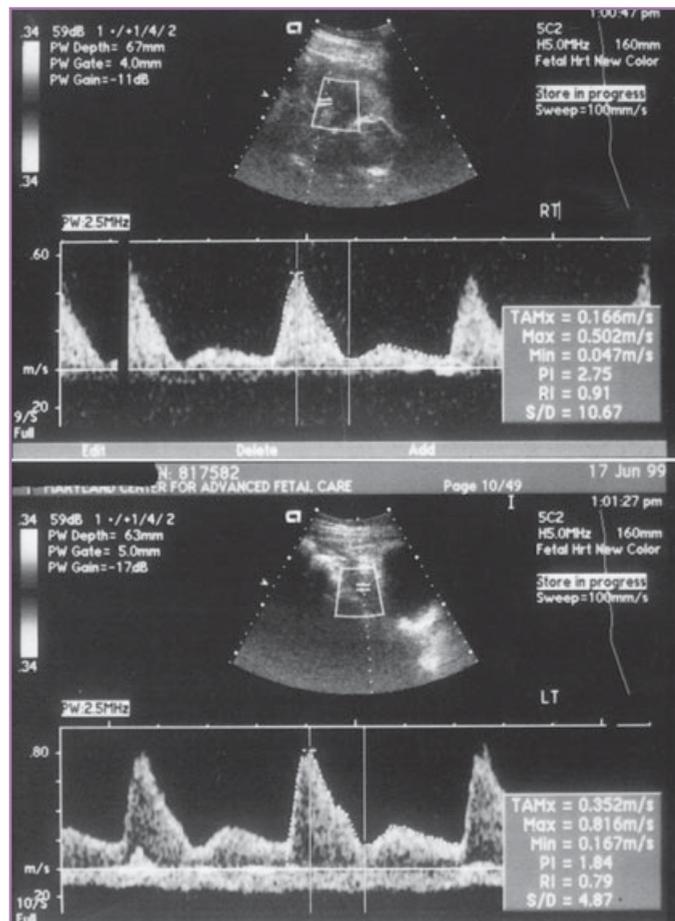

FIGURE 21-19 Uterine arteries. Markedly abnormal uterine arteries in mother with lupus, hypertension, superimposed preeclampsia, and intrauterine growth restriction (at same gestational age as woman in Fig. 21-18). Note the increased resistance, the persistent diastolic notching, and the significant difference between right (RT) and left (LT).

veins, respectively), becomes of increasing importance in accurately depicting fetal status. Combining these Doppler techniques can be done efficiently in the context of a regular fetal assessment examination. Doppler information from all these sources (placental, systemic arterial, and systemic venous), coupled with biophysical variables, provides the ideal depiction of fetal status. Although these techniques have evolved separately, the reasons to use this multivessel approach are compelling.

Patterns of Deterioration

In general, placental abnormalities may persist for months before other Doppler parameters deteriorate. As placental resistance increases (e.g., as more and more placental infarcts occur), the cerebroplacental ratio shifts, reflecting a change in balance between placental and systemic perfusion—that is, there is redistribution. Then, brain sparing is invoked, with progressive abnormalities in umbilical artery circulation (AEDV, progressing to REDV) being associated with increasingly higher diastolic velocities in the MCA. By this time, subjective elements of behavior, such as increasing intervals of quiet sleep (state 1F), decreased velocity of fetal movements (often perceived by the mother as “weaker” movements), and elements of subjectively decreased

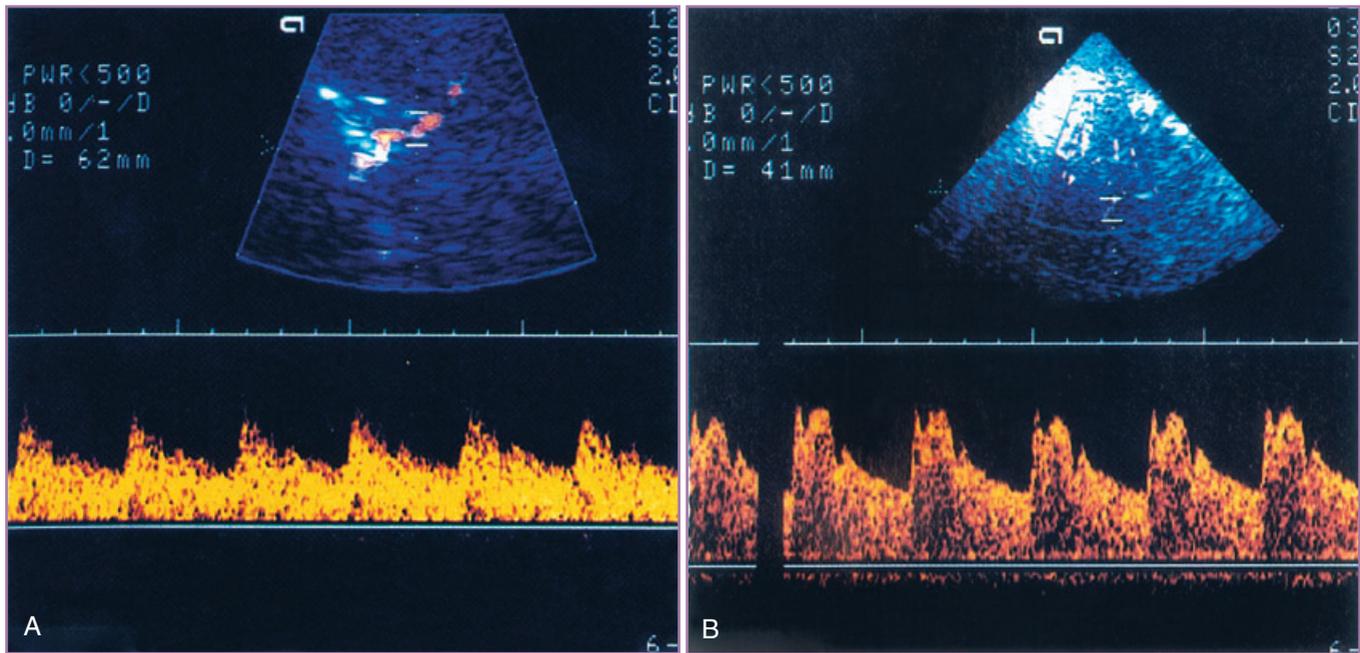

FIGURE 21-20 Maternal intracranial Doppler examination. **A**, Normal middle cerebral artery (MCA) Doppler waveform has a modest systolic peak less than 60 cm/sec, a diastolic peak less than 30 cm/sec, and slight notching. **B**, Abnormal maternal MCA in preeclamptic woman at 26 weeks has higher velocities (102 and 50 cm/sec, respectively), with systolic and diastolic notching.

amniotic fluid, may begin to appear.¹⁰⁷ With onset of AEDV, progressive redistribution yields overt centralization, and oligohydramnios becomes more common. The NST often becomes flatter, with overt nonreactivity at or just before deterioration of precordial veins, including retrograde ductus venosus a-wave. At about this time, reversal of end-diastolic velocities in the umbilical artery may occur (although this progression is completed in only 20% of fetuses with severe IUGR), with progressive loss of fetal breathing movements, followed by loss of fetal tone, and then abolition of all movements, as the BPS becomes overtly abnormal (Fig. 21-21).³⁴

Integrated Fetal Testing

This stereotypical path of deterioration is not always followed, and it does not always progress at a predictable rate. Thus, management strategies cannot be based on the anticipation that one specific finding inevitably means that delivery must occur within a specified short period of time. The Growth Restriction Intervention Trial (GRIT) (see later) demonstrated that reacting to Doppler findings in such an automatic fashion led to unnecessary prematurity, with long-term neurologic consequences.¹⁷³ Responding to absent end-diastolic umbilical artery velocities simply by delivery is not only unnecessary but has substantial consequences. When IUGR is studied using multiformat testing (multiple Doppler indices plus biophysical parameters), the overriding principle is that gestational age determines outcome over a wide range.⁴² Only as severely compromised fetuses reach the third trimester does umbilical venous Doppler become a statistically important correlate of outcome, and its performance in indicating delivery is inferior to ductus venosus Doppler plus biophysical parameters. Studies to date constitute complex observations in severely compromised FGR fetuses. These are difficult studies, requiring intensive detail of both multivessel Doppler and BPS, but the resulting data produce many valuable insights into monitoring. They are not, however, ran-

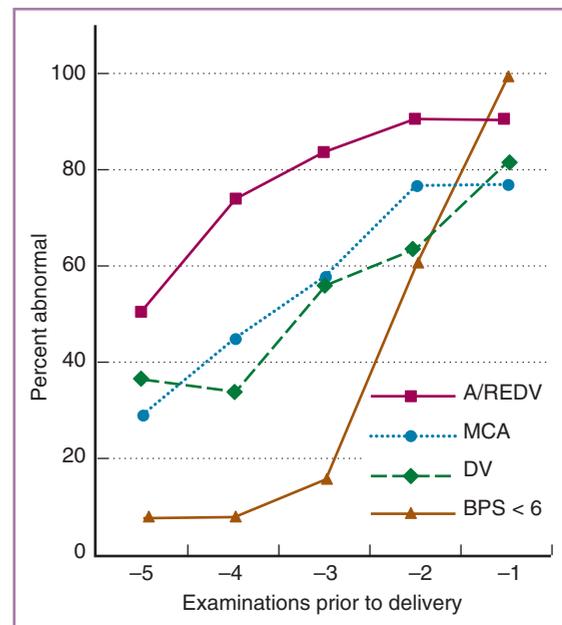

FIGURE 21-21 Deterioration in Doppler waveforms before delivery for abnormal biophysical profile score (BPS). All fetuses had prospective Doppler studies, and management decisions were made according to BPS. A/REDV, Absent or reversed end-diastolic velocity; DV, ductus venosus; MCA, middle cerebral artery.

domized controlled trials. So, the system of combined Doppler and biophysical parameters displayed in Table 21-7, although it follows the principles clarified in those studies, remains to be validated as a superior method by randomized controlled trials.

In our clinical application of this protocol, the rigorous monitoring of all systems inevitably generates data that can further refine its

TABLE 21-7 **PROTOCOL FOR MANAGEMENT OF SUSPECTED INTRAUTERINE GROWTH RESTRICTION (IUGR) BY INTEGRATED FETAL TESTING****IUGR Unlikely**

Normal AC, AC growth rate, and HC/AC ratio.
 UA and MCA Doppler normal, BPS and AFV normal.
 Asphyxia very rare, low risk for intrapartum distress.
 Monitor growth monthly. Deliver for obstetric or maternal factors.

IUGR Uncomplicated

AC < 5th percentile, slow AC growth rate, high HC/AC ratio.
 UA elevated, MCA and DV normal. BPS and AFV normal.
 Asphyxia very rare, at risk for intrapartum distress.
 Monitor with weekly BPS, multivessel Doppler biweekly. Deliver for obstetric or maternal factors.

IUGR with Blood Flow Redistribution

IUGR is diagnosed based on above criteria. MCA centralized, DV normal.
 BPS and AFV normal.
 Hypoxemia possible, asphyxia rare. Increased risk for intrapartum distress.
 Monitor with BPS twice per week, weekly Doppler. Deliver for obstetric or maternal factors, or at term.

IUGR with Marked Blood Flow Redistribution

Umbilical artery progresses to A/REDV, MCA continues centralized, DV normal. BPS \geq 6/10, oligohydramnios frequent. These Doppler changes mark the onset of fetal compromise. Hypoxemia common, acidemia or overt asphyxia are possible.
 >34 weeks: deliver. Majority will not tolerate labor with oligohydramnios. (Cesarean section rate 85% for this group.)
 Before 34 weeks, monitor daily with integrated fetal testing, give antenatal steroids, consider transfer to tertiary center.

IUGR with Proven Fetal Compromise

Significant redistribution is present, evident by markedly abnormal UA resistance, MCA centralization, increased DV pulsatility, without a-wave reversal or UV pulsations. BPS \geq 6/10, oligohydramnios is frequent.
 More serious fetal compromise, delivery decision is imminent. Acidemia or asphyxia increasingly possible.
 Integrated fetal testing daily, up to three times daily, depending on individual characteristics. Beyond 32 weeks, steroids given, deliver at tertiary center. Before 32 weeks, admit for monitoring, give steroids, transfer to tertiary center.

IUGR with Fetal Decompensation

All the above criteria are met. DV abnormalities progress to absent or reversed a-wave, with or without pulsatile UV. BPS must be 6/10 or greater to delay delivery.
 This is the preterminal stage of fetal decompensation, featuring cardiovascular instability, metabolic compromise, imminent stillbirth, high perinatal mortality irrespective of intervention.
 Beyond 28 weeks or if steroids given, deliver by cesarean section at a tertiary care center with highest level NICU.
 Before 28 weeks, monitor continuously and administer at least one dose of antenatal steroids.

AC, abdominal circumference; AFV, amniotic fluid volume; A/REDV, absent/reversed end diastolic velocity; BPS, biophysical profile scoring; DV, ductus venosus; HC, head circumference; NRFHR, non-reassuring fetal heart rate; MCA, middle cerebral artery; NICU, neonatal intensive care unit; UA, umbilical artery; UV, umbilical vein.

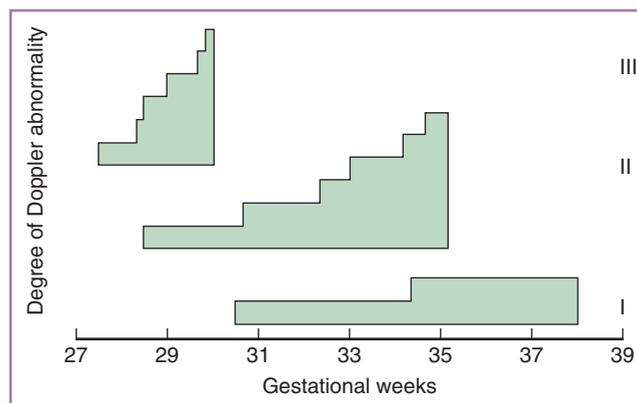

FIGURE 21-22 Patterns of Doppler deterioration in severe placental disease. In pattern I (*lower box*), diagnosis is at average of 29 to 30 weeks. Progression from abnormal umbilical artery alone to umbilical artery abnormalities plus brain sparing occurs in some, but deterioration to severe placental insufficiency generally does not occur and delivery is close to term. In pattern II (*middle box*), gradual escalation with changes in stages occurring about every 10-14 days causes gradual progression to severe Doppler parameter changes in a minority. Onset is at 28 to 30 weeks and delivery somewhat before term, but outcome is generally favorable. In pattern III (*upper box*), progression is rapid, with deterioration from the relatively early onset of multiple vessel disease to full involvement of all vascular targets requiring urgent premature delivery of potentially compromised fetuses over only 2 to 3 weeks. A primary advantage of identification of these patterns is that differentiation is enabled in the first few weeks of careful monitoring using integrated fetal testing, allowing timely planning, individualized monitoring, and optimal delivery conditions.

application. These findings emphasize the need for flexibility, even when integrated fetal testing is applied. There are generally three patterns of change after a diagnosis of placenta-based FGR by umbilical artery Doppler criteria; these three patterns follow different time courses, and they require different levels of monitoring and different degrees of intervention (Fig. 21-22). Clearly, although the acute group requires intensive monitoring over a short period of time, that degree of resource allocation would be redundant in the other groups. That these patterns can be discriminated from one another during as few as 2 weeks of careful assessment means valuable resources can be properly allocated.

In many situations, a maternal disorder has a prominent vascular component (e.g., lupus, chronic renal disease, chronic hypertension, diabetes with vascular involvement, monochorionic twins, and dichorionic twins with marked discordance). When the vascular abnormalities of such conditions affect the fetus and placenta, integrated fetal testing may be ideal for fetal monitoring. The management of the fetus with IUGR is also addressed in detail in Chapter 34.

Ancillary Tests

As with any patient, the history and physical come first. Maternal risk factors, such as cigarette smoking, hypertension, antiphospholipid antibody syndrome, thrombophilia, vascular effects of diabetes, cocaine and other toxic substance abuse, and other sources of placental impairment, have a primary role in indicating surveillance for fetuses. Nuchal translucency and first-trimester maternal serum analytes, detailed

review of fetal anatomy, serial evaluation of growth, amniotic fluid volume, and Doppler patterns all set the stage for the monitoring protocols described here. Overlapping risk factors mean modifying surveillance protocols to focus on vascular issues, reduce testing intervals based on severity, and apply ancillary testing. The provision of adequate prenatal care is itself a monitoring tool, capable of direct impact on perinatal and long-term outcome.¹⁷⁴⁻¹⁷⁶ Such information is not static, and sonographers should interact freely with patients at every visit. Receptiveness to all channels of information about maternal and fetal well-being is a statistically important supplement to any monitoring technique.

Contraction Stress Test and Oxytocin Challenge Test

The contraction stress test (CST) and the oxytocin challenge test (OCT) are active tests using FHR responses to uterine activity to evaluate fetal health. The CST uses spontaneously occurring contractions or contractions induced by maternal nipple stimulation.¹⁷⁷ The OCT uses intravenous oxytocin to cause repetitive uterine activity¹⁷⁸ (Fig. 21-23). Interpretation includes standard NST parameters (accelerations, FHR baseline, and variability) and the FHR response once a contraction pattern has been established.

The technique is similar to that of the NST, except that the mother may not be monitored sitting or supine. (Postural artifact and restric-

tion of fetal movement in response to contractions may generate falsely alarming tests.) Once a contraction pattern is established, with at least three contractions in 10 minutes, evaluation is possible. A negative OCT has no decelerations or other unclassifiable changes from baseline with contractions.¹⁷⁸ There may be isolated decelerations or times when the FHR is not adequately monitored, so normal criteria suggested by Schifrin¹⁷⁹ include any monitored segment in which three consecutive contractions are not associated with FHR decelerations.

Interpretation of a positive (abnormal) CST or OCT is also disputed. The classic standard is that FHR decelerations must accompany at least three consecutive contractions.¹⁷⁹ Another interpretation categorizes the CST as positive if at least 50% of the contractions cause late decelerations (when there are at least three contractions in 10 minutes), or when all the contractions are associated with late decelerations but there are fewer than three in 10 minutes.¹⁸⁰ An equivocal CST or OCT demonstrates repetitive decelerations not late in timing and pattern, usually classified as variable decelerations. Because this is a marker for oligohydramnios or cord entrapment, further assessment is required for this category of tests as well.^{181,182}

For the OCT, intravenous oxytocin by continuous infusion pump is started at 0.5 mU/min, titrating upward in 1-mU increments until three contractions occur in each 10-minute window. This is done in a hospital setting to enable emergency response to hyperstimulation, unremitting contractions despite discontinuing the oxytocin, tetanic

FIGURE 21-23 Oxytocin challenge test and contraction stress test. **A**, Oxytocin challenge test. Once contractions were established, repetitive late decelerations occurred with each contraction (a positive oxytocin challenge test). Delivery was by cesarean section because of fetal distress as induction of labor was attempted. Note that different strengths of contractions produced different depths of deceleration, all late in timing. **B**, Contraction stress test. Even trivial uterine activity caused late decelerations (a positive contraction stress test) in this fetus with severe intrauterine growth restriction and with abnormal Doppler parameters. Biophysical profile score was 4/10 at 25 weeks.

contractions, and fixed fetal bradycardia. Although the more dangerous consequences of these events are rare, hyperstimulation occurs in more than 10% of tests.¹⁸³

Clinical application of these tests has become marginalized for several reasons. First, the method may have significant complications. Second, even for normal testing, the method is time consuming and expensive, usually taking up to 40 minutes to provoke contractions and ensure normality, and much longer if the test is equivocal or abnormal. Third, although these tests are good indicators of fetal well-being when negative (negative predictive values exceeding 99.8%), a positive test is not accurate enough to form the basis for clinical action. Positive predictive values for perinatal mortality of 8.7% to 14.9%, and for morbidity up to 70% for low 5-minute Apgar scores, fetal distress, and cesarean delivery for abnormal FHR in labor, show correlations but do not justify emergency delivery. When BPS is the backup test for a positive CST or OCT, at least 50% of pregnancies may be safely allowed to continue 1 week or more.⁵² Furthermore, when multivariable testing is evaluated, outcomes correlate better with BPS variables than with elements of the CST or OCT, and the stress portions of the testing are irrelevant.^{184,185} Few centers use either of these tests as a first-line method for high-risk pregnancy fetal monitoring. A residual role for OCT may be in allowing a trial of labor in patients with third-trimester FGR and oligohydramnios (if OCT is negative) and in monitoring some fetuses with unique presentations. For the preterm fetus with FGR who has normal amniotic fluid and normal BPS but who also has markedly abnormal Doppler velocimetry in multiple vessels, highly suggestive of placental insufficiency, the combination of stressed testing and fetal blood sampling for pH and cord blood gases may allow continuation of the pregnancy.

Vibroacoustic Stimulation

Where NST or other forms of FHR monitoring are the primary means of evaluating fetal health, the nonreactive test resulting from fetal quiet sleep (state 1F) is a major source of falsely alarming tests and consumes an inordinate amount of time (usually nursing time) waiting for state change. Vibroacoustic stimulation (VAS) (i.e., stimulating the fetus with a noxious vibration and noise) is effective in producing state change, fetal startle movements, and increased FHR variability, and thus in shortening the time it takes to demonstrate fetal well-being.^{186,187}

Mechanism of Action

It is not clear whether these responses require the combination of vibration and audible noise or whether they can be provoked by vibration alone. Vibration sense is fully developed throughout the body by 22 to 24 weeks,¹⁸⁸ and auditory response about a month later.¹⁸⁹ From this time on, the fetal sound environment is significant.

The normal fetus is exposed to low-frequency sound energy from a variety of sources. Direct human data are scarce, but detailed evaluation of hearing in the fetal sheep appears analogous.^{190,191} High-frequency sound is attenuated significantly, whereas low-frequency sound, such as thunder, airport noise, or the rhythm section of music, produces measurable evoked potentials in the cerebrum and appropriate deformation within the fetal ear.¹⁹² High-decibel impact may even produce damage in low-frequency areas.¹⁹³ This discrimination probably extends to differentiation of vowels (low frequency, easily heard) from consonants (higher frequency, probably heard poorly) and produces apparent learning behavior.¹⁹⁴ The latter includes recognition of or favoring the maternal voice over other voices, apparent recognition of music played in fetal life (whether it is the actual music and its

multiple tones or simply the rhythm is unclear), and perceived responsiveness to intrauterine music.¹⁹⁵ Again, it is unclear whether it is the actual music or merely its vibratory pattern that the fetus favors; apparently low-amplitude music with a slow rhythm is soothing, whereas high-amplitude, high-frequency, high-rate rhythmic music produces significant accelerations¹⁹⁶ and perhaps even a state change to hyperactive 4F.¹⁹⁷

Given these observations about fetal hearing and the exquisite sense of vibration that is developed even earlier, it is not surprising the fetus can be “stimulated” by electromechanical devices that induce a very broad band of atonal white noise from 0.1 to 10 kHz.¹⁹⁸ Depending on the instrument used, this may deliver sound pressure exceeding 130 decibels (enough to produce permanent damage) and at almost all points in the entire range in excess of 70 decibels (comfortable hearing).¹⁹⁹ A number of different instruments, including ordinary alarm clocks, tin cans, electric toothbrushes, clapping hands, and electric door buzzers, have been used to provoke the classic fetal response.

VAS induces reproducible state changes in fetuses.¹⁹⁷ When the fetus is in quiet sleep (1F), even short bursts of VAS provoke the movement patterns, type of movement, fetal posture, FHR, and FHR variability typical of state 2F. If the fetus is already in state 2F (moving actively), the VAS may generate conversion to 4F (hyperactive “jogging” fetus) and almost always results in increased frequency of movements, amplitude of movements, rise in heart rate, and exaggerated FHR variability. On occasion, fetal bradycardia has been incited.²⁰⁰ That VAS is useful in persuading a breech-presenting fetus to turn spontaneously into the transverse position with one or two applications²⁰¹ is seen by some as a useful or even essential adjunct to external cephalic version²⁰² but by others as undue punishment for malpresentation.²⁰³ The high frequency of state change in the human fetus, especially close to term, means that VAS achieves its purpose of shortening the monitoring time, converting a nonreactive NST to a reactive one, and avoiding prolonged testing times,²⁰⁴ but even the most recent review expresses safety concerns.²⁰⁵

Problems with Vibroacoustic Stimulation

A large number of studies demonstrated false-positive rates as high as 67%.^{206,207} This characteristic means that the backup test (full BPS) must be available on site for the majority of patients. Of even more concern is the potential for falsely reassuring rates. Because the frequency of true fetal compromise, manifest as asphyxia before labor, intrapartum fetal distress, low Apgar scores, and abnormal pH, is very low in most of these populations, very large numbers of patients must be studied to evaluate the liability of failed detection. In trials of VAS where the prevalence of adverse outcome was reasonably high, the false-negative rate was unacceptable. For example, Serafini and colleagues²⁰⁸ documented a 55% falsely reassuring rate in the detection of intrapartum fetal distress (prevalence 20%), and Kuhlman and colleagues²⁰⁹ showed a 53% falsely reassuring rate for pH less than 7.20 (prevalence 16%).

Among the higher-risk target groups, where cases of oligohydramnios, FGR, and preterm fetuses were not excluded, preterm infants may require more sound to elicit significant responses, raising the odds of hearing injury when VAS is applied before 33 weeks' gestation.^{210,211} Responsiveness is decreased in abnormal fetuses,²¹² fetuses of mothers with hypertension,²¹³ fetuses exposed to cocaine in fetal life,¹⁹⁷ fetuses whose mothers have depression,²¹⁴ and fetuses with severe IUGR²¹⁵ treated with magnesium, antenatal steroids, or β -mimetics for preterm labor.^{216,217} Thus, the greatest liability for inaccuracies with VAS is compounded in those fetuses at greatest need for monitoring.

Is There a Role for Vibroacoustic Stimulation?

When the BPS ultrasound variables are normal (score, 8/8), there is no need for additional reassurance by NST in the majority of cases, and testing time averages 11 minutes in routine antenatal surveillance. When specifically studied in a trial of multiformat testing in FGR, VAS offered no additional information beyond the combination of biophysical and Doppler assessments. The proven convenience of VAS in shortening NST times is simply outweighed by the combination of safety concerns, an annoying false-negative rate, and a dangerous falsely reassuring rate. VAS should not be part of routine testing in high-risk pregnancies.

Fetal Movement Counting

Maternal awareness of fetal activity in the unprovoked setting has been documented for many generations. Multiple factors may influence the systematic application of movement counting as a method of fetal surveillance (Table 21-8). Sudden absolute cessation of fetal movement is alarming, but this may be a premortem event, rather than one with any realistic warning period. Second, NST alone is ineffective in monitoring the fetus with decreased movement, as shown in a large randomized trial.²¹⁸ That trial used the count-to-10 method and produced several interesting effects. First, the control group experienced a very significant drop in perinatal mortality compared with patients not enrolled in the study at all—a clear example of the Hawthorne effect, where the presence of a trial in the community produces responses even in those not undergoing the experimental maneuver. Second, the compliance for immediate reporting of decreased fetal movement was low compared with other studies. It is critical, of course, that women report the decrease on the day it happens and not at their next prenatal visit. Finally, the rescue methodology was simple FHR monitoring, with the result that a large proportion of the fetuses who ultimately died were monitored and discharged without ultrasound evaluation. The authors concluded that “routine daily counting . . . seems to offer no advantage over informal inquiry about movements during standard antenatal care.” Recent reviews of 24 available studies including two trials,^{218,219} however, conclude that positive benefits may be found, but that properly constructed trials are needed before clinical implementation is merited.^{220,221} It may well be that the information about fetal activity, especially focusing on significant changes in routine rather than absolute loss of

movement, may be effective, especially in the context of multisystem monitoring.

Invasive Fetal Testing

Fetal Blood Sampling

Fetal blood sampling as early as 17 to 18 weeks, reliably in almost every fetus by 22 weeks, has led to a wealth of experience in determining fetal metabolic, respiratory, hematologic, and genetic correlates in normal and abnormal situations. These studies offered tremendous insight into the mechanisms of disease and the application of normative values. At the same time, a catalog of noninvasive observations was also assembled—ultrasound, heart rate testing, and Doppler—which all provide key correlations to values obtained invasively. As experience was gained, it became clear that virtually any test possible in the newborn or infant could be obtained and evaluated with reliability in the fetus. Although the risks of these techniques were measurable, experienced teams were able to perform ultrasound-guided fetal blood sampling in normal-appearing fetuses (e.g., for rapid karyotype of women who attended genetic counseling late) with fetal loss rates much less than 1%, and in several series only modestly more than amniocentesis.²²²⁻²²⁴

Fetal blood sampling has specific applications:

- For fetal abnormalities, especially hydrops (red cell alloimmunization, viral infection, asphyxial injury)
- When history, maternal alloimmune titers, or MCA Doppler studies indicate a risk of anemia
- For rare metabolic, hematologic, or gene disorders testable only by fetal blood sampling
- For infrequent confirmation of ambiguous test results from amniocentesis or chorionic villus sampling
- Even more rarely, for documentation of fetal respiratory status

Ultimately, the noninvasive correlates, proven through the experience of fetal blood sampling, have rendered the actual blood test less important. Key examples include MCA Doppler peak velocity to assess the degree of fetal anemia, which has markedly reduced the need for initial fetal blood sampling.¹³⁵ The correlation between BPS and fetal

TABLE 21-8 PROBLEMS WITH FETAL MOVEMENT COUNTING (FMC)

Factors	Effect
Highly variable methodology	Confusion and inconsistent instructions
Efficacy	Physician noncompliance
Fetal/maternal variation:	
Different activity between fetuses	These factors require flexible, individualized FMC methodology.
Changing activity in the same fetus	
Different perceptions between mothers	
Different perceptions by same mother	
Public misinformation (e.g., it's OK for the baby to stop moving before labor)	Failure to follow protocol directions in unusual circumstances
Poor maternal compliance	Up to 20% of women do not count, and may falsify records
Faulty clinical response	
	Despite proper maternal performance, no definitive testing or intervention is undertaken, or too much reliance placed on the cardiotocogram alone. Biophysical profile scoring is the only acceptable response to bona fide decreased fetal movement.
Lack of public awareness	Insufficient family participation

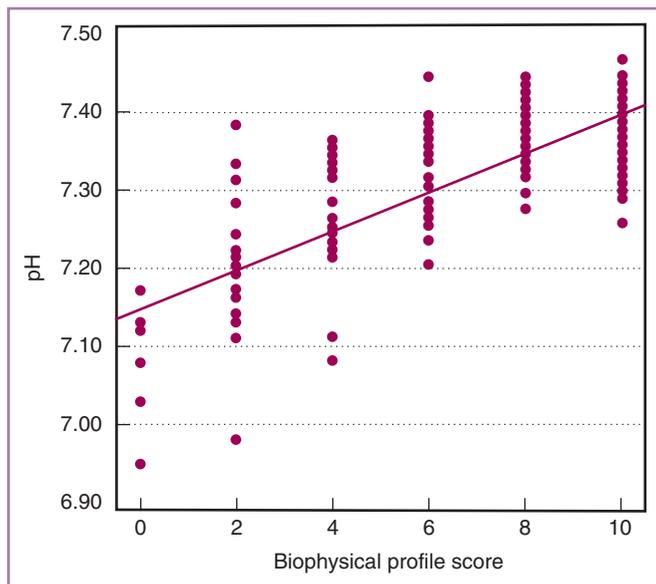

FIGURE 21-24 Correlation between biophysical profile score (BPS) and fetal pH on cordocentesis. Cordocentesis in 493 fetuses with concomitant BPS shows correlation of score with unlabored fetal umbilical venous pH. (BPS 10/10, pH > 7.20 in 100%. BPS 0/10, pH always < 7.20.) Note wide variation in pH for scores of 2 to 4/10.

pH on cordocentesis (Fig. 21-24 and see Fig. 21-2) means that BPS can be safely relied on to indicate fetal pH without the blood test.⁸⁹ Furthermore, the application of sensitive polymerase chain reaction techniques for gene amplification (together with the emergence of many new genetic markers) has replaced essential blood tests with tests of improved accuracy from fetal cells obtained by simple amniocentesis. Table 21-9 lists changes in indications for cordocentesis, noting that the modern distribution of the procedure reflects a 90% reduction in application of cordocentesis.

Cordocentesis Procedure

The umbilical vein is the target of choice, and it may be approached at virtually any point in its course. At the placental insertion, it is stable and usually easily entered, but this is also true of free loops of cord that may be pinned against the posterior wall of the uterus, the umbilical vein at the abdominal skin insertion, or in the intrahepatic portion of the vessel. The procedure itself has been greatly simplified and can usually be accomplished in a few minutes. Several previous adjuncts have been discarded, including maternal sedation, narcotic analgesia, prophylactic antibiotics, tocolysis, and admission to the hospital. Except in unusual circumstances, the mother is not prepared for emergency surgery and does not have an intravenous catheter, standby services such as obstetric anesthesia, or a reserved operating room.

A 22-gauge spinal needle of appropriate length usually suffices. Echotip needles and larger-bore introducers are seldom needed. Figure 21-25 demonstrates use of a needle guide, fixed to the ultrasound transducer. This limits excursion and angulation of the needle shaft, and the path of the needle is illustrated by software additions to standard ultrasound machines. Whereas debate has been vigorous in the last decade about measurable differences in outcome related to the use of the needle guide,²²⁵ it now appears to be truly a matter of personal preference. Most senior authors reporting large series do not use needle guides.

TABLE 21-9 CHANGE IN INDICATIONS FOR CORDOCENTESIS FROM 1991 TO 2007

Indication	1991	2007
Rapid karyotype	28%	0%
Investigate other abnormal tests	10%	15%
Red blood cell alloimmunization	23%	20%
Infection	10%	15%
Nonimmune hydrops	7%	23%
Blood gases and pH	5%	3%
Twin-twin transfusion	5%	0%
Neonatal alloimmune thrombocytopenia	5%	13%
Immune thrombocytopenia	2%	—
Immune deficiency	2%	3%
Coagulopathy	1%	—
Hemoglobinopathy	1%	2%
Paralysis for fetal magnetic resonance imaging	—	2%
Late feticide (anomalies)	—	4%

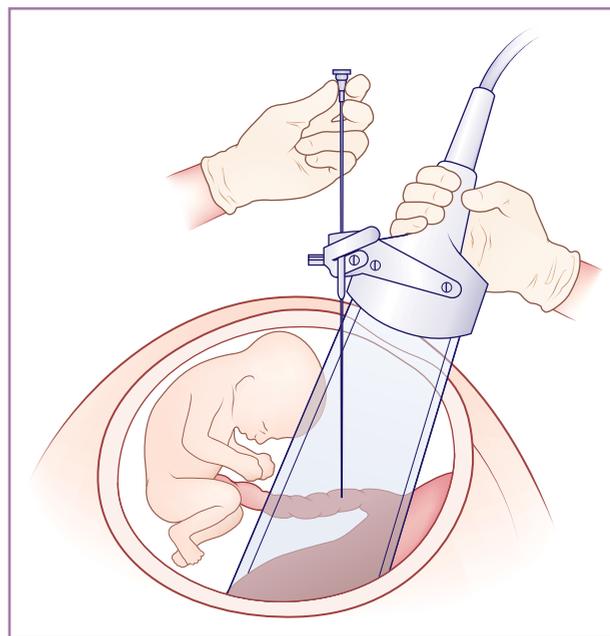

FIGURE 21-25 Cordocentesis. A needle guide is attached to the transducer, and the shaft of the needle is visualized in the ultrasound plane for this style of cordocentesis.

The maternal skin is marked for the approximate point of needle insertion, taking as much time as necessary to define the ideal approach to the clearest target vessel. Under sterile technique, the needle is inserted into the skin and imaged continuously. As the needle approaches the target vessel, the magnified field feature of the ultrasound machine is used, and the last few millimeters are completed to allow the needle tip to rest against the vessel wall. This is followed by a sharp 3- to 5-mm “pop” to overcome tissue resistance. Once the needle is seen in the lumen of the vessel, the stylette is removed and backflow is observed, which will usually gently fill the needle hub. The sample is obtained by directed flow rather than vigorous suction, as the latter tends to pull the vessel wall up against the needle and stop

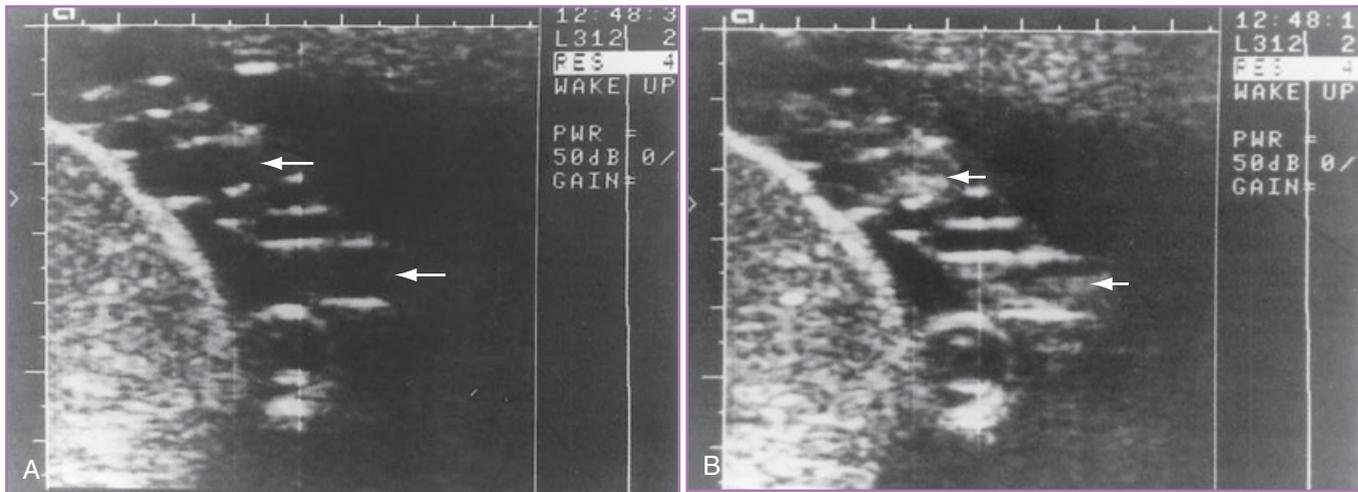

FIGURE 21-26 Turbulence during cordocentesis procedure. **A**, The umbilical cord in longitudinal section, adjacent to the fetal abdomen. The needle produced excellent return of fetal blood. No infusion. **B**, Infusion of 250 μ L of normal saline demonstrates bright turbulence, identifying the umbilical vein (arrows).

flow altogether. If free blood flow is not obtained, the needle is withdrawn in very small increments, with continuous gentle suction and rotation of the needle through a few degrees. The stylette is not replaced unnecessarily, because each stylette insertion introduces an echogenic microbubble into the ultrasound field directly above the target.

Vessel identity is confirmed by infusion of a small bolus (0.2 to 0.3 mL) of normal saline, which usually produces unmistakable turbulence (Fig. 21-26). Samples that may have been contaminated by amniotic fluid should not be discarded, because they are as reliable as pure fetal blood for polymerase chain reaction techniques or other genetic testing. On the other hand, metabolic measurements, fetal blood gases and pH, and especially hematologic measurements require absolutely pure fetal blood obtained under free-flowing conditions (without heparin in the syringe) and delivered immediately into the appropriate tubes for testing.²²⁶⁻²²⁹ For routine blood sampling, the needle is in the fetal vessel for a very short time (usually less than 2 minutes) and fetal movement is not perilous—paralysis with intravenous pancuronium (0.4 to 0.6 mg) is now rarely used.²³⁰

The needle is withdrawn gently but firmly, without changing the angle used to insert it. Bleeding from the needle puncture site is visible for all transamniotic punctures, but because this is variable, it is always monitored to cessation. Later in gestation, when a free loop is used, Wharton jelly in the cord is usually completely hemostatic, and only one or two drops escape. If vessel puncture through an anterior placenta has been completely extra-amniotic, bleeding may exist but will be invisible, so postprocedure monitoring would be hemodynamic rather than visible. Ten minutes of direct Doppler-assisted ultrasound monitoring will account for that small possibility. In the Rh-negative woman, anti-D immunoglobulin is given at the end of the procedure.

Typical turbulence and a free-flowing blood sample provide assurance that the needle was properly placed. Laboratory confirmation should be obtained that the sample is pure fetal blood without maternal contamination, which can be ensured by a variety of tests. At term, there may be a broad distribution of fetal cell sizes, so the final confirmation of pure fetal origin is not morphologic but by the Kleihauer-Betke test.²³¹ This test takes 45 to 70 minutes to complete and is thus not suitable for bedside use; only after it is reported to show 100% fetal cells should a final interpretation of results be made.

TABLE 21-10 FETAL CONDITION AND CORDOCENTESIS LOSS

Condition	Average (%)	Range (%)
Nonimmune hydrops	35	3-80
Hydramnios	20	5-33

*Statistically not different.

DS, Down syndrome; IUGR, intrauterine growth restriction.

Postprocedural Monitoring

When the immediate procedural monitoring is completed, the fetus should be moving and should have a stable heart beat with no active bleeding. The uterus should relax completely between any contractions that may have been provoked by the procedure, and the absence of a prelabor contraction pattern is confirmed by a brief period (30 minutes or less) of cardiotocography. Sample validation and verification of normal maternal and fetal status after the procedure allow discharge from the hospital, usually within 1 hour.

Complications

Overall pregnancy loss rate depends largely on the fetal condition for which the cordocentesis was done (Table 21-10).^{232,233} The rate of pregnancy loss is worse in cases of fetal hydrops, multiple anomalies, and abnormal karyotype.²³⁴

Immediate Complications

Fetal bradycardia has been reported in as many as 52% of procedures and is the most common complication of cordocentesis. It is almost always of short duration, self-limited, and usually with no long-term consequences. More serious bradycardia may occur as often as 3% of

FIGURE 21-27 Cord puncture site. Normal small bruise when transamniotic needle insertion is through Wharton's jelly. Cordocentesis produced no visible bleeding when needle was withdrawn.

the time and may indicate umbilical artery spasm. Maternal oxygen administration may relieve this spasm, and frequently it relents after a few minutes without untoward fetal effect.¹¹

In about 1 in 300 cordocentesis procedures, profound or prolonged bradycardia occurs. Undetected cord hematoma, transplacental hemorrhage, uterine activity, or combinations of these may lead to fetal death on these rare occasions.^{230,235} Reinsertion of the needle to try to aspirate a hematoma is usually unsuccessful and may cause further intrafundic bleeding.

Fetal bleeding is common, and 50% to 60% of simple vein punctures bleed for 15 to 60 seconds. Bleeding over 300 seconds or massive hemorrhage requiring resuscitation occurs less than once per 200 cordocentesis procedures.²³⁰ When this does occur, frequently the result of severe fetal thrombocytopenia, the time to act is short.²³⁶

Most often, cord hematoma is not specifically detected but is noted incidentally after delivery or as a result of emergency intervention for intractable bradycardia (Fig. 21-27). The incidence of symptomatic cord hematoma causing significant fetal bradycardia is very low.²³⁷ This is more commonly the result of difficult procedures with multiple attempts, including infusion of saline to try to identify the needle tip, infusion of pancuronium to paralyze a very active fetus,²³⁸ or deliberate infusion of platelets or blood,²³⁹ with malposition of the needle tip.

Acute maternal complications are rarely seen. Cordocentesis takes longer than amniocentesis, and the mother is likely to have more discomfort. The test is less uncomfortable than transabdominal chorion villus sampling, so for most women pain, contractions, and anxiety are not dominant complaints. Acute rupture of membranes is rare and usually associated with gross hydramnios or prolonged difficult procedures. Preterm labor is very rare.

Delayed Complications

Evidence for transmission of viral infection to the fetus from contaminated amniotic fluid or transplacentally from mothers with active diseases is not convincing. Amniocentesis does not increase hepatitis B transmission,²⁴⁰ so it has been argued that cordocentesis for human immunodeficiency virus (HIV) testing may also be safe.²⁴¹ However, the possibility of vertical transmission exists.²⁴² Therefore, the application of fetal blood sampling in mothers infected with HIV may be of

very limited value. Chorioamnionitis after cordocentesis in previously uninfected women is unusual but may be severe on rare occasions.²⁴³ Infectious agents are skin staphylococcal species and enteric organisms.

In the case of maternal alloimmunization, fetal transfusion with donor blood may cause new red cell antibody development in up to 20% of women. For simple cordocentesis, however, serologic data are much less pronounced. Between 15% and 26% of women do show significant volumes of transplacental bleeding, as judged by maternal Kleihauer-Betke test, or up to 40% as judged by elevation of maternal serum α -fetoprotein after the test.²⁴⁴ This is associated with transplacental insertion, and infrequently (in 7 of 90 women) it results in elevation of already present red cell antibody levels.²⁴⁵ No cases of clinically significant new alloimmunization developed as a consequence of cordocentesis within a 17-year surveillance window.²³⁰ This experience includes the following:

- Knowing maternal Rh before all procedures
- Administration of Rh immune globulin at the end of the procedure
- Maternal Kleihauer test after all procedures
- Follow-up additional Rh immune globulin for any case of transplacental hemorrhage of more than 10 mL of fetal red blood cells
- Avoiding the placenta if at all possible in women with known fetal-maternal incompatibility

Fetal Respiratory Status by Cordocentesis

Table 21-11 presents normative data for fetal blood gases and pH and demonstrates the progression of changes in these values with advancing gestation.²⁴⁶⁻²⁴⁸ Of course, on the rare occasions when fetal blood sampling is performed to evaluate indices of infection, acidosis in the macrosomic diabetic fetus, hematologic indices in cases of hydrops, intracranial hemorrhage, or other presentation with abnormal fetal testing, specific knowledge of the individual variables, within the gestational age limitations, is essential.

TABLE 21-12 INDICATIONS FOR ANTENATAL SURVEILLANCE*

Maternal Conditions	Placental Conditions	Fetal Conditions	Miscellaneous
Severe hyperthyroidism	Antiphospholipid antibody syndrome	Decreased fetal movement	In vitro fertilization pregnancy
Symptomatic hemoglobinopathy	Systemic lupus erythematosus	Oligohydramnios	Teratogen exposure
Cyanotic heart disease	Hypertensive disorders, including	Polyhydramnios	Previous stillbirth
Chronic renal disease	pregnancy-induced hypertension	Intrauterine growth restriction	Prior neurologic injury
Type I diabetes	of all severities	Post-term pregnancy	Previous recurrent abruption
Marked uterine anomalies	Thrombophilia	Alloimmunization	
	Marked placental anomalies	Macrosomia	
		Fetal anomalies or aneuploidy	
		Multiple gestation (all)	

*Monitoring of pregnancies with abnormal Doppler parameters and no apparent underlying disorder remains controversial. Modified from American College of Obstetricians and Gynecologists Practice Bulletin #9, October 1999.

TABLE 21-13 SUGGESTED ANTENATAL FETAL SURVEILLANCE

Condition	Begin Surveillance*	Timing
Pregnancy-induced hypertension	At diagnosis	Weekly UA Doppler
Preeclampsia	At diagnosis	Twice weekly UA Doppler + BPS
Chronic hypertension	28-32 weeks	Weekly BPS or MBPS
Fetal growth restriction (FGR)	At diagnosis	Integrated fetal testing
Gestational diabetes		
A1	At 40 weeks	Weekly BPS or MBPS
A2	At 36 weeks	Weekly BPS or MBPS
Pregestational diabetes	At 28-32 weeks	Twice weekly BPS/MBPS
Diabetes w/macrosomia	At diagnosis	Twice weekly BPS/MBPS
Vascular disease	At 24-28 weeks	Integrated fetal testing
Postterm	At 41 weeks	Twice weekly BPS/MBPS
Multiple gestation, concordant fetus FGR	At 32-34 weeks	Weekly BPS/MBPS
Multiple gestation, discordant fetus FGR	At diagnosis	Integrated fetal testing

*Start earlier for severe disease, complicated disease, prior pregnancy losses. Patient care should be individualized. Some patients may require biophysical profile scoring, amniotic fluid index, Doppler flow studies, or other testing in addition. BPS, modified biophysical profile score; MBPS, modified BPS, consisting of fetal nonstress test and ultrasound measurement of amniotic fluid maximum vertical pocket depth; UA, uterine artery.

Practical Fetal Testing

Who, When, How to Test

The monitoring methods discussed to this point lack the certainty of multiple randomized controlled trials. At the same time, an inference is clear—outcome improves in monitored populations. Table 21-12 shows factors that should prompt scheduled fetal surveillance. This table is not exclusive, as many historical factors and combinations of influences dictate fetal surveillance. There is not yet general agreement on whether isolated Doppler findings indicate a full program of surveillance, or simply repeating the Doppler studies after an appropriate interval (e.g., 4 to 6 weeks when uterine artery Doppler parameters are abnormal in the mid trimester). For a number of pregnancy complications of vascular origin, Doppler surveillance has been proven effective in randomized controlled fashion. Thus, in many circumstances, abnormal umbilical artery Doppler studies might indicate placental conditions, and abnormal fetal systemic Doppler studies might indicate fetal conditions.

When to initiate monitoring has not been established by randomized trial, nor is it likely to be. General guidelines, such as those established by the American College of Obstetricians and Gynecologists, suggest starting monitoring at 32 to 34 weeks. If the threshold of viabil-

ity at a tertiary institution is 24 weeks and the presentation is one of severe fetal growth restriction, monitoring is likely to be started early and repeated often, customized to the maternal and fetal status. Testing frequency is also determined by the severity of the disorder and varies from 6 weeks for general review of fetal growth, to three times a day for severe FGR with abnormal venous Doppler. Some examples of onset and testing frequency are displayed in Table 21-13. This table emphasizes the individualization of fetal testing and the important principle of disorder-specific surveillance. Understanding the mechanism by which the high-risk disorder affects the fetus is the key for selecting the monitoring method and adding other variables, such as modifying recommended intervals and prioritizing specific observations. For example, in chronic placental insufficiency with asymmetric IUGR, a combination of multivessel Doppler, measuring fetal growth, and modifying heart rate interpretation (FGR fetuses have delayed maturation of heart rate variability) is added to the base BPS framework.¹⁰⁴

Why? Impacts of Monitoring on Perinatal Mortality

Two examples are useful here. First, using BPS in the context of a multidisciplinary perinatal team is associated with significant changes in perinatal mortality (Table 21-14).^{53,249-251} These data reflect changes

not only in monitoring but also in referral patterns, awareness of complications, and a comprehensive management scheme, not just statistical associations with outcome. Although the strength of this evidence is not ideal, it becomes difficult to evaluate further such a relationship, because this level of monitoring is now considered standard of practice. It seems clear from these results, however, that an ultrasound-based system of fetal assessment can produce important benefits. The power of these studies is in the large number of subjects, giving these data effective strength similar to a smaller randomized trial.

Similar analysis has demonstrated the impact of Doppler velocimetry on perinatal mortality. This assessment is more complicated because of the number of Doppler techniques, the various thresholds for intervention, and the degree of integration of biophysical variables. In general, perinatal mortality frequency rises exponentially—from isolated umbilical artery Doppler index elevation, to complex Doppler abnormalities, including REDV in the umbilical artery and reversal of the a-wave in the ductus venosus. The data²⁵²⁻²⁵⁵ displayed in Table 21-15 are not sufficiently uniform to form a cohesive meta-analysis. Several studies that examined umbilical artery Doppler alone are more than a decade old. More modern studies looked at umbilical artery Doppler in the context of multivessel Doppler, with or without FHR testing, full BPS or integrated fetal testing. On the other hand, the conclusion seems clear that when pregnancy is complicated by vascular disorders (including placenta-based IUGR), Doppler should form part of the monitoring scheme. This principle will be further clarified with publication of the TRUFFLE (Trial of Umbilical and Fetal Flow in Europe) study and others examining randomized clinical application.

Program (ref)	N	PNM per 1000	
		Tested	Not Tested
Ireland (250)	3,200	4.1	10.7
Nova Scotia (249)	5,000	3.1	6.6
Manitoba (251)	56,000	1.9	7.7
California (53)	15,000	1.3	8.8

Testing the Tests

Even more important than short-term measures are the impacts on long-term development. Randomized trials are not yet available that prove the impact of antenatal monitoring on long-term neurologic and intellectual health. Long-term outcome studies are expensive, are difficult to construct, and suffer from progress: by the time most such studies are completed, their premises have been overcome by further advances. Two examples, however, are illustrative.

Growth Restriction Intervention Trial

The Growth Restriction Intervention Trial (GRIT)²⁵⁶ studied 573 high-risk pregnancies in a multicenter randomized intervention trial. When physicians enrolled patients with clinical IUGR, the patients were randomly allocated to be delivered immediately or to have delivery delayed until the clinician was certain that delivery was required. No set criteria were mandated by the trial about when that certainty was reached. As such, the results of GRIT, displayed in Table 21-16, represent a management approach with an extremely variable intervention arm. Perinatal mortality was the same with either approach. Those who were delivered immediately had a lower stillbirth rate (0.67%) but a much higher neonatal death rate from prematurity (9%). In contrast, those who waited until diagnostic certainty before delivery had a stillbirth rate of 2.4% and neonatal death rate of 6%. Cesarean delivery was almost three times as likely in those who were delivered immediately. Critical information about GRIT, which became available when follow-up data were presented, included differences in cerebral palsy and total disability rate among survivors and clearly favored retention of the pregnancy, optimizing intrauterine time.

Emotional disorders of childhood (control variable)	1.2	1.0	1.2, NS

*Rates are per 1000 live births.

Neurologic Outcome in Biophysical Profile Score Management

Manning and colleagues did use the fixed criteria of BPS to indicate delivery timing.²⁵⁷⁻²⁶⁰ However, this study (Table 21-17) includes high-risk pregnancies of many kinds, including pregnancies with maternal complications such as diabetes and hypertension, which did not necessarily include IUGR or Doppler abnormalities. They used health records of children who were live-born after BPS was used to manage the complicated pregnancy, compared with all other children born during the same years in a regional health district in Canada. Patients were not randomized. In fact, the preferential selection of high-risk cases for monitoring means that differences in pregnancy parameters favored the untested group, whose outcomes could have been expected to improve. Differences in mean birth weight (2090 g versus 2280 g), frequency of babies less than 1 kg (14% versus 6.7%), mean gestational age (32.4 weeks versus 34.4 weeks), and deliveries before 28 weeks (13.5% versus 10.9%) meant that the tested population had higher frequencies of factors expected to have adverse neurologic outcomes. The diagnostic grouping “emotional disorders of childhood” did not differ between groups, excluding the role of ascertainment bias. As discussed (see Biophysical Profile Scoring earlier), there is a direct correlation between worsening scores and increased cerebral palsy rate.²⁶¹ The data displayed in Figure 21-28 suggest that intervention on the basis of BPS may lower that rate. Review of the origins of cerebral palsy demonstrates meaningful reduction in intrapartum causes (6% in the tested group, 9% in the untested group) and neonatal time period (28% versus 33%, respectively).²⁵⁷

Summary

The first prenatal visit initiates a process of monitoring. Identification of family, historical, and maternal risk factors begin to customize fetal monitoring at the onset. Specific fetal data, including first- and second-trimester screening, biochemical testing, and growth evaluation, further refine that assessment. As indicated by the presence of risk factors, multivariable fetal assessment, biophysical profile scoring as a central element, and the liberal addition of multivessel Doppler assessment of placental and fetal circulations can achieve the optimal balance between maturity and safety. The process continually renews the balance between the risks of neonatal injury resulting from prematurity and the risks of stillbirth and permanent injury from waiting too long. The details of fetal testing continue to evolve as further data become available, but these principles endure: multivariable testing,

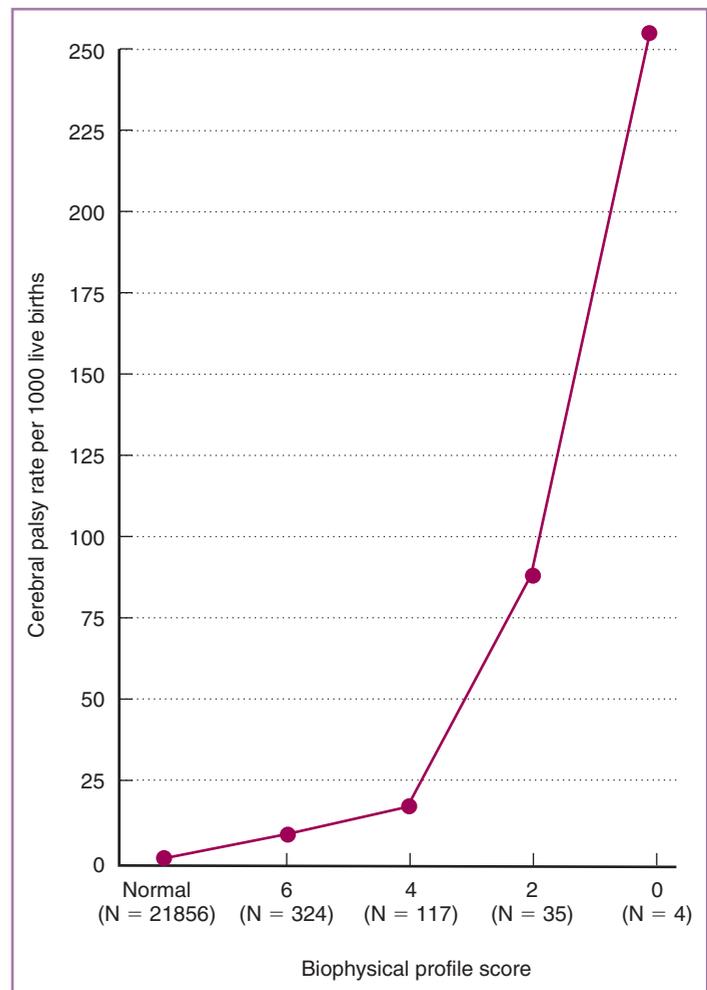

FIGURE 21-28 Abnormal biophysical profile score (BPS) reflects cerebral palsy rate. Cerebral palsy rate is related exponentially to worsening BPS.

individualized testing reflecting maternal and fetal condition, continuous validation by reliable outcome measures.

Chapter 22

Intrapartum Fetal Surveillance

Michael P. Nageotte, MD, and Larry C. Gilstrap III, MD

Factors Controlling Fetal Heart Rate

Fetal heart rate (FHR) analysis is the most common means by which a fetus is evaluated for adequacy of oxygenation. Knowledge of the rate and regulation of the fetal heart is therefore of great importance to the obstetrician. At 20 weeks of gestation, the average FHR is 155 beats/min; at 30 weeks, it is 144 beats/min; and at term, it is 140 beats/min. This progression is thought to be related to maturation of vagal tone, with consequent slowing of the baseline FHR. Variations of 20 beats/min faster or slower than these baseline values are present in normal fetuses.

The fetal heart is similar to the adult heart in that it has its own intrinsic pacemaker activity which results in rhythmic myocardial contractions. The sinoatrial node, found in one wall of the right atrium, has the fastest rate of conduction and sets the rate in the normal heart. The next fastest pacemaker rate is found in the atrium. Finally, the ventricle has a slower rate than either the sinoatrial node or the atrium. In cases of complete or partial heart block in the fetus, variations in rate markedly slower than normal can be seen. The rate in a fetus with a complete heart block is often 60 to 80 beats/min.

Variability of the FHR is important clinically and is of prognostic value with respect to its specific amplitude as part of the FHR pattern. The heart rate is the result of many physiologic factors that modulate the intrinsic rate of the fetal heart, the most common being signals from the autonomic nervous system.

Parasympathetic Nervous System

The parasympathetic nervous system consists primarily of the vagus nerve (10th cranial nerve), which originates in the medulla oblongata. The vagus nerve innervates both the sinoatrial and the atrioventricular nodes. Stimulation of the vagus nerve results in a decrease in FHR in the normal fetus, because vagal influence on the sinoatrial node decreases its rate of firing. In a similar fashion, blockade of this nerve in a normal fetus causes an increase in the FHR of approximately 20 beats/min at term.¹ This finding demonstrates a normally constant vagal influence on the FHR, which tends to decrease it from its intrinsic rate.

The vagus nerve has another very important function: It is responsible for transmission of impulses causing beat-to-beat variability of FHR. Blockade of the vagus nerve results in disappearance of this vari-

ability. Hence, there are two possible vagal influences on the heart: a tonic influence tending to decrease FHR and an oscillatory influence that results in FHR variability.² Further, vagal tone is not necessarily constant. Its influence increases with gestational age.³ In fetal sheep, vagal activity increases as much as fourfold during acute hypoxia⁴ or experimentally produced fetal growth restriction.⁵

Sympathetic Nervous System

Sympathetic nerves are widely distributed in the muscle of the heart at term. Stimulation of the sympathetic nerves releases norepinephrine and causes increases in both the rate and the strength of fetal cardiac contractions, resulting in higher cardiac output. The sympathetic nerves are a reserve mechanism to improve the pumping activity of the heart during intermittent stressful situations. There is normally a tonic sympathetic influence on the heart. Blocking the action of these sympathetic nerves causes a decrease in FHR of approximately 10 beats/min. As with the vagal tone, tonic sympathetic influence increases as much as twofold during fetal hypoxia.

Chemoreceptors

Chemoreceptors are found in both the peripheral and the central nervous system. They have their most dramatic effects on the regulation of respiration but are also important in control of the circulation. The peripheral chemoreceptors are in the aortic and carotid bodies, which are located in the arch of the aorta and the area of the carotid sinus, respectively. The central chemoreceptors in the medulla oblongata respond to changes in oxygen and carbon dioxide tension in the blood or in the cerebrospinal fluid perfusing this area.

In the adult, when oxygen is decreased or the carbon dioxide content is increased in the arterial blood perfusing the central chemoreceptors, a reflex tachycardia occurs. There is also a substantial increase in arterial blood pressure, particularly when the carbon dioxide concentration is increased. Both effects are thought to be protective, representing an attempt to circulate more blood through the affected areas and thereby bring about a decrease in carbon dioxide tension (PCO_2) or an increase in oxygen tension (PO_2). Selective hypoxia or hypercapnia of the peripheral chemoreceptors alone in the adult produces a bradycardia, in contrast to the tachycardia and hypertension that results from central hypoxia or hypercapnia.

The interaction of the central and peripheral chemoreceptors in the fetus is poorly understood. It is known that the net result of hypoxia or hypercapnia in the unanesthetized fetus is bradycardia with hyper-

tension. During basal conditions, the chemoreceptors contribute to stabilization of FHR and blood pressure.⁶

Baroreceptors

In the arch of the aorta, and in the carotid sinus at the junction of the internal and external carotid arteries, are small stretch receptors in the vessel walls that are sensitive to increases in blood pressure. When pressure rises, impulses are sent from these receptors via the vagus or glossopharyngeal nerve to the midbrain; this results in further impulses' being sent via the vagus nerve to the heart, tending to slow it. This is an extremely rapid response, occurring almost with the first systolic rise of blood pressure. It is a protective, stabilizing attempt by the body to lower blood pressure by decreasing the heart rate and cardiac output when blood pressure is increasing.

Central Nervous System

In the adult, the higher centers of the brain influence the heart rate. Heart rate is increased by emotional stimuli such as fear and sexual arousal. In fetal lambs and monkeys, the electroencephalogram or electro-oculogram shows increased activity, at times in association with increased variability of the FHR and body movements. At other times, apparently when the fetus is sleeping, body movement slows and FHR variability decreases, suggesting an association between these two factors and central nervous system activity.⁷

The medulla oblongata contains the vasomotor centers, integrative centers in which the net result of all the inputs is either acceleration or deceleration of the FHR. It is probably in these centers that the net result of numerous central and peripheral inputs is processed to generate irregular oscillatory vagal impulses, giving rise to FHR variability.

Hormonal Regulation

Adrenal Medulla

The fetal adrenal medulla produces epinephrine and norepinephrine in response to stress. Both substances act on the heart and cardiovascular system in a way similar to sympathetic stimulation to produce a faster FHR, greater force of contraction of the heart, and higher arterial blood pressure.

Renin-Angiotensin System

Angiotensin II may play a role in fetal circulatory regulation at rest, but its main activity is observed during hemorrhagic stress on a fetus.

Prostaglandins

Various prostaglandins and arachidonic acid metabolites are found in the fetal circulation and in many fetal tissues. Their main roles with respect to cardiovascular function seem to be regulating umbilical blood flow and maintaining the patency of the ductus arteriosus during fetal life.

Other Hormones

Other hormones, such as nitric oxide, α -melanocyte-stimulating hormone, atrial natriuretic hormone, neuropeptide Y, thyrotropin-releasing hormone, cortisol, and metabolites such as adenosine, are also present in the fetus and participate in the regulation of circulatory function.

Blood Volume Control

Capillary Fluid Shift

In the adult, when the blood pressure is elevated by excessive blood volume, fluid moves out of the capillaries into interstitial spaces, thereby decreasing the blood volume toward normal. Conversely, if the adult loses blood through hemorrhage, some fluid shifts out of the interstitial spaces into the circulation, increasing the blood volume toward normal. There is normally a delicate balance between the pressures inside and outside the capillaries. This mechanism of regulating blood pressure is slower than the almost instantaneous regulation observed with the reflex mechanisms discussed previously. Its role in the fetus is imperfectly understood, although imbalances may be responsible for the hydrops seen in some cases of red cell alloimmunization and the high-output failure sometimes seen with supraventricular tachycardia.

Intraplacental Pressures

Fluid moves along hydrostatic pressure gradients and in response to osmotic pressure gradients. The specific role of these factors within the human placenta, where fetal and maternal blood closely approximate, is unclear. It seems likely, however, that some delicate balancing mechanisms within the placenta prevent rapid fluid shifts between mother and fetus. The mean arterial blood pressure of the mother (approximately 100 mm Hg) is much higher than that of the fetus (approximately 55 mm Hg), but the osmotic pressures are not substantially different. Therefore, some compensatory mechanism must be present to equalize the effective pressures at the exchange points so as to prevent dramatic fluid shifts.

Frank-Starling Mechanism

The amount of blood pumped by the heart is determined by the amount of blood returning to the heart; that is, the heart normally pumps the blood that flows into it without excessive damming of blood in the venous circulation. When the cardiac muscle is stretched before contraction by an increased inflow of blood, it contracts with a greater force and is able to pump out more blood. This mechanism of response to preload is apparently not the same in the fetal heart as in the adult heart. In the fetus, increases in preload produce minor, if any, changes in combined ventricular output, suggesting that the fetal heart normally operates near the peak of its function curve.

The output of the fetal heart is essentially related to the FHR. Some researchers have shown that spontaneous variations of FHR relate directly to cardiac output (i.e., as the rate increases, output also increases). However, different responses have been observed during right or left atrial pacing studies.⁸ Clearly, additional factors are required to explain such differences. In addition to FHR and preload, cardiac output depends on afterload and intrinsic contractility.^{8,9}

The fetal heart appears to be highly sensitive to changes in afterload, represented by the fetal arterial blood pressure. Increases in afterload dramatically reduce the stroke volume or cardiac output. As already stated, the fetal heart is incompletely developed. Many ultrastructural differences between the fetal and adult heart account for a lower intrinsic capacity of the fetal heart to alter its contraction efficiency. The determinants of cardiac output do not work separately; each interacts dynamically to modulate the fetal cardiac output during changing physiologic conditions. In clinical practice, it is reasonable to assume that modest variations of FHR from the normal range produce relatively small effects on the cardiac output. However, at the extremes

(e.g., tachycardia >240 beats/min, bradycardia <60 beats/min), cardiac output and umbilical blood flow are likely to be substantially decreased.

Umbilical Blood Flow

The umbilical blood flow is approximately 40% of the combined fetal ventricular output, and not all of this blood flow to the placenta exchanges with maternal blood. Umbilical blood flow is unaffected by acute moderate hypoxia but is decreased by severe hypoxia affecting the myocardial function. There is no innervation of the umbilical cord, and there are no known means of increasing umbilical flow. However, variable decelerations in the FHR commonly occur with transient umbilical cord compression, and flow is certainly diminished or stopped for a time, depending on the degree and duration of cord compression or occlusion.

Fetal Heart Rate Monitor

The electronic FHR monitor is a device with two components: One establishes the FHR, and the other measures uterine contractions.¹⁰ To recognize FHR, the device uses either the R wave of the fetal electrocardiogram (ECG) complex (fetal scalp electrode) or the modulation of an ultrasound signal generated by movement of a cardiovascular structure (Doppler ultrasound transducer or cardiometer). Uterine contractions are detected either directly, by a pressure transducer attached to a catheter within the amniotic cavity (intrauterine pressure catheter), or by an belt-like external device (tocodynamometer) that recognizes the tightening of the uterus during a contraction. Monitoring with devices attached directly to the fetus or placed within the uterine cavity is called “internal,” and monitoring with devices that are on the maternal abdomen is called “external.”

Fetal Heart Rate Detection

Fetal Electrode

The fetal electrode consists of a small, stainless steel, spiral wire that is typically attached to the fetal scalp. A second contact is bathed by the vaginal fluids. The wires traverse the vaginal canal and are connected to a maternal leg plate, which in turn is attached to the fetal monitor. The internal mode gives the most accurate FHR tracing, because this technique directly measures the fetal cardiac electrical signal and true beat-to-beat variability.

Doppler Ultrasound Transducer

The FHR monitoring device most commonly employed is the cardiometer or Doppler ultrasound transducer. This device emits a high-frequency ultrasound signal (approximately 2.5 MHz) that is reflected from any moving structure (e.g., ventricle wall, valvular leaflets), with the reflected signal being altered in frequency. The change in frequency with each systole is recognized as a cardiac contraction and is processed by the transducer. The interval between cardiac events is measured (in seconds) and then divided into 60 to yield a rate for each interval between beats. These calculated rates are transcribed onto a paper strip that is moving at a specific speed (usually 3 cm/min). The resulting tracing appears as a jiggly line and is a very close representation of true FHR variability. If the intervals between heartbeats are persistently identical, the resultant FHR line is straight, suggesting minimal or absent variability.

Although this device is simple to apply, it is often inconsistent in obtaining a signal because of interference caused by maternal and fetal movements. Improvements in the logic and technology of the monitors have made the external devices more accurate and easier to use. In particular, the technique of “autocorrelation” is now used to define the timing of the cardiac contraction more accurately. A very large number of points on the “curve” depicting the Doppler frequency shift are analyzed, and this produces a signal that much more accurately represents the FHR variability.

Uterine Activity Detection

Intra-amniotic Catheter

The internal means of detecting uterine activity typically uses a soft plastic, transducer-tipped catheter placed transcervically into the amniotic cavity. The pressure of the baseline uterine tone and that of any uterine contraction is translated into an electrical signal, which is calibrated and displayed directly (in millimeters of mercury of pressure).

Tocodynamometer

The tocodynamometer is an external device that is placed on the maternal abdominal wall, over the uterine fundus. The tightening of the fundus with each contraction is detected by pressure on a small button in the center of the transducer, and uterine activity is displayed on the recorder. It acts just like a hand placed on the uterine fundus through the abdominal wall to detect uterine activity. This device detects the frequency and duration of uterine contractions but not true contraction intensity. One disadvantage of the tocodynamometer is that it works best with the mother in the supine position. This limitation may not always be compatible with maternal comfort, fetal well-being, or progression of labor. With repositioning of the patient, it is important to reestablish accurate monitoring of both the fetal heart and uterine activity.

Fetal Responses to Hypoxia/Acidemia

Studies of chronically prepared animals have shown that a number of responses occur during acute hypoxia or acidemia in the previously normoxic fetus. Little or no change in combined cardiac output and umbilical (placental) blood flow occurs, but there is a redistribution of blood flow favoring certain vital organs—namely, heart, brain, and adrenal gland—and a decrease in blood flow to the gut, spleen, kidneys, and carcass.¹¹ This initial response is presumed to be advantageous to a fetus in the same way as the diving reflex is advantageous to an adult seal, in that the blood containing the available oxygen and other nutrients is supplied preferentially to vital organs. This series of responses may be thought of as temporary compensatory mechanisms that enable a fetus to survive for moderately long periods (e.g., up to 30 minutes) of limited oxygen supply without decompensation of vital organs, particularly the brain and heart.

The close matching of blood flow to oxygen availability to achieve a constancy of oxygen consumption has been demonstrated in the fetal cerebral circulation¹² and in the fetal myocardium.¹³ In studies on hypoxic lamb fetuses, cerebral oxygen consumption was constant over a wide range of arterial oxygen concentrations, because the decrease in arteriovenous oxygen content accompanying hypoxia was offset by

an increase in cerebral blood flow. However, during more severe acidemia or sustained hypoxemia, these responses were no longer maintained, and decreases in cardiac output, arterial blood pressure, and blood flow to the brain and heart resulted.¹⁴ These changes may be considered to be a stage of decompensation after which tissue damage and even fetal death may follow.¹⁵ The implications of such a scenario are of obvious importance to the fetus in utero.

Fetal Acid-Base Balance

Physiology

Normal metabolism in the fetus results in the production of both carbonic and organic acids. These acids are buffered by various mechanisms which regulate the fetal pH within a very narrow range. Although the concentration of hydrogen ions is extremely low, changes in fetal pH as small as 0.1 unit can have profound effects on metabolic activity and on the cardiovascular and central nervous systems. Extreme changes in pH can be fatal.

The maternal acid-base status can adversely affect fetal acid-base status. In normal pregnancies, the difference between maternal and fetal pH is usually 0.05 to 0.10 units.¹⁶

Carbonic Acid

Carbonic acid (H_2CO_3) is a volatile acid that is produced from the metabolism of glucose and fatty acids. During fetal oxidative metabolism (i.e., aerobic glycolysis or cellular respiration), the oxidation of glucose uses oxygen (O_2) and produces carbon dioxide (CO_2).

From a practical standpoint, carbonic acid formation is equivalent to carbon dioxide generation, and most of the free hydrogen ion formed is buffered intracellularly. As blood passes through the placenta (or through the lung in the adult), bicarbonate ion (HCO_3^-) reenters erythrocytes and combines with hydrogen ions to form carbonic acid, which then dissociates to carbon dioxide and water. The carbon dioxide thus formed in the fetus diffuses across the placenta and is excreted by the maternal lung. Carbon dioxide diffuses rapidly across the human placenta, so that even large quantities produced by the fetus can be eliminated rapidly if maternal respiration, uteroplacental blood flow, and umbilical blood flow are normal.

The rate of fetal carbon dioxide production is roughly equivalent to the fetal oxygen consumption rate.¹⁷ In order for carbon dioxide to diffuse from fetus to mother, a gradient must be maintained between PCO_2 in fetal umbilical blood and that in maternal uteroplacental blood; in addition, adequate perfusion of both sides of the placenta must be preserved. Secondary to progesterone-stimulated maternal hyperventilation, the maternal arterial PCO_2 is reduced from a mean of 39 mm Hg during nonpregnancy to a mean of 31 mm Hg during pregnancy. Renal compensation, in turn, results in an increase in bicarbonate excretion, resulting in plasma levels of 18 to 22 mEq/L during pregnancy.¹⁸

Noncarbonic Acids

Anaerobic metabolism in the fetus results in the production of non-volatile or noncarbonic acids via two mechanisms: (1) use of non-sulfur-containing amino acids, which results in uric acid formation, and (2) incomplete combustion of carbohydrates and fatty acids, which results in the production of lactic acid and the ketoacids (e.g., β -hydroxybutyric acid).

Because of relatively immature renal function, the fetus is unable to effectively excrete these acids; instead, they are transported to the

placenta, where they diffuse slowly (in contradistinction to carbon dioxide) into the maternal circulation. The maternal kidney excretes noncarbonic acids produced by both maternal and fetal metabolism and thus helps regenerate bicarbonate. Because the maternal glomerular filtration rate increases significantly during normal pregnancy, the maternal kidney filters and reabsorbs large quantities of bicarbonate daily.

The fetus does have the ability to metabolize accumulated lactate in the presence of sufficient oxygen; however, this is a slow process, and for practical purposes it is not thought to account for a large proportion of lactic acid elimination from the fetal compartment.

Buffers

Dramatic changes in pH are minimized by the action of buffers. The two major buffers are plasma bicarbonate and hemoglobin. Other, quantitatively less important buffers include erythrocyte bicarbonate and inorganic phosphates.¹⁹

Terms that are used for the expression of buffering capacity include the following:

1. *Delta base*—a measure of “change” in the buffering capacity of bicarbonate
2. *Base deficit*—bicarbonate values lower than normal
3. *Base excess*—bicarbonate values higher than normal

Although the fetus has a limited ability to buffer an increase in acid production with bicarbonate and hemoglobin, the placental bicarbonate pool could also play a role in buffering the fetus against changes in maternal pH or blood gas status. Aarnoudse and colleagues²⁰ studied bicarbonate permeability in the perfused human placental cotyledon model and found that acidification of the maternal circulation to pH 7.06 for 30 minutes did not significantly alter fetal pH. Instead, there was an efflux of total carbon dioxide from the placenta into the maternal circulation in the form of bicarbonate, which was not matched by an influx of total carbon dioxide from the fetal circulation. By this mechanism, bicarbonate transfer could take place between the placental tissue pool and the maternal circulation, while the transmission of maternal pH and blood gas changes to the fetal circulation would be minimized.

pH Determination

The pH is a measure of the acid-base status of various body fluids. Specifically, pH is the negative logarithm of the hydrogen ion concentration. It is directly related to the concentration of bicarbonate (base) and inversely related to the concentration of carbonic acid (acid). The H_2CO_3 equals $0.03 \times \text{PCO}_2$ and the pK equals 6.11 for normal plasma at 37°C. This relation is best illustrated by the Henderson-Hasselbalch equation for determining the pH of a buffered system, in which pK is the negative logarithm of the acid dissociation constant:

$$\text{pH} = \text{pK} + \log \frac{[\text{base}]}{[\text{acid}]}$$

In the case of fetal acid-base balance determinations,

$$\text{pH} = \text{pK} + \log \frac{[\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]}$$

$$\text{pH} = \text{pK} + \log \frac{[\text{HCO}_3^-](\text{mEq/L})}{0.03[\text{PCO}_2](\text{mmHg})}$$

In simplest terms, the HCO_3^- represents the “metabolic” component, whereas the H_2CO_3 (or PCO_2) represents the “respiratory” component.²¹

Terminology

Acidemia refers to an increase in hydrogen ions in the blood; *acidosis* refers to an increase in hydrogen ions in tissue. Similarly, *hypoxemia* is a decrease in oxygen content in blood, whereas *hypoxia* is a decrease in oxygen content in tissue (Table 22-1).

Although an umbilical artery pH of less than 7.20 has traditionally been used to define newborn acidemia, most clinicians define acidemia as two standard deviations below the mean umbilical artery pH (7.10 to 7.18). The concept of clinically significant or “pathologic” acidemia is discussed later in this chapter.

Acidemia in the newborn can be classified into three basic types: metabolic, respiratory, and mixed. The type is based primarily on the levels of HCO_3^- and PCO_2 (Table 22-2). With marked elevations of the PCO_2 , there is a compensatory increase in HCO_3^- of 1 mEq/L for each 10 mm Hg increase in PCO_2 .²²

Factors Affecting Acid-Base Balance

With regard to acid-base balance in the fetus, the placenta acts as both “lungs” and “kidneys” by supplying oxygen and removing carbon dioxide and various metabolites. The pH in the fetus is thus controlled within a very tight range. Umbilical blood oxygen content and saturation and fetal arterial delta base depend primarily on uterine blood flow. Oxygen supply, in turn, depends on the following:

- Adequate maternal oxygenation
- Blood flow to the placenta
- Transfer across the placenta
- Fetal oxygenation
- Delivery to fetal tissues

TABLE 22-1 TERMINOLOGY

Acidemia	Increased concentration of hydrogen ions in blood
Acidosis	Increased concentration of hydrogen ions in tissue
Asphyxia	Hypoxia with metabolic acidosis
Base deficit	HCO_3^- concentration lower than normal
Base excess	HCO_3^- concentration higher than normal
Delta base	Measure of change in buffering capacity of bicarbonate
Hypoxemia	Decreased oxygen content in blood
Hypoxia	Decreased level of oxygen in tissue
pH	Negative logarithm of hydrogen ion concentration

Adapted from American College of Obstetricians and Gynecologists: **Umbilical Artery Blood Acid-Base Analysis. Technical Bulletin No. 216. Washington, DC, ACOG, November 1995.**

TABLE 22-2 TYPES OF ACIDEMIA*

Metabolic	Normal PCO_2 and decreased HCO_3^-
Respiratory	Increased PCO_2 and normal HCO_3^- (after correction of PCO_2)
Mixed	Increased PCO_2 and decreased HCO_3^-

*Umbilical artery pH <7.10.

Removal of carbon dioxide depends on fetal blood flow to the placenta and transport across the placenta. Fixed-acid equilibrium depends on a continued state of balance between production and removal.

Respiratory Factors

Respiratory acidosis results from increased PCO_2 and subsequently decreased pH. In the fetus, this picture is usually associated with a decrease in PO_2 as well. The most common cause of acute respiratory acidosis in the fetus is a sudden decrease in placental or umbilical perfusion. Umbilical cord compression, uterine hyperstimulation, and abruptio placentae are good examples, with transient cord compression being the most common factor.

Conditions associated with maternal hypoventilation or hypoxia can also result in respiratory acidosis in the fetus (and in metabolic acidosis, if severe enough). Coleman and Rund²³ reviewed the association of maternal hypoxia with nonobstetric conditions (e.g., asthma, epilepsy) during pregnancy, noting that the normal physiologic changes that occur during pregnancy may make early recognition of maternal hypoxia difficult. For example, in a mother with asthma, a pH of less than 7.35 and a PCO_2 higher than 38 mm Hg could indicate respiratory compromise.²⁴ To minimize the risk of concurrent hypoxemia in the fetus, early intubation in mothers who have borderline or poor blood gas values or evidence of respiratory compromise is recommended.

Other conditions can result in maternal hypoventilation (acute or chronic) during pregnancy. Induction of anesthesia or narcotic overdose can depress the medullary respiratory center. Hypokalemia, neuromuscular disorders (e.g., myasthenia gravis), and drugs that impair neuromuscular transmission (e.g., magnesium sulfate) can, in toxic doses, result in hypoventilation or even paralysis of the respiratory muscles. Finally, airway obstruction from foreign bodies can also result in maternal respiratory acidosis. Restoration of normal fetal acid-base balance depends on the reversibility of maternal etiologic factors.

Maternal respiratory alkalosis may occur when hyperventilation reduces the PCO_2 and subsequently increases pH. Severe anxiety, acute salicylate toxicity, fever, sepsis, pneumonia, pulmonary emboli, and acclimation to high altitudes are etiologic factors. As in respiratory acidosis, restoration of the maternal acid-base balance by appropriate treatment of causative factors results in normalization of fetal blood gases.

Metabolic Factors

Fetal metabolic acidosis is characterized by loss of bicarbonate, high base deficit, and a subsequent fall in pH. This type of acidosis results from protracted periods of oxygen deficiency to a degree that results in anaerobic metabolism. The etiology can be fetal or maternal and usually implies the existence of a chronic metabolic derangement. Conditions such as growth restriction resulting from chronic uteroplacental hypoperfusion can be associated with fetal metabolic acidosis secondary to decreased oxygen delivery.

Maternal metabolic acidosis can also cause fetal metabolic acidosis and is classified according to the status of the anion gap. In addition to bicarbonate and chloride, the remaining anions required to balance the plasma sodium concentration are referred to as “unmeasured anions” or the *anion gap*. Reduced excretion of inorganic acids (as in renal failure) or accumulation of organic acids (as in alcoholic, diabetic, or starvation ketoacidosis and lactic acidosis) results in an increased anion gap metabolic acidosis. Bicarbonate loss (as in renal tubular acidosis, hyperparathyroidism, and diarrheal states) or failure of bicarbonate regeneration results in metabolic acidosis characterized

TABLE 22-3 FETAL SCALP BLOOD VALUES IN LABOR*

Measurement	Early First Stage	Late First Stage	Second Stage
pH	7.33 ± 0.03	7.32 ± 0.02	7.29 ± 0.04
PCO ₂ (mm Hg)	44.00 ± 4.05	42.00 ± 5.1	46.30 ± 4.2
PO ₂ (mm Hg)	21.8 ± 2.6	21.3 ± 2.1	16.5 ± 1.4
Bicarbonate (mMol/L)	20.1 ± 1.2	19.1 ± 2.1	17 ± 2
Base excess (mMol/L)	3.9 ± 1.9	4.1 ± 2.5	6.4 ± 1.8

*Mean ± standard deviation.

by a normal anion gap. Fetal responses to these maternal conditions are manifested by a pure metabolic acidosis with normal respiratory gas exchange as long as placental perfusion remains normal.

Prolonged fetal respiratory acidosis (as in cord compression and abruptio placentae) can also result in accumulation of noncarbonic acids produced by anaerobic metabolism; this condition is characterized by blood gas measurements that reflect a mixed respiratory and metabolic acidosis.

Effects of Labor

Each uterine contraction transiently diminishes uterine blood flow, reduces placental perfusion, and impairs transplacental gaseous exchange. A sample of blood may be obtained from the fetal presenting part to help evaluate fetal status during labor. Typical fetal scalp blood values during labor are shown in Table 22-3.

Umbilical Cord Blood Acid-Base Analysis

Umbilical cord blood acid-base analysis provides an objective method of evaluating a newborn's condition, especially with regard to hypoxia and acidemia.¹⁶ Assessing umbilical cord blood pH has become an important adjunct in defining perinatal hypoxia that is severe enough to result in acute neurologic injury.²⁵ Moreover, the technique is simple and relatively inexpensive.

Technique

A segment of cord (approximately 10 to 20 cm) should be doubly clamped immediately after delivery in all women, in the event that cord blood analysis is desired or deemed necessary. The cord is clamped immediately because a delay as short as 20 seconds can significantly alter the arterial pH and PCO₂.²⁶ Specimens should be obtained ideally from the umbilical artery and the umbilical vein, but the umbilical artery sample provides a more direct assessment of fetal condition, whereas the umbilical vein reflects placental acid-base status. In cases such as cord prolapse, the umbilical artery pH may be extremely low, even in the presence of a normal umbilical vein pH.²⁷ Nevertheless, some clinicians still prefer to use the umbilical vein, which is easier to access for drawing blood, especially in the very premature infant. In one study of 453 term infants, D'Souza and colleagues²⁸ determined that umbilical venous and arterial blood pH are significantly related to each other and that umbilical venous pH measurements do provide useful information regarding newborn acidemia at birth.

Samples should be drawn in plastic or glass syringes that have been flushed with heparin (1000 U/mL). Commercial syringes (1 to 2 mL) containing lyophilized heparin are also available for obtaining specimens. Kirshon and Moise²⁹ reported that the addition of 0.2 mL of

10,000 U/mL of heparin to 0.2 mL of blood significantly decreased the pH, PCO₂, and bicarbonate. Therefore, any residual heparin (as well as air) should be ejected, and the needle should be capped.

A few practical points merit mention. First, it is not necessary to draw the sample from the umbilical artery immediately, provided that the cord is clamped. Adequate specimens have been obtained from a clamped segment of cord as long as 60 minutes after delivery without significant changes in pH or PCO₂.³⁰ Moreover, once the specimens have been drawn into the syringe, they are relatively stable at room temperature for up to 60 minutes³¹ and do not need to be transported to the laboratory on ice.³² The same may not be true for specimens obtained from placental vessels.³³

Chauhan and colleagues³⁴ prepared a mathematical model that allows for the calculation of umbilical artery pH for up to 60 hours after delivery. This model permits the estimation of fetal pH at birth.

Normal Values

Although there is no consensus as to what the most appropriate umbilical artery pH cutoff should be to define acidemia, the mean pH values from four studies are shown in Table 22-4. The mean value for umbilical artery pH appears to be very close to 7.28. The subjects in the study reported by Riley and Johnson²⁷ were from 3522 unselected women undergoing vaginal delivery.

The mean pH for umbilical venous blood has been reported to be 7.32 to 7.35. In a study of umbilical venous blood pH, D'Souza and associates²⁸ reported a mean venous pH of 7.34 (± 0.07). Huisjes and Aarnoudse³⁵ also reported good correlation between umbilical venous and arterial pH.

Although the Apgar scores of premature infants may be low because of immaturity, mean values for both arterial and venous pH and blood gas values are similar to those of the term infant. Mean values for almost 2000 premature infants are summarized in Table 22-5.

Pathologic Fetal Acidemia

What level of umbilical artery pH should be considered abnormal, "pathologic," or clinically significant? It is now well established that the former pH cutoff of 7.20 is not appropriate.^{16,36} Most newborns with an umbilical artery pH lower than 7.20 are vigorous and without systemic evidence of hypoxia. Recent evidence suggests that significant neonatal morbidity is more likely to occur in neonates with umbilical artery pH values lower than 7.00, especially if associated with a low Apgar score (i.e., ≤3). For example, in a study of 2738 term newborns, hypotonia, seizures, and need for intubation were significantly correlated with an umbilical artery pH of less than 7.00 and an Apgar score of 3 or less at 1 minute.³⁷ The authors concluded that a newborn must be severely depressed at birth for birth hypoxia to be implicated as the cause of seizures.

Goldaber and coworkers,²² in an attempt to better define the critical cutoff for pathologic fetal acidemia, studied the neonatal outcome of 3506 term newborns. They determined the critical pH cutoff point to be 7.00 (Table 22-6). Many of these babies, however, had no complications and went to the newborn nursery. In a follow-up study from the same institution, King and associates³⁸ reported on 35 term newborns with an umbilical artery pH greater than 7.00 who were triaged to the newborn nursery. These authors concluded that term newborns who had this degree of acidemia at birth but had a stable appearance in the delivery room (and were without other complications) did not have evidence of hypoxia or ischemia during the 48 hours after birth. It has been reported that fewer than half of neonates with an umbilical artery pH lower than 7.00 actually have neonatal complications.³⁹

The critical pH cutoff for neonatal morbidity may actually be even lower than 7.00. Data presented by Andres and colleagues⁴⁰ suggest a value closer to 6.90. In a review of 93 neonates (>34 weeks' gestational age) with an umbilical artery pH greater than 7.00, the median pH for the group was 6.92 (range, 6.62 to 6.99); however, the median pH was 6.75 for neonates with seizures (25th to 75th percentile, 6.72 to 6.88), compared with 6.93 for those without seizures ($P = .02$). The median pH for newborns with hypoxic-ischemic encephalopathy was also significantly lower (6.69; 25th to 75th percentile, 6.62 to 6.75) than for

TABLE 22-6 NEONATAL MORBIDITY AND MORTALITY ACCORDING TO pH CUTOFF

Rights were not granted to include this table in electronic media. Please refer to the printed publication.

those without this diagnosis (6.93; 25th to 75th percentile, 6.85 to 6.97; $P = .03$). The median pH was also less than 6.90 in newborns who required intubation (6.83) or cardiopulmonary resuscitation (6.83) and was significantly lower ($P < .05$) than in newborns without these complications. It should also be noted that the median PCO₂ and base deficit were significantly higher in neonates with these morbidities.⁴⁰

Acute Neurologic Injury

There is poor correlation between neurologic outcome and the 1-minute and 5-minute Apgar scores. The correlation does improve if the scores remain between 0 and 3 at 10, 15, and 20 minutes; however, many such babies will still be "normal" if they survive. Similarly, a low umbilical artery pH in and of itself also has poor correlation with adverse outcome. The American College of Obstetricians and Gynecologists (ACOG)⁴¹ has established the following essential criteria (all four must be met) to indicate hypoxia proximate to delivery severe enough to be associated with acute neurologic injury:

1. Evidence of a metabolic acidosis in fetal umbilical cord arterial blood obtained at delivery (pH <7 and base deficit ≥12 mmol/L)
2. Early onset of severe or moderate neonatal encephalopathy in infants born at 34 or more weeks of gestation

- Cerebral palsy of the spastic quadriplegic or dyskinetic type
- Exclusion of other identifiable etiologies, such as trauma, coagulation disorders, infectious conditions, or genetic disorders

In two publications, Low and associates^{42,43} reported on the association of severe or significant metabolic acidosis (as determined by the umbilical artery blood gas profile) and newborn complications. Low⁴³ proposed a classification of intrapartum fetal asphyxia, the severity of which is based on newborn encephalopathy and other organ system dysfunction.

Other Clinical Events and Umbilical Blood Acid-Base Analysis

Beyond its use in assessing prematurity and neurologic injury, umbilical blood gas analysis has been reported in a variety of clinical situations, such as acute chorioamnionitis, nuchal cords, meconium, prolonged pregnancy, FHR anomalies, operative vaginal delivery, breech delivery, and use of oxytocin.³⁶ Such analysis may also prove useful in assessing the interval to delivery in shoulder dystocia cases.

ACUTE CHORIOAMNIONITIS

In one study of 123 women with acute chorioamnionitis, compared with more than 6000 noninfected women, Maberry and coauthors⁴⁴ found no significant association between infection and fetal acidemia (Table 22-7). Hankins and colleagues⁴⁵ found no association between acute chorioamnionitis and newborn acidemia. Meyer and colleagues,⁴⁶ however, reported an association of fetal sepsis with a decrease in umbilical artery pH compared with controls (7.21 versus 7.26).

NUCHAL CORDS

In a study of 110 newborns with nuchal cords, Hankins and colleagues⁴⁷ reported that significantly more newborns with nuchal cords were acidemic (umbilical artery pH <7.20), compared with controls (20% versus 12%; $P < .05$); however, there were no significant differences in mean pH (7.25 versus 7.27); PCO_2 (49 versus 48 mm Hg), or HCO_3^- (20.5 versus 21.0 mEq/L).

MECONIUM

In one study of 53 term pregnancies with moderate to thick meconium, Mitchell and colleagues⁴⁸ reported that approximately half of the newborns were acidemic, and that significantly more acidemic newborns had meconium below the cords, compared with controls (32%

versus 0%; $P < .05$). These authors, however, used an umbilical artery pH cutoff of 7.25 to define acidemia.

In another report of 323 newborns with meconium by Yeomans and associates,⁴⁹ there was a significantly increased frequency of meconium below the cords in acidemic fetuses than in nonacidemic fetuses (31% versus 18%; $P < .05$). Meconium aspiration syndrome, however, was an uncommon event, occurring in only 3% of newborns. Ramin and colleagues,⁵⁰ in a study of meconium, reported that 55% of meconium aspiration syndrome cases occurred in newborns with an umbilical artery pH greater than 7.20.

In a review of 4985 term neonates born to mothers with meconium-stained amniotic fluid, Blackwell and colleagues⁵¹ identified 48 cases of severe meconium aspiration syndrome in which umbilical artery pH measurements were obtained; the pH was 7.20 or higher in 29 of these patients and less than 7.20 in 19. There was no difference in frequency of seizures between the two pH groups. The authors concluded that severe meconium aspiration syndrome occurred in the presence of normal acid-base status at delivery in many of the cases, suggesting that a "preexisting injury or a nonhypoxic mechanism is often involved."⁵¹

PROLONGED PREGNANCY

In a study of 108 women with a prolonged pregnancy, Silver and colleagues⁵² reported a mean umbilical artery pH of 7.25. Moreover, significantly more newborns who were delivered for FHR indications had acidemia than newborns who were not (45% versus 13%; $P < .05$).

FETAL HEART RATE ABNORMALITIES

Gilstrap and colleagues,⁵³ in a study of 403 term newborns with FHR abnormalities in the second stage of labor compared with 430 control newborns, reported an association of abnormalities and acidemia (Table 22-8). This was confirmed in a follow-up study.⁵⁴ Honjo and Yamaguchi⁵⁵ also reported a correlation between second-stage baseline FHR abnormalities and fetal acidemia at birth. Although there may be an association between FHR abnormalities and acidemia, the association with adverse long-term neurologic outcome is uncommon. For example, Nelson and colleagues,⁵⁶ in a population-based study of children with cerebral palsy and a birth weight of 2500 g or more, reported that specific FHR abnormalities (i.e., late deceleration and decreased beat-to-beat variability) were associated with an increased risk of cerebral palsy. However, of all the children with these abnormal FHR findings only 0.19% had cerebral palsy. Therefore, the false-positive rate was 99.8%.

TABLE 22-7 COMPARISON OF UMBILICAL ARTERY pH IN PATIENTS WITH AND WITHOUT ACUTE CHORIOAMNIONITIS

Umbilical Artery pH	Patients with Chorioamnionitis (n = 123)	Controls (n = 6769)
<7.20	18 (15.0%)	701 (10.0%)
<7.15	4 (3.0%)	242 (4.0%)
<7.00	0	6 (0.1%)
Metabolic acidemia	1 (0.8%)	9 (0.1%)

OPERATIVE VAGINAL DELIVERY

Gilstrap and coworkers⁵⁷ found no significant difference in the frequency of newborn acidemia according to method of delivery (Table 22-9). This was true even when the indication for delivery was fetal distress.

BREECH DELIVERY

Although the mean umbilical artery pH was lower for infants delivered vaginally in breech presentations compared with cephalic presentations in two studies,^{58,59} pH levels were not significantly low from a clinical standpoint (7.23 and 7.16, respectively). It seems unlikely that delivery of breech presentations by the vaginal route is related to significant newborn acidemia.

SHOULDER DYSTOCIA

Most adverse outcomes associated with shoulder dystocia are due to actual physical injury to the brachial plexus⁶⁰ and not to acidemia or asphyxia (unless an extremely protracted period is needed to extract the fetus). In a review of 134 infants born after shoulder dystocia, Stallings and colleagues⁶¹ reported that this complication was associated with a “statistically significant but clinically insignificant” reduction in mean umbilical artery pH levels, compared to their obstetric population (7.23 versus 7.27).

OXYTOCIN

In a study of 556 women who received oxytocin compared with 704 who did not, Thorp and colleagues⁶² found no significant difference in mean umbilical artery pH measurements (7.23 versus 7.24, respectively).

Summary

The fetus maintains its pH within a very limited range and is dependent on the placenta and the maternal circulation to maintain acid-base balance. Several methods for assessing fetal-newborn acid-base status have been described. Of these methods, umbilical blood gas analysis is probably the most useful and the easiest (and relatively the least expensive) to perform.

There are few data to justify a policy of umbilical blood gas analysis for all newborns. In a survey of 133 universities in the United States, Johnson and Riley⁶³ reported that approximately 27% of centers used cord blood for assessing newborn acid-base status in all deliveries. Two thirds of the programs used them for tracing abnormal FHRs or for low Apgar scores. The Royal College of Obstetricians and Gynecologists and the Royal College of Midwives⁶⁴ recommend routine

cord blood measurements for all cesarean deliveries and instrumental deliveries for fetal distress. The ACOG⁴¹ recommends umbilical cord blood acid-base analysis in the following situations:

- Cesarean delivery for fetal compromise
- Low 5-minute Apgar score
- Severe growth restriction
- Abnormal FHR tracing
- Maternal thyroid disease
- Intrapartum fever
- Multifetal gestations

Characteristics of Fetal Heart Rate Patterns

Basic Patterns

The characteristics of the FHR pattern are classified as baseline or periodic/episodic.^{65,66} The *baseline* features—rate and variability—are those recorded between uterine contractions. *Periodic* changes occur in association with uterine contractions, and *episodic* changes are those not obviously associated with uterine contractions.

Baseline Features

The baseline features of the FHR are those predominant characteristics that can be recognized between uterine contractions. They are the baseline rate and variability of the FHR.

BASELINE RATE

The definition of baseline rate is the FHR recorded between contractions. More rigidly described, it is the approximate mean FHR rounded to 5 beats/min during a 10-minute segment, excluding the following: (1) periodic or episodic changes, (2) periods of marked FHR variability, and (3) segments of the baseline that differ by at least 25 beats/min. In any 10-minute window, the minimum baseline duration must be at least 2 minutes; otherwise, the baseline for that period is indeterminate.

The normal baseline FHR is between 110 and 160 beats/min. Rates slower than 110 beats/min are termed *bradycardia*, and rates faster than 160 beats/min are termed *tachycardia*. Baseline bradycardia and tachycardia are quantified by the actual rate observed in keeping with the definition of baseline rate.

FETAL HEART RATE VARIABILITY

Electronic fetal heart rate monitoring (EFM) in most cases produces a tracing with an irregular line, demonstrating the FHR variability. The irregularities represent the slight differences in time interval, and therefore in calculated FHR, that occur from beat to beat. If all intervals between heartbeats were identical, the line would be straight. Fluctuations in the baseline FHR are irregular in amplitude and frequency. (A pattern called “sinusoidal,” discussed later, differs from variability in that it has a smooth sine wave of regular frequency and amplitude and therefore is excluded from the definition of FHR variability.)

Baseline variability is defined as fluctuations in the FHR of 2 or more cycles per minute and is quantitated as the peak-to-trough amplitude of the FHR in beats per minute. Variability is *absent* when the amplitude range is undetectable. It is *minimal* when there is an amplitude range but it is less than 5 beats/min. Variability is *normal* or

moderate when the amplitude is between 6 and 25 beats/min. Variability is *marked* when the amplitude ranges greater than 25 beats/min⁶⁷ (see Classification and Significance of Baseline Variability).

Periodic Heart Rate Patterns

Periodic patterns are the alterations in FHR that are associated with uterine contractions or changes in blood flow within the umbilical cord vessels. These patterns are termed late decelerations, early decelerations, variable decelerations, and accelerations. In each case, the decrease or increase in FHR is calculated from the most recently determined portion of the baseline.

LATE DECELERATIONS

In late deceleration of the FHR, there is a visually apparent decrease and subsequent return to baseline FHR that is associated with a uterine contraction. The decrease is gradual, with the time from onset of deceleration to nadir being at least 30 seconds, and is delayed in timing, with the nadir of the deceleration occurring late in relation to the peak of the uterine contraction. In most cases, the onset, nadir, and recovery are all late in relation to the beginning, peak, and ending of the contraction, respectively.

EARLY DECELERATIONS

Early deceleration of the FHR is similar to late deceleration except that the decrease is coincident in timing, with the nadir of the deceleration occurring at the same time as the peak of the uterine contraction. In most cases, the onset, nadir, and recovery are all coincident with the beginning, peak, and ending of the contraction, respectively.

VARIABLE DECELERATIONS

Variable deceleration is defined as a visually apparent *abrupt* decrease (less than 30 seconds from onset of deceleration to beginning of nadir) in FHR from the baseline. The decrease in FHR is at least 15 beats/min, and its duration (from baseline to baseline) is at least 15 seconds but not more than 2 minutes. When variable decelerations are associated with uterine contractions, their onset, depth, and duration commonly vary with successive contractions.

Prolonged deceleration is a visually apparent abrupt decrease in FHR below the baseline of at least 15 beats/min that has a duration between 2 and 10 minutes from onset to return to baseline.

ACCELERATIONS

Acceleration is defined as a visually apparent abrupt increase (<30 seconds from onset of acceleration to peak) in FHR above the baseline. The acme is at least 15 beats/min above the baseline, and the acceleration lasts between 15 seconds and 2 minutes from onset to return to baseline. Before 32 weeks of gestation, accelerations are defined as having an acme of at least 10 beats/min above the baseline and a duration of at least 10 seconds. *Prolonged acceleration* is an acceleration that lasts at least 2 minutes but less than 10 minutes.

There is a close association between the presence of accelerations and normal FHR variability. At times it may be difficult to decide whether a recorded pattern represents “acceleration” or a normal long-term variability complex. The final decision is not important, because both accelerations and normal variability have the same positive prognostic significance, indicating normal fetal oxygenation.

QUANTIFICATION

Any deceleration is quantified by the depth of the nadir in beats per minute below the baseline. The duration is quantified in minutes

and seconds from the beginning to the end of the deceleration. Acceleration is quantified similarly. Decelerations are defined as recurrent or persistent if they occur with more than 50% of uterine contractions in any 20-minute period. Bradycardia and tachycardia are quantified by the actual FHR in beats per minute.

Normal and Abnormal Heart Rate Patterns

The normal or reassuring FHR pattern (Fig. 22-1) is accepted as that with a baseline FHR of between 110 and 160 beats/min; an FHR variability amplitude between 6 and 25 beats/min; and no decelerative periodic changes (although there may be periodic or episodic accelerations). It is widely accepted in clinical practice that a fetus born with this FHR pattern is normally oxygenated if delivery occurs when the normal FHR pattern is traced.^{4,68,69}

In contrast to the high predictability of fetal normoxia and vigor in the presence of the normal pattern, variant patterns are not as accurately predictive of fetal compromise. However, when these non-reassuring patterns are placed in the context of the clinical case (e.g., the progressive change in the patterns, the duration of the variant patterns), one can make reasonable judgments about the likelihood of fetal decompensation. With this screening approach, impending intolerable fetal acidosis can be presumed or, in certain cases, ruled out by the use of ancillary techniques (e.g., fetal scalp stimulation, vibroacoustic stimulation, fetal scalp blood sampling).

As a predictor for significant neurologic morbidity such as cerebral palsy, EFM has a very poor specificity and positive predictive value. The positive predictive value of a nonreassuring FHR is stated to be 0.14%. This means that for every 1000 fetuses born with a nonreassuring FHR tracing, 1 or 2 of them develop cerebral palsy.⁷⁰ Thus, the false-positive rate is greater than 99%.

Baseline Rate BRADYCARDIA

Bradycardia is defined as a baseline FHR slower than 110 beats/min. Certain fetuses have a baseline FHR of less than 110 beats/min and are cardiovascularly normal. Their baseline FHR simply represents a variation outside the limits of normal. Others with an FHR slower than 110 beats/min may have congenital heart block and a well-compensated status despite a low FHR.

Bradycardia is a term that relates to baseline FHR and is distinguished from a deceleration. However, a prolonged deceleration resulting in a new baseline bradycardia may result from vagal activity in response to fetal hypoxia (Fig. 22-2). Reasons for such decreases in FHR include the following:

1. A sudden drop in oxygenation, such as occurs with placental abruption, maternal apnea, or amniotic fluid embolus
2. A decrease or cessation in umbilical blood flow, such as occurs with a prolapsed cord or uterine rupture
3. A decrease in uterine blood flow, such as occurs with severe maternal hypotension

TACHYCARDIA

Tachycardia is defined as a baseline FHR of more than 160 beats/min; it is distinguished from an acceleration in that its duration is at least 10 minutes. With tachycardia, there is commonly a loss of variability of the FHR. Although fetal tachycardia is potentially associated with fetal hypoxia, particularly when it is accompanied by decelerations of the FHR, the more common association is with maternal or

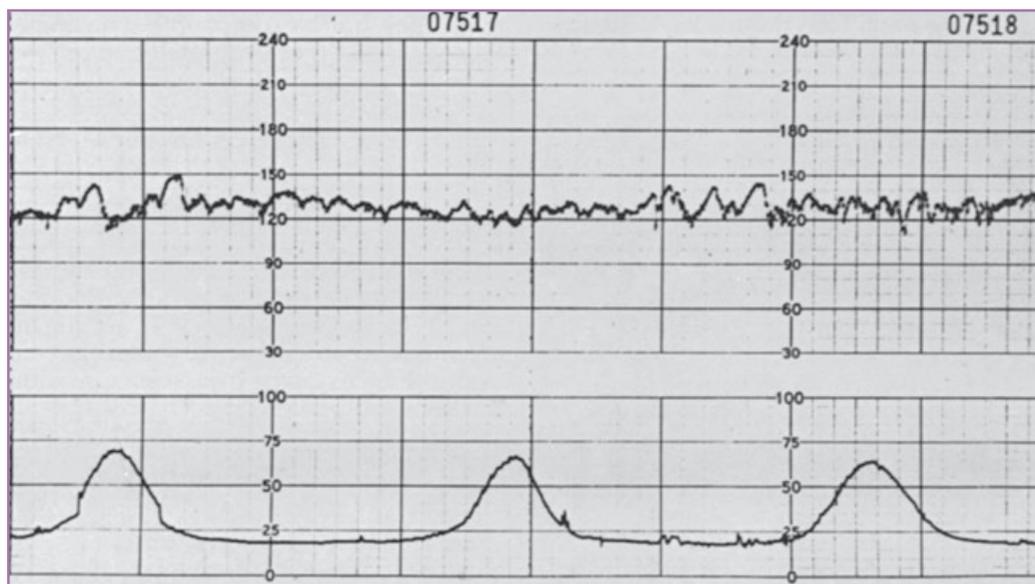

FIGURE 22-1 Normal fetal heart rate pattern. The tracing exhibits normal rate (approximately 130 beats/min), normal variability (amplitude range about 15 beats/min), and absence of periodic changes. This pattern represents a nonacidemic fetus without evidence of hypoxic stress. Uterine contractions are 2 to 3 minutes apart and about 60 to 70 mm Hg in intensity.

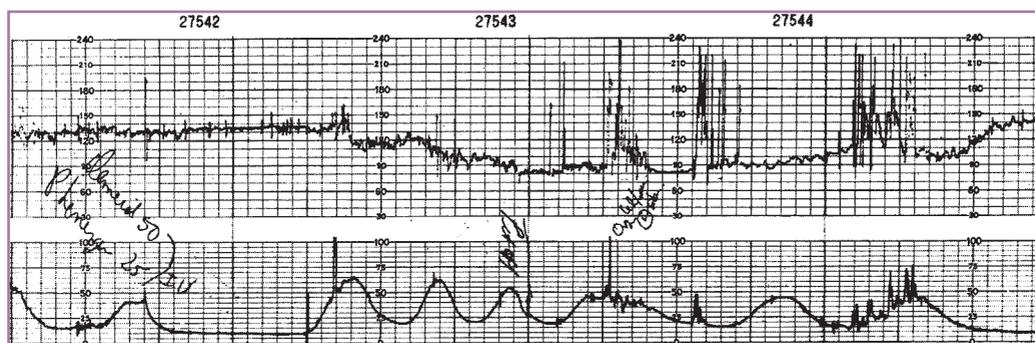

FIGURE 22-2 Prolonged fetal bradycardia resulting from excessive oxytocin-induced hyperstimulation of the uterus after intravenous infusion of meperidine (Demerol) and promethazine (Phenergan) into the same tubing. The heart rate is returning to normal at the end of the tracing, after appropriate treatment (signified by the notes "Pit off," "O₂ 6 L/min," and "side"). Note that fetal heart rate variability was maintained throughout this asphyxial stress, signifying adequate central oxygenation.

fetal infection (e.g., chorioamnionitis). In most of these instances, the fetus is not hypoxic but has an elevated baseline FHR.

It is not uncommon for the FHR baseline to rise in the second stage of labor. Certain drugs also cause tachycardia, such as β -mimetic agents used for attempted tocolysis or illicit drugs such as methamphetamine and cocaine.

Tachycardia should not be confused with the rarer finding of a fetal cardiac tachyarrhythmia, in which the FHR is faster than 240 beats/min. These arrhythmias may be intermittent or persistent and are the result of abnormalities of the intrinsic determinants of cardiac rhythm. Such findings of supraventricular tachyarrhythmias need to be monitored closely and possibly treated with medical therapy or delivery, because they may be associated with deterioration of the fetal status.

Classification and Significance of Baseline Variability

As described earlier, FHR variability may be absent, minimal, moderate, or marked, based on the amplitude range. The moderate (normal) amplitude range is between 6 and 25 beats/min. If the FHR variability is normal, regardless of what other FHR patterns may be present, the fetus is not experiencing cerebral tissue acidemia. This is because the fetus is able to centralize the available oxygen and is thus physiologically compensated. If excessive hypoxic stress persists, however, this compensation may break down, and the fetus may have progressive hypoxia in cerebral and myocardial tissues. In such cases, the FHR variability decreases and eventually is lost.

There are several possible nonhypoxic causes of decreased or absent FHR variability:

FIGURE 22-3 No variability of fetal heart rate. The mother had severe preeclampsia and was receiving magnesium sulfate and narcotics. The normal scalp blood pH (7.28) ensures that the absence of variability is nonasphyxic in origin and that the fetus is not chronically asphyxiated and decompensating. The uterine activity channel has an inaccurate trace in the first half.

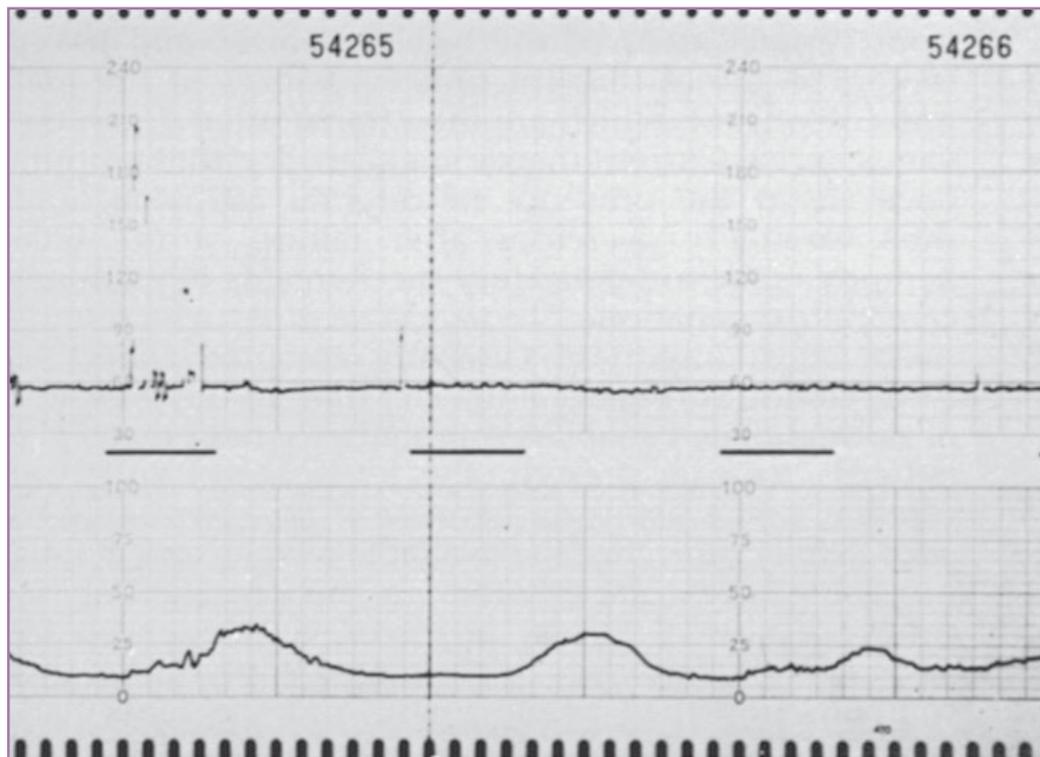

FIGURE 22-4 Unremittant fetal bradycardia. This tracing does not signify asphyxia, because this fetus had complete heart block, with a ventricular rate of about 55 beats/min. Note the absence of fetal heart rate variability. There were serious cardiac structural defects, and the fetus died shortly after birth.

1. Absence of the cortex (anencephaly)
2. Narcotized or drugged higher centers (e.g., by morphine, meperidine, diazepam) (Fig. 22-3)
3. Vagal blockade (e.g., by atropine or scopolamine)
4. Defective cardiac conduction system (e.g., complete heart block) (Fig. 22-4)

Periodic Changes in Fetal Heart Rate

LATE DECELERATIONS

Late decelerations (Fig. 22-5) are of two varieties: reflex and nonreflex.^{4,71-73}

Reflex late deceleration is sometimes seen when an acute insult (e.g., reduced uterine blood flow resulting from maternal hypotension) is superimposed on a previously normally oxygenated fetus in the presence of contractions. These late decelerations are caused by a decrease in uterine blood flow (with the uterine contraction) beyond the capacity of the fetus to extract sufficient oxygen. The relatively deoxygenated blood is carried from the fetal placenta through the umbilical vein to the heart and is distributed to the aorta, neck vessels, and head. Here, the low PO_2 is sensed by chemoreceptors, and neuronal activity results in a vagal discharge, which causes the transient deceleration. The deceleration is presumed to be “late” because of the circulation time from

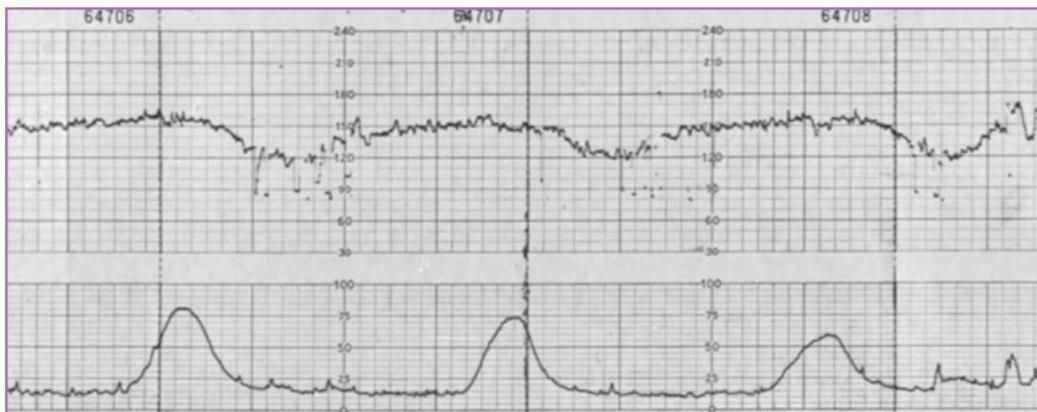

FIGURE 22-5 Late decelerations. These were recorded via Doppler ultrasound in the antepartum period in a severely growth-restricted (1700-g) term infant born to a 32-year-old preeclamptic primipara. Delivery was by cesarean section because neither a direct fetal electrocardiogram nor a fetal blood sample could be obtained due to a firm closed posterior cervix. The infant subsequently did well.

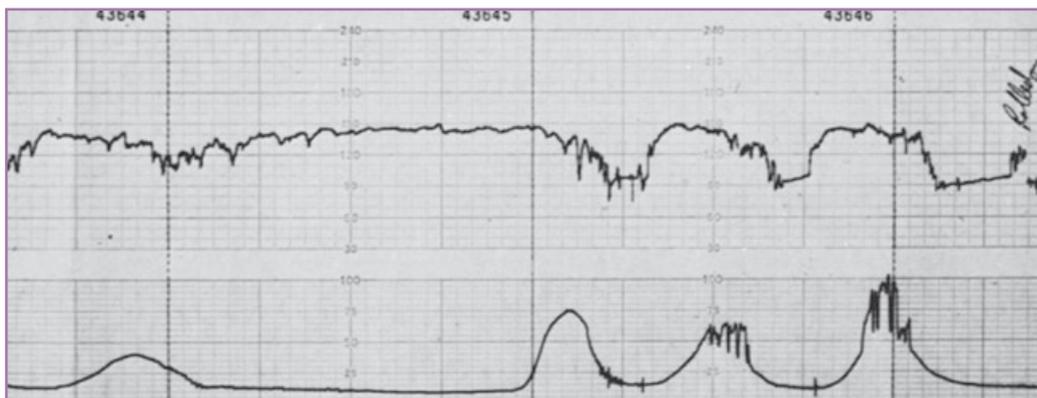

FIGURE 22-6 Reflex late decelerations. The fetal heart rate pattern was previously normal, but late decelerations appeared after severe maternal hypotension (70/30 mm Hg), which was a result of sympathetic blockade caused by a caudal anesthetic agent.

the fetal placental site to the chemoreceptors and because the progressively decreasing PO_2 must reach a certain threshold before vagal activity occurs. There may also be baroreceptor activity causing the vagal discharge.⁷¹ Between contractions, oxygen delivery is adequate and there is no additional vagal activity, so the baseline FHR is normal. These reflex late decelerations are accompanied by normal FHR variability and thus signify normal central nervous system integrity (i.e., the fetus is physiologically “compensated” in the vital organs) (Fig. 22-6).

The second type of late deceleration results from the same initial mechanism, except that the deoxygenated bolus of blood from the placenta is presumed to be insufficient to support myocardial action. Thus, for the period of the contraction, there is direct myocardial hypoxic depression (or failure) and vagal activity.^{71,73} These *nonreflex late decelerations* are seen without variability (Fig. 22-7), signifying fetal “decompensation” (i.e., inadequate fetal cerebral and myocardial oxygenation). They are seen most commonly in states of decreased placental reserve (e.g., preeclampsia, intrauterine growth restriction) or after prolonged hypoxic stress (e.g., a long period of severe reflex late decelerations).

Further support for the two etiologic mechanisms of late decelerations comes from observations on chronically catheterized fetal monkeys in spontaneous labor during the course of intrauterine

death.⁷⁴ The animals were initially observed with normal blood gases, normal FHR variability, presence of accelerations, and no persistent periodic changes. After a variable period of time, they first demonstrated late decelerations and retained accelerations. This period was associated with a small decline in ascending aortic PO_2 , from 28 to 24 mm Hg, and a normal acid-base state. These late decelerations were probably of the vagal reflex type caused by chemoreceptor activity. At an average of more than 3 days after the onset of these reflex decelerations, accelerations were lost in the presence of worsening hypoxia (PO_2 , 19 mm Hg) and acidemia (pH, 7.22). Fetal death followed an average of 36 hours of persistent late decelerations, and these latter decelerations without accelerations were presumed to be of the non-reflex myocardial depression type.

When late decelerations are present, one should make efforts to optimize placental blood flow and maternal oxygenation and ensure that maternal blood pressure is normal.

VARIABLE DECELERATIONS

Variable decelerations (Fig. 22-8), have the following characteristics:

1. They are variable in duration, depth, and shape.
2. They are usually abrupt in onset and cessation.

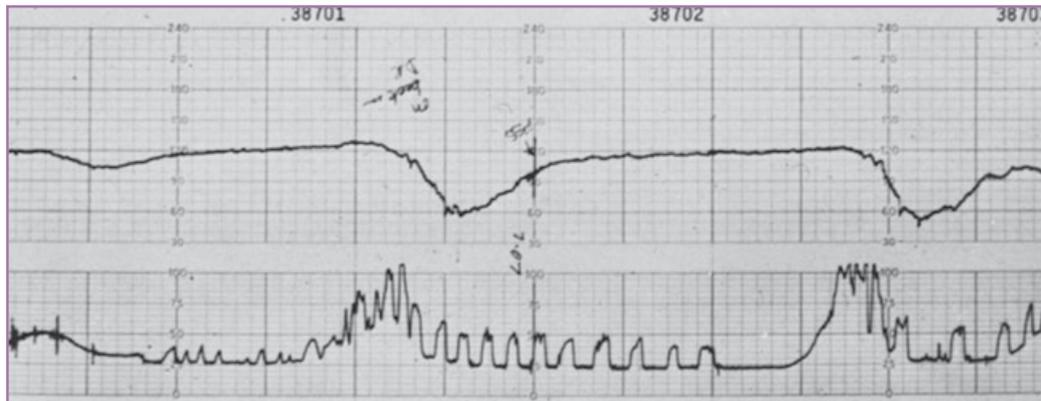

FIGURE 22-7 Nonreflex late decelerations with virtual absence of fetal heart rate (FHR) variability. The decelerations represent transient asphyxic myocardial failure as well as intermittent vagal decreases in heart rate. The lack of FHR variability also signifies decreased cerebral oxygenation. Note the acidemia in fetal scalp blood (7.07). The infant, a 3340-g girl with Apgar scores of 3 (1 minute) and 4 (5 minutes) was delivered soon after this tracing. Cesarean section was considered to be contraindicated because of a severe preeclamptic coagulopathy.

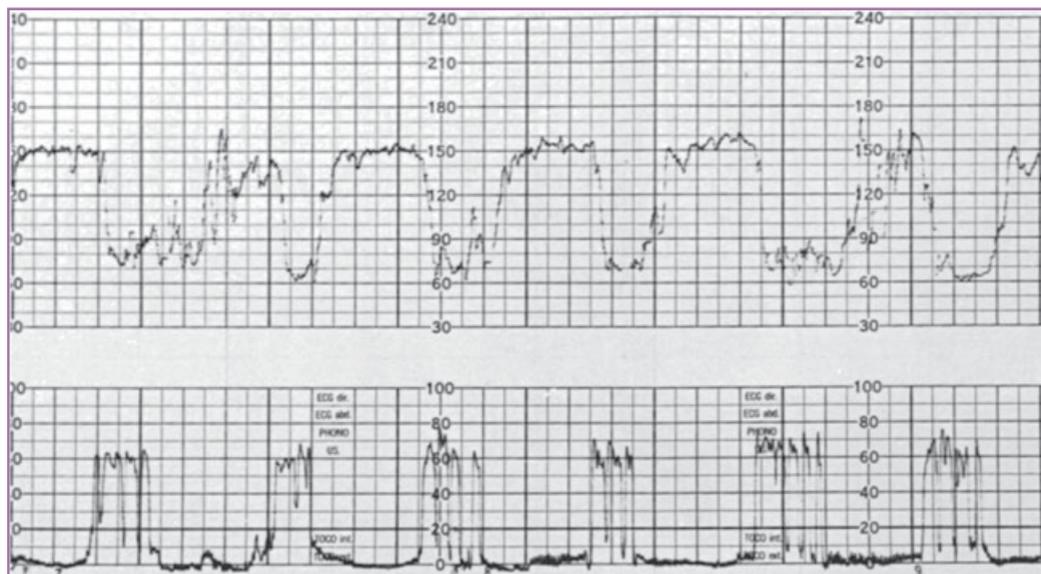

FIGURE 22-8 Variable decelerations. Intrapartum recording using fetal scalp electrode and tocodynamometer. The spikes in the uterine activity channel represent maternal pushing efforts in the second stage of labor. The normal baseline variability between contractions signifies normal central oxygenation despite the intermittent hypoxic stress represented by the moderate variable decelerations.

- They are not reassuring when there is either a slow return to baseline, a rise in baseline, or an absence of variability in the baseline between decelerations.

EFFECT OF IN UTERO TREATMENT

Fetal oxygenation can be improved, acidemia relieved, and variant FHR patterns abolished by certain modes of treatment. The events that result in fetal stress (recognized by FHR patterns) are presented in Table 22-10 together with the recommended treatment maneuvers and presumed mechanisms for improving fetal oxygenation. These should be the primary maneuvers carried out; if the hypoxic event is acute and the fetus was previously normoxic, there is an excellent chance that the undesired FHR pattern will be abolished.

If the FHR pattern cannot be improved (i.e., if the stress patterns indicative of peripheral tissue or central tissue hypoxia persist for a

significant period), further diagnostic steps or delivery may be indicated. Certain patterns are of such a severe character that immediate delivery is warranted if they cannot rapidly be relieved (Figs. 22-9 and 22-10).

Other Patterns

SINUSOIDAL PATTERN

The sinusoidal pattern is a regular, smooth, sine wave–like baseline, with a frequency of approximately 3 to 6 cycles per minute and an amplitude range of up to 30 beats/min. The regularity of the waves distinguishes this pattern from long-term variability complexes, which are crudely shaped and irregular. Another distinguishing feature is the absence of beat-to-beat or short-term variability (Fig. 22-11).

The sinusoidal pattern was first described in a group of severely affected Rh-alloimmunized fetuses but was subsequently noted in

TABLE 22-10 INTRAUTERINE TREATMENT FOR VARIANT FETAL HEART RATE (FHR) PATTERNS

Causes	Possible Resulting FHR Patterns	Corrective Maneuver	Mechanism
Hypotension (e.g., supine hypotension, conduction anesthesia)	Bradycardia, late decelerations	Intravenous fluids, position change, ephedrine	Return of uterine blood flow toward normal
Excessive uterine activity Transient umbilical cord compression	Bradycardia, late decelerations Variable decelerations	Decrease in oxytocin, lateral position Change in maternal position (e.g., left or right lateral, Trendelenburg) Amnioinfusion	Same as above Presumably removes fetal part from cord Relieves compression of cord
Head compression	Early or variable decelerations	Push only with alternate contractions	Allows fetal recovery
Decreased uterine blood flow associated with uterine contraction	Late decelerations	Change in maternal position (e.g., left lateral or Trendelenburg) Tocolytic agents (e.g., terbutaline)	Enhancement of uterine blood flow toward optimum Decrease in contractions or tone
Prolonged asphyxia	Decreasing FHR variability*	Change in maternal position (e.g., left lateral or Trendelenburg), establishment of maternal hyperoxia	Enhancement of uterine blood flow to optimum, increase in maternal-fetal oxygen gradient

*During labor, this is virtually always preceded by a heart rate pattern signifying asphyxial stress (e.g., late decelerations, usually severe), severe variable decelerations, or a prolonged bradycardia. This is not necessarily so in the antepartum period, before the onset of uterine contractions.

FIGURE 22-9 Sinister heart rate pattern in a 28-week fetus (gestational age determined after delivery) with baseline tachycardia, absence of heart rate variability, and severe periodic changes. The scalp blood pH was 7.0, and the fetus died shortly after this tracing was made. Cesarean section was not performed because the fetus was believed to be previable, although in fact it weighed 1100 g. There is much artifact in the uterine activity channel.

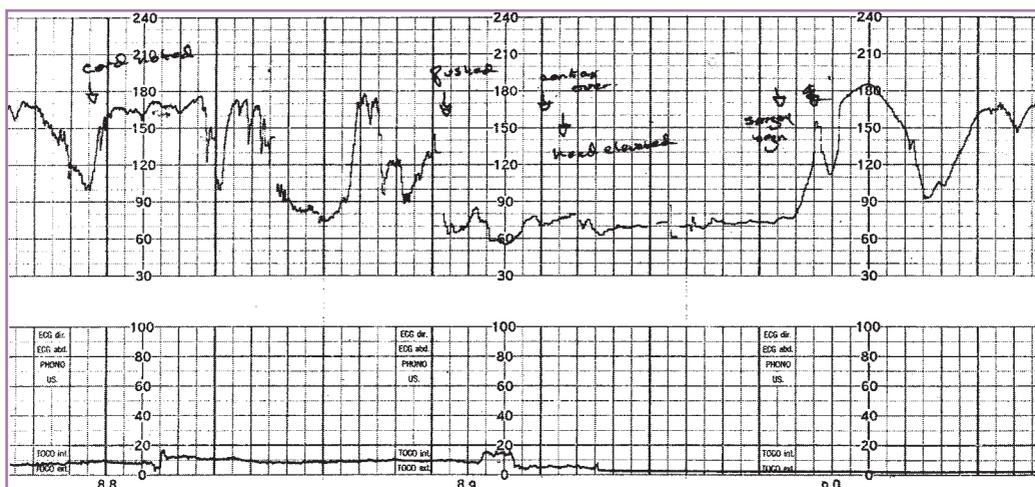

FIGURE 22-10 Bradycardia resulting from cord prolapse. The infant was delivered by cesarean section and did well.

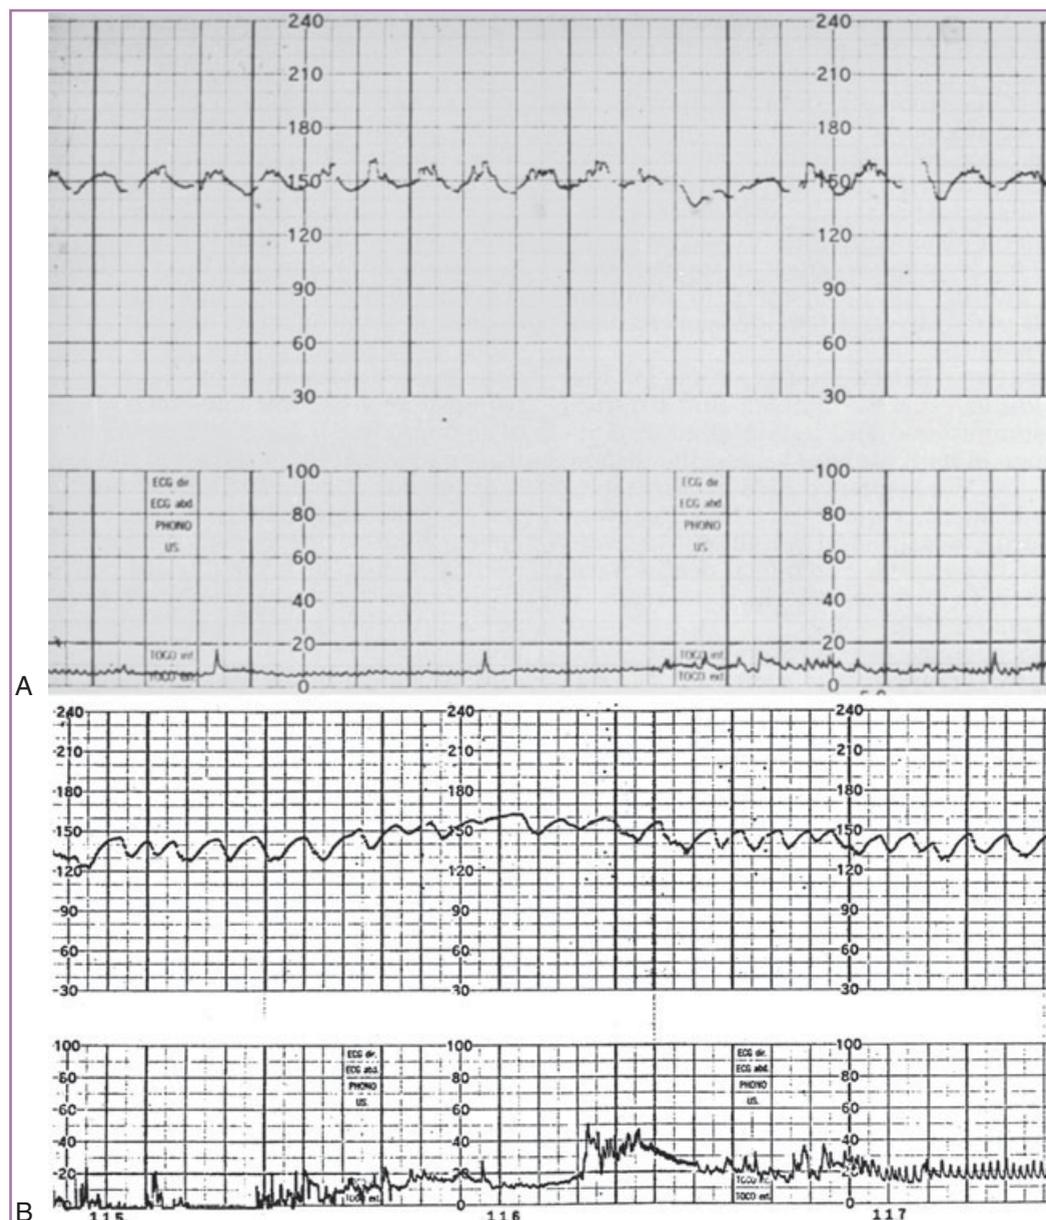

FIGURE 22-11 Sinusoidal pattern. **A** and **B**, Sinusoidal pattern in a term fetus with severe hemolysis caused by Rh disease. Cord hematocrit was 20%, and the infant, delivered by cesarean section, was subsequently normal. Recording by direct fetal electrode.

association with fetuses that were anemic for other reasons and in severely depressed infants. It was also described in cases of normal infants born without depression or acid-base abnormalities, but in these cases there is dispute about whether the patterns were truly sinusoidal or whether, because of the moderately irregular pattern, they were variants of long-term variability. Such patterns, often called pseudosinusoidal, may also be seen after administration of narcotics to the mother.

It is believed that an essential characteristic of the sinusoidal pattern is extreme regularity and smoothness. Murata and colleagues⁷⁵ implicated arginine vasopressin in the sinusoidal pattern. The presence of a sinusoidal pattern or variant of this in an Rh-sensitized patient usually suggests anemia with a fetal hematocrit value of less than 30%. The presence of hydrops in such a fetus suggests a fetal hematocrit of 15%

or lower. Many severely anemic Rh-affected fetuses do not have a sinusoidal pattern but rather have a rounded, blunted pattern, and accelerations are usually absent.

If a sinusoidal pattern is seen in an Rh-sensitized patient and severe hemolysis is confirmed (by peak systolic velocity measurement of flow in the middle cerebral artery of the fetus, by cordocentesis, or by the deviation in optical density at 450 nm determination by spectrophotometry of amniotic fluid), rapid intervention is needed. This step may take the form of delivery or intrauterine transfusion, depending on gestational age and the fetal status (see Chapter 26).

Management of a sinusoidal pattern in the absence of alloimmunization is somewhat more difficult to recommend. If the pattern is persistent, monotonously regular, and unaccompanied by short-term variability and cannot be abolished by the maneuvers just described,

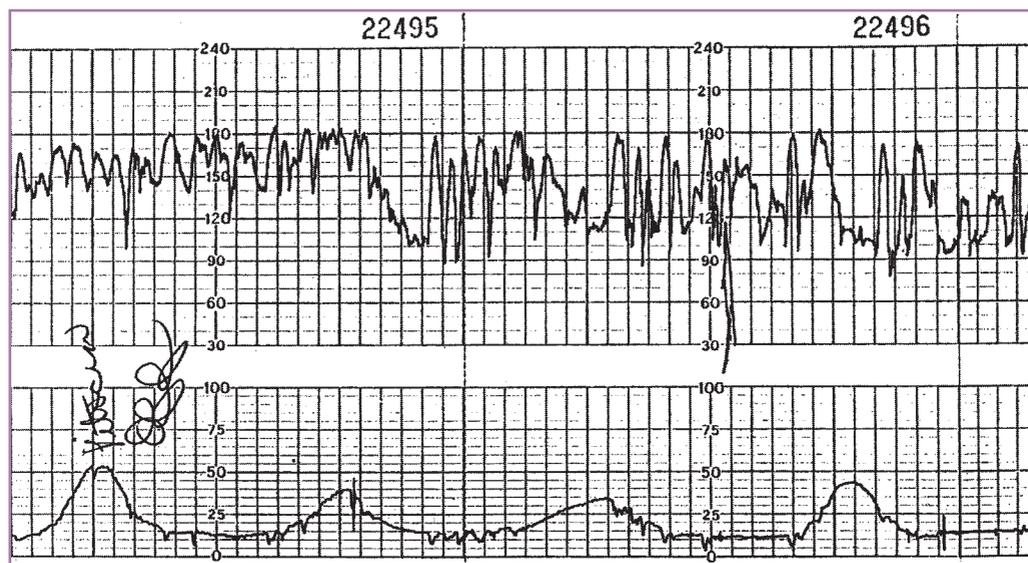

FIGURE 22-12 Saltatory pattern. Saltatory pattern showing excessive fetal heart rate variability of up to 60 beats/min in brief intervals, probably representing mild hypoxic stress.

further workup and evaluation of the adequacy of fetal oxygenation (e.g., contraction stress test, fetal stimulation test, biophysical profile, fetal blood sampling) are indicated. Nonalloimmune sinusoidal patterns have been associated with severe fetal acidemia and with fetal anemia resulting from fetal-maternal bleeding. The latter diagnosis is supported by the identification of fetal red blood cells in maternal blood, detected by the Kleihauer-Betke test. If the pattern is irregularly sinusoidal or pseudosinusoidal, intermittently present, and not associated with intervening periodic decelerations, fetal compromise is unlikely, and immediate delivery is not warranted.

SALTATORY PATTERN

The saltatory pattern consists of rapid variations in FHR with a frequency of 3 to 6 cycles per minute and an amplitude range greater than 25 beats/min (Fig. 22-12). It is qualitatively described as a marked variability, and the variations have a strikingly bizarre appearance. The saltatory pattern is seen during labor rather than in the antepartum period. The etiology is uncertain, but it may be similar to that of the increased FHR variability seen in animal experiments with brief and acute hypoxia in a previously normoxic fetus. Therefore, efforts should be made to optimize placental blood flow and fetal oxygenation if such a pattern appears during labor.

Congenital Anomalies

Except as described for the dysrhythmias, most fetuses with congenital anomalies have essentially normal FHR patterns and respond to hypoxia in a manner similar to the normal fetus. There are several exceptions, including complete heart block and anencephaly. Aneuploid fetuses and fetuses with aplastic lungs, meningomyelocele, and/or hydrocephalus may give no FHR warning of such underlying defects, because they are not necessarily experiencing hypoxia or acidosis. However, even though there was no pathognomonic pattern in such fetuses, the rate of cesarean section for fetal intolerance to labor was reported to be significantly increased, presumably because of nonreassuring patterns during or preceding labor.⁷⁶

Efficacy, Risks, and Recommendations for Usage

Electronic Monitoring versus Auscultation

Because there are no prospective randomized clinical trials comparing EFM with no fetal heart monitoring during labor, most efforts to suggest its efficacy have relied on research reports comparing EFM with intermittent auscultation. Efficacy is generally held to be an expected decrease in complications, which, for FHR monitoring, could include fetal death in labor or severe neonatal and pediatric morbidity (e.g., neonatal seizures, cerebral palsy). Ideally, the improved outcomes would be accompanied by appropriate interventions and appropriate noninterventions.

In a meta-analysis of the nine published clinical studies comparing EFM with intermittent auscultation of the FHR, several conclusions were reached.⁷⁷ (It should be noted that in several of these trials, patients with conditions considered to be high risk were not randomized for study inclusion.) The use of EFM was associated with significant increases in the rate of cesarean delivery for fetal intolerance to labor, the overall cesarean delivery rate, and the use of instrumentation for vaginal delivery (both vacuum and forceps). However, there was no reduced overall perinatal mortality in these patients. As a result of such reports, either option of monitoring the fetus during labor is acceptable for patients not considered to be at high risk.⁶⁷ However, it should be noted that the optimal frequency for intermittent auscultation in such low-risk patients has not been established. At a minimum, the FHR should be assessed at least every 30 minutes in the first stage of labor and every 15 minutes in the second stage.⁶⁷ Another method is to auscultate and record FHR every 15 minutes in the active first stage of labor and every 5 minutes in the second stage, without limiting such a modality to low-risk patients.⁷⁸

Adjuncts to Electronic Fetal Heart Rate Monitoring

The initial belief with EFM when it was introduced into clinical practice more than 35 years ago was that it would identify fetuses with impending stillbirth or damaging asphyxia in an appropriate and timely manner to allow for the prevention of untoward outcomes. The result would be improved perinatal and neonatal outcomes. However, several well-designed, randomized clinical studies from different clinical centers involving almost 40,000 women in labor suggest that intrapartum EFM, when compared with intermittent auscultation, does not result in any measurable improvement in outcome.^{79,80} This is certainly disappointing, and it also suggests that the thinking about the risks associated with intrapartum events and adverse long-term neurologic outcomes needs to be re-evaluated. Of note, these studies did reveal a strong correlation between certain EFM patterns and fetal acidosis as measured by both the base deficit and the umbilical artery pH. In addition, with respect to the specific end point of neonatal seizures, several of these trials reported that there were significantly fewer such cases after intrapartum EFM than after labors monitored with intermittent auscultation. This end point, however, does not serve as a true surrogate for long-term neurologic brain damage, because, in many of these cases, damage was no longer evident with repeat examination as the child grew older.

Nevertheless, the clinical reality is that, because of the labor intensity demanded of the nursing staff when intermittent auscultation is employed as in these prospective studies, along with the diminishing number of nurses available to most hospital labor and delivery units, it is not practical to offer most laboring patients the option of intermittent auscultation. This is particularly true for “high-risk” patients, and, as a result, EFM has become the default option for most modern obstetric units. At least for the foreseeable future, despite its limitations and disappointments, EFM will continue to be utilized frequently in the management of labor in this country.

With full knowledge of these issues, as well as the significant lack of concordance in the interpretation of monitor data showing anything but a reassuring pattern, efforts continue to be made to provide appropriate adjuncts to EFM. There continues to be an unacceptably high false positive rate with EFM, as well as an occasional false-negative result. Historically, fetal scalp blood sampling was used in an effort to accurately identify the fetus with an acidotic pH. Unfortunately, this is a cumbersome and challenging procedure that is associated with complications and is currently not an option in most hospitals providing obstetric care. Efforts to obtain a continuous measure of the fetal pH have also been unsuccessful for a number of reasons.

More recently, efforts to directly assess fetal oxygenation (fetal pulse oximetry) or to more closely interpret the fetal ECG (ST-waveform analysis) have been studied as complementary technologies to improve both sensitivity and specificity for prediction of fetal intrapartum hypoxia and/or acidosis.

Fetal Pulse Oximetry

EFM is intended to assess fetal oxygenation indirectly, as reflected in specific changes in FHR. FHR monitoring is not a direct measure of fetal oxygenation, and it has insufficient specificity and sensitivity to correctly identify the fetus who is in oxygen debt. Continuous direct assessment of fetal oxygenation has been proposed as a technique to overcome the suboptimal specificity and sensitivity of continuous FHR monitoring. Ideally, a monitor that measures fetal oxygenation or pH directly would be preferable to accurately identify the physiologically compromised fetus. Efforts to develop instrumentation to measure

fetal oxygenation or pH continuously have been limited by difficulty with fetal access, safety, and accuracy of the information generated (e.g., stasis of capillary blood in the fetal scalp during active labor).

Pulse oximetry has been a significant advance in the assessment of oxygenation status for adult and pediatric patients. Essentially all patients in surgery, recovery, and intensive care units are monitored continuously with a noninvasive, transcutaneously applied pulse oximeter. Pulse oximetry provides a continuous source of reliable information about oxygen status in intraoperative and critically ill patients that has been shown to dramatically reduce the number of hypoxia-related anesthetic deaths.⁸¹ Several obstacles have prevented the use of this technology for intrapartum fetal assessment, including access to the fetus (ruptured membranes are required), an appropriate surface on which to apply the sensor (a stable surface is needed that will not change significantly during labor), and differences in fetal versus adult physiology (the fetal blood pressure is lower, whereas the pulse and hemoglobin are higher, and the oxyhemoglobin dissociation is different than in the adult).

Adult and pediatric pulse oximetry uses transmission oximetry technology, in which light is passed through tissue to a sensor on the opposite side of the patient’s finger or earlobe. The noninvasive determination of oxygen saturation is founded on the differential absorption of red and infrared light by oxyhemoglobin and deoxyhemoglobin: Less red light and more infrared light are absorbed by oxyhemoglobin than by deoxyhemoglobin. The ratio of these differences is used to measure the oxygen saturation during each arterial pulse.

Detection of oxygen saturation in the fetus has been difficult because the fetus has no body part that can be used for transmission oximetry. This technical problem has been addressed by the development of a sensor that remains stable when applied to the fetal cheek or back and that uses reflectance oximetry, in which light is emitted and then reflected to a photosensor located on the same probe by the underlying fetal tissue (OxiFirst Fetal Oxygen Saturation Monitoring System, Mallinckrodt/Nellcor, Pleasanton, CA).

Studies have related the oxygen saturation as measured by reflectance pulse oximetry to fetal arterial oxygen saturation measured directly in fetal lambs⁸² and to fetal scalp pH in humans.⁸³ Dildy and coworkers⁸⁴ suggested that an arterial oxygen saturation of 30% is a reasonable threshold to detect acidemia. This conclusion was based on their analysis of 1101 paired umbilical artery and vein gases, in which significant umbilical acidemia (arterial pH <7.13) occurred rarely (1.6%) when arterial oxygen saturation exceeded 30%; acidemia was more common (10.4%) when the arterial oxygen saturation was lower than 30%. Other studies^{85,86} investigated the time required to produce metabolic acidosis in the human fetus in labor. They found that fetal acidemia did not occur unless the fetal pulse oximeter revealed a saturation lower than a critical threshold of 30% for longer than 2 minutes.

Garite and colleagues⁸⁷ applied fetal pulse oximetry to a population of more than 1000 laboring women who had FHR tracings that were worrisome but not sufficiently ominous to require immediate delivery, including (1) mild or moderate decelerations for longer than 30 minutes, (2) a baseline FHR of 100 to 110 beats/min without accelerations, (3) a baseline FHR of less than 100 or more than 160 beats/min, (4) variability less than 5 or greater than 25 beats/min, (5) late decelerations, or (6) prolonged decelerations. Patients were randomly assigned to receive FHR monitoring alone or FHR plus fetal pulse oximetry. In those assigned to the latter group, if the FHR tracing was reassuring, labor was allowed to continue regardless of the fetal pulse oximetry level. If the FHR tracing was ominous, delivery was accomplished, again regardless of the fetal pulse oximetry data. However, the

pulse oximetry data were used if the FHR tracing was nonreassuring which was not uncommon in these patients. In such cases, labor was allowed to continue if the fetal oxygen saturation was greater than 30%, and delivery was recommended if the fetal oxygen saturation was lower than 30% for the entire interval between two contractions. The primary end point was the rate of cesarean section performed for fetal intolerance to labor. This rate was significantly decreased with fetal pulse oximetry, but the rate of cesarean delivery for dystocia was correspondingly increased, and the overall rate of cesarean section was not different in the FHR versus FHR plus pulse oximetry groups.

In response to the various reports of the potential use of fetal pulse oximetry, the ACOG Committee on Obstetric Practice did not endorse the adoption of this device "because of concerns that its introduction could further escalate the cost of medical care without necessarily improving clinical outcome."⁸⁸ As with other technologic developments, obstetricians have been anxious to adopt new techniques despite the lack of adequate trials demonstrating clinical efficacy. In a recent large study, use of fetal pulse oximetry was not associated with a reduction in cesarean delivery rate or improved neonatal outcome in patients monitored continuously with EFM.⁸⁹ Although other investigators have reported clinical efficacy with this modality and the argument can be made that this added information regarding fetal status during labor is helpful in selected patients, the discussion regarding the clinical value of fetal pulse oximetry is now moot, because the device is no longer being produced and marketed for use in this country.

ST Analysis of Fetal Electrocardiography

Adult humans experiencing metabolic acidosis, anaerobic metabolism, and hypoxia of the myocardium demonstrate changes in their ECG. Specifically, there may be depression or elevation of the ST segment, as well as T wave changes. An increase in the ST segment and in the T wave of the fetal ECG in response to hypoxia has been demonstrated in fetal animal studies.⁹⁰ T-wave height compared with QRS height (T/QRS ratio) can be used as a means to express such changes.⁹¹

ST analysis, or STAN (Neoventa Medical, Moelndal, Sweden), is a fetal monitoring technology that has evolved to address these basic physiologic changes associated with hypoxia. STAN combines the routine visual assessment of the intrapartum EFM tracing with an automated analysis of the fetal ECG. A modified gold-plated fetal scalp electrode is used. STAN performs a computer analysis of the fetal ECG specific to the detection of ST-segment changes that may be predictive of fetal hypoxia during labor. In a randomized control trial, Swedish investigators reported that fetal ECG analysis using STAN, when combined with the standard EFM techniques, lowered the rates of operative delivery for fetal intolerance to labor, severe fetal metabolic acidosis (pH <7.05 and base deficit >12 mmol/L), and neonatal encephalopathy, compared with EFM alone, in term laboring patients who were deemed to be candidates for continuous EFM.^{92,93} In a report from the United States, the appropriate use of STAN technology was measured and confirmed.⁹⁴ In this nonrandomized feasibility study, trained clinicians demonstrated the ability to appropriately apply STAN in cases requiring delivery interventions or noninterventions, compared with experienced STAN users. A negative predictive value of 95.2% was reported for nonintervention in cases with nonreassuring EFM patterns, with normal STAN readings and normal neonatal outcomes with umbilical arterial pH greater than 7.12. Further, there was an 84% agreement for intervention and a 90% agreement for nonintervention between investigators and three STAN experts when the cases were retrospectively reviewed.

It is important to note that these reports are essentially limited to singleton pregnancies in labor at or beyond 36 weeks' gestation. In

addition, the STAN system requires a period of time, usually 20 minutes, to assess the fetal ECG and establish the normal and abnormal parameters before it is able to identify significant changes suggestive of fetal hypoxia. Other concerns include a frequency of 2% to 3% for missing ST data due to poor signal quality or continuous absence of data for unclear reasons. With correct scalp electrode placement and further improvements in the processing of the ECG signal, it is hoped that these errors will become less frequent.

Chapter 23

Assessment and Induction of Fetal Pulmonary Maturity

Brian M. Mercer, MD

Respiratory distress syndrome (RDS) results when immature lungs fail to produce adequate surface-acting proteins and phospholipids to reduce alveolar surface tension and prevent alveolar collapse during expiration. Because the work necessary to open a collapsed alveolus is much more than that needed to expand an already open alveolus, the increased work of breathing leads to muscular exhaustion and mechanical respiratory failure. Alveolar collapse, fluid buildup in the immature alveolus, and diminished respiratory gas exchange lead to hypoxia, hypercarbia, and, consequently, acidosis. RDS is the most common major acute morbidity at any gestational age between viability and 36 weeks. Neonatal RDS and complications of its treatment are associated with an increased risk of serious acute and long-term morbidities, including intraventricular hemorrhage (IVH), patent ductus arteriosus, retinopathy of prematurity, and chronic lung diseases, including bronchopulmonary dysplasia. Although the frequency and severity of RDS tend to be worse when delivery occurs remote from term, RDS occurring near term can also lead to serious complications or even death.

When preterm delivery is inevitable, treatment is directed to optimizing the timing of delivery, newborn condition, and resources for neonatal care. If continuation of pregnancy is an option, the relative fetal and maternal risks of conservative management versus delivery must be considered. Because cardiopulmonary function is a principal requirement for neonatal survival, identification of fetuses at risk for RDS and methods to induce fetal maturity before preterm birth are important.

Assessment of Fetal Pulmonary Maturity

Direct Evaluation of Amniotic Fluid

Both invasive and noninvasive tests for prediction of fetal pulmonary maturity have been evaluated. An optimal test of maturity would provide clear discrimination between the mature fetus and the fetus likely to suffer RDS. Because central respiratory drive, muscular strength, infection, hypoxia, and hypotension can also alter the clinical course, antenatal pulmonary maturity testing cannot completely differentiate between the mature and the immature fetus. Currently, biochemical and biophysical analyses of the amniotic fluid offer the most

accurate means to predict fetal pulmonary maturity. In general, the predictive value of a test indicating maturity is 97% to 100%. The risk of RDS after a test indicating immaturity varies from 5% to almost 100%, depending on gestational age and the degree of immaturity predicted by the test.

Clinical tests to determine fetal pulmonary maturity from amniotic fluid specimens have been available since the early 1970s, when Gluck and coworkers first introduced the lecithin/sphingomyelin ratio (L/S ratio).^{1,2} The relative proportions of lecithin (disaturated phosphatidylcholine) and sphingomyelin are stable until the middle of the third trimester, at which time the pulmonary active phospholipid, lecithin, increases relative to the nonpulmonary sphingomyelin. An L/S ratio of at least 2:1 is considered indicative of fetal maturity.

The L/S ratio has in the past been considered the gold standard for assessment of fetal pulmonary maturity, but it is neither 100% sensitive nor specific. Phosphatidylglycerol (PG) is one of the last pulmonary phospholipids to become evident in the amniotic fluid, and its detection is highly predictive of fetal pulmonary maturity.^{3,4} An advantage of PG determination is reliability in the presence of blood, meconium, or vaginal secretions. However, when the test is performed before 36 weeks' gestation, it carries a high false immaturity rate. The slide agglutination test for PG can provide more rapid results and requires less technical expertise than traditional thin-layer chromatography.⁵⁻⁸

Recognizing that the relative proportions of the fetal pulmonary phospholipids change with increasing gestational age, Kulovich and associates introduced the fetal "lung profile" in 1979.⁹ The lung profile includes information obtained by two-dimensional thin-layer chromatography regarding the L/S ratio, the presence of PG, and the relative fractions of lecithin, PG, and phosphatidylinositol (PI); the PI fraction typically rises to 35 weeks and then declines with the appearance of PG in the amniotic fluid. The lung profile was proposed to improve prediction of pulmonary maturity and to help determine the optimal timing of subsequent testing if immaturity was recognized.

Each of these traditional tests requires considerable time, technical expertise, and cost to perform. Therefore, the L/S ratio determination and the PG assay are used as secondary tests, should simpler and less expensive automated testing indicate immaturity, or as primary tests in special clinical circumstances. Amniotic fluid prolactin, cholesterol palmitate, desmosine, surfactant apoproteins, fluorescent polarization microviscosity, and drop volume have also been related to fetal pulmonary maturity but are not commonly assessed in clinical practice.

Several functional tests of fetal pulmonary maturity were developed in the 1970s and 1980s, including the shake test, the Foam Stability Index (FSI), the automated Lumadex-FSI (Beckman Instruments, Carlsbad, CA), and the tap test. Each assessed the ability of the fetal pulmonary surfactants to maintain a stable ring of foam bubbles when amniotic fluid was diluted and mixed with various reagents.¹⁰⁻¹³ Each test was highly predictive of the presence of fetal pulmonary maturity, but false immature results were common, and these tests are not often used in clinical practice in North America today. Indirect amniotic fluid markers of fetal pulmonary maturity include amniotic fluid density based on spectrophotometric absorbance at 650 nm, amniotic fluid turbidity, and evaluation for the presence of vernix caseosum in the amniotic fluid. Although each of these measurements is correlated to fetal pulmonary maturity, they are not adequately accurate to supplant biochemical testing. Like the PG and L/S ratio, functional tests and assessment of indirect amniotic fluid markers have largely been replaced by simpler automated tests. Currently, the surfactant/albumin ratio (S/A ratio) and the lamellar body count (LBC) are commonly used primary tests for assessment of fetal pulmonary maturity in clinical practice.

Developed in the late 1980s, the S/A ratio is performed by evaluating competitive binding to surfactant and albumin by a ligand that exhibits fluorescence polarization (TDx FLM, Abbott Laboratories, Abbott Park, IL).^{14,15} The TDx FLM assay is simple to perform, accurate, and reproducible. Results are independent of amniotic fluid volume. Because the test can be performed with equipment already found in clinical laboratories, no additional equipment or special expertise is needed. The TDx FLM assay and its subsequent modification, the TDx FLM II assay, have compared favorably with the L/S ratio, shake test, FSI, and PG test.¹⁶⁻¹⁹ In a multicenter study, Russell and colleagues found the sensitivity and specificity of the TDx FLM to be 96% and 58%, respectively, using a cutoff of 50 mg/g; in addition, the results of the TDx FLM test in predicting pulmonary maturity were similar to those of the PG test and the L/S ratio.¹⁴ In a subsequent study of 218 pregnancies, Winn-MacMillan and Karon found a TDx FLM result of 45 mg/g or greater to be 100% predictive of the absence of newborn RDS.²⁰

Lamellar bodies are surfactant-containing particles secreted by type II pneumocytes; they are 1 to 5 μm in diameter (1.28 to 6.4 fL).^{21,22} The number of lamellar bodies found in the amniotic fluid increases with the onset of functional fetal pulmonary maturity. Because lamellar bodies are similar in size to platelets (2 to 20 fL), they can be estimated using an automated particle counter calibrated for platelet quantitation. Centrifugation of the specimen leads to underestimation of the total lamellar body number. In a study of 833 women who delivered within 72 hours of testing, the LBC compared favorably with the L/S ratio and the PG test in predicting fetal pulmonary maturity, with predictive values of 97.7%, 96.8%, and 94.7%, respectively.²³ In an attempt to introduce standardization in LBC testing, Neerhof and associates formed a consensus group that reached agreement on the following points:²⁴

1. Centrifugation is not required to remove cellular debris in the amniotic fluid and should be abandoned.
2. In the absence of centrifugation, a count greater than or equal to 50,000/ μL should be considered to indicate maturity, and a count less than or equal to 15,000/ μL should be considered to indicate immaturity. A transitional count of 15,000-50,000/ μL should lead to consideration of an additional test to clarify the result.
3. Because meconium can interfere with the cell counter and can reduce the count, either the LBC should not be performed in the

presence of meconium, or clinical judgment should be exercised in interpretation of the results.

4. If there is blood contamination, a hematocrit (Hct) should be performed, and the clinician should be notified if the value is greater than 1%.
5. Although vaginal pool specimens may be acceptable, such specimens should not be analyzed if there is evident mucus, because it can obstruct the counter channels.
6. Severe oligohydramnios can increase the LBC, and polyhydramnios can lead to a false determination of immaturity.

Should centrifugation be performed, a cutoff of 30,000/ μL has been suggested for prediction of fetal pulmonary maturity.^{25,26}

Noninvasive Assessment of Fetal Pulmonary Maturity

Amniocentesis is not without risk, even when it is performed near term. Before ultrasound was used routinely to guide amniocentesis, invasive testing was associated with high rates of complications (19%), including tachycardia and bradycardia (1%), spontaneous membrane rupture (3%), bloody specimens (15%), and failure to obtain fluid (11%).²⁷ Although ultrasound guidance is associated with a much lower failure rate (1.6%), there remains a low but significant risk of complications in experienced hands, including a 0.7% risk of emergent delivery and a 6.6% risk of bloody fluid.²⁸ Because of these concerns, noninvasive markers, including direct and ultrasonographic amniotic fluid visualization, placental grading, fetal biometry, and fetal lung imaging, have been studied for their predictive value regarding fetal pulmonary maturity.

At term, free-floating particles visualized on ultrasound correlate to the presence of fetal vernix,²⁹ but such particles may be seen at any gestational age³⁰ and do not correlate well with biochemical fetal pulmonary maturity test results.³¹ Although a grade III placenta at term has been correlated to a mature L/S ratio, placental grade before preterm birth correlates less well with the L/S ratio (7% immature) and the PG test (25% absent), limiting the utility of this finding.³² When assessed at term, a biparietal diameter of at least 92 mm or the presence of a grade III placenta has been found to correlate to the absence of neonatal pulmonary complications,^{33,34} but the correlation with biochemical testing at term and the relationship with pulmonary complications for those delivering preterm are not consistent.^{35,36} These restrictions severely limit the potential utility of biometric and placental grade evaluations for assessment of fetal pulmonary maturity, particularly for women with unsure dating and those who are anticipating preterm delivery.

Noninvasive imaging of the fetal lung has been proposed to predict fetal pulmonary maturity. In evaluations of lung echogenicity, texture, and through-transmission, Cayea and colleagues³⁷ and Fried and associates³⁸ found a poor correlation between ultrasound findings and mature amniotic fluid indices. Lecithin has a characteristic magnetic resonance signal that may be amenable to assessment by magnetic resonance spectroscopy or by echoplanar magnetic resonance imaging.^{39,40} Although the preliminary data are interesting, technical difficulties in these modalities remain to be resolved, and the cost related to such testing is likely to be prohibitive.

Impact of Gestational Age on Fetal Pulmonary Maturity Testing

Because fetal pulmonary maturity is highly correlated with gestational age, the predictive value of the test result varies significantly with the gestational age at which the test is performed (Fig. 23-1).⁴¹ At term, the

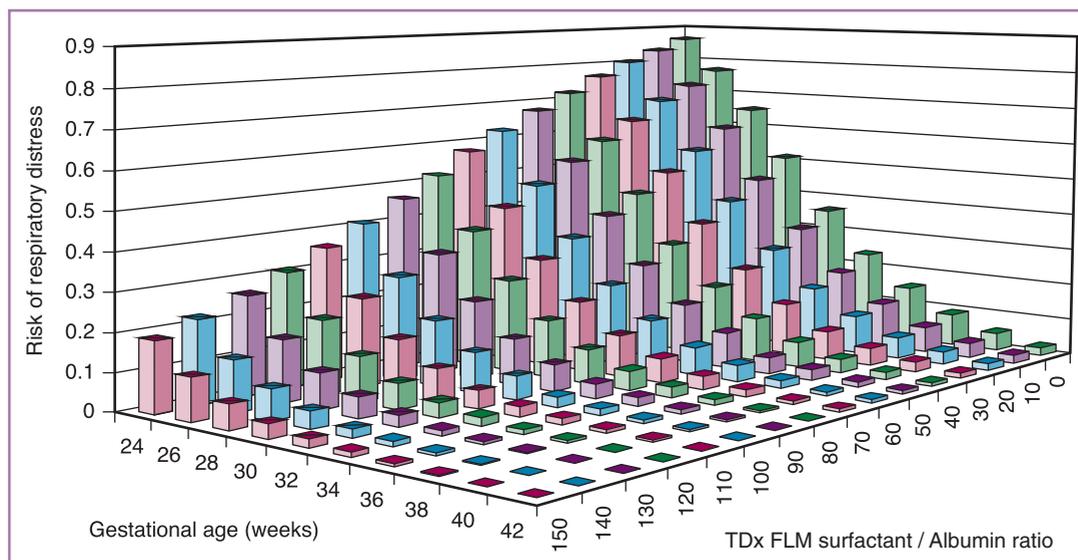

FIGURE 23-1 Risk of neonatal respiratory distress based on gestational age and TDx FLM surfactant/albumin assay result (mg/g). (Adapted from Tanasijevic MJJ, Wybenga DR, Richardson D, et al: A predictive model for fetal lung maturity employing gestational age and test results. *Am J Clin Pathol* 102:788, 1994.)

risk of RDS resulting from pulmonary immaturity is 1% or less. Although a test result indicating immaturity at term is associated with RDS, the risk is low, and severe disease is unlikely. However, in a preterm infant delivered remote from term, an amniotic fluid test suggesting fetal pulmonary immaturity carries a high risk of RDS.

Both at and near term, the likelihood of RDS is low after a test result indicating pulmonary maturity. On the other hand, significant risks of RDS (19.2%), severe IVH (8.1%), and necrotizing enterocolitis (4.8%) were found to exist despite a mature L/S ratio or a positive PG test when preterm birth occurred before 34 weeks.⁴² Lauria and associates found a similar progressive increase in infant morbidity, despite a mature L/S ratio or a positive PG test, with decreasing gestational age at delivery; they also found a low risk of RDS (8.3%) after an immature result at term.⁴³

Assessment of Fetal Pulmonary Maturity in Special Groups

Several investigators have found a lower incidence of RDS among African-American infants and a lower risk of RDS among African-American infants at any cutoff value for the TDx FLM assay.^{44,45} Similarly, female fetuses appear to have higher L/S ratios at any given gestational age and earlier appearance of PG than males.⁴⁶ When matched for gestational age at delivery, twin neonates and singletons have similar morbidity rates,^{47,48} but twin fetuses may have accelerated TDx FLM results after 31 weeks.⁴⁹ It remains controversial whether there is an altered risk for RDS in pregnancies affected by Rh isoimmunization, growth restriction, or preeclampsia, compared with gestational age–matched controls.^{50–55} Regardless of potential differences in the rate of fetal pulmonary maturation or the predictive value of testing in any of these settings, the differences that are observed do not adequately allow differentiation between those who will and will not suffer pulmonary complications, and recommendations for testing and cutoff values for fetal maturity are not altered.

Diabetes complicating pregnancy can alter the rate of fetal lung development and has been proposed to alter the validity of diagnostic

tests for fetal pulmonary maturity. Delayed pulmonary maturity in fetuses of women with class A, B, and C diabetes mellitus (White classification; see Chapter 46), despite a mature L/S ratio of 2:1, has been reported,^{56–58} and some have suggested that an L/S ratio cutoff value of 3:1 should be used in the setting of diabetes. The apparently false maturity associated with a “mature” L/S ratio in such cases was elucidated by a case-control study of 295 subjects in which the L/S ratio was found to be comparable between diabetic and nondiabetic women with increasing gestational age whereas PI levels were significantly higher in women with pregestational diabetes at 33 to 35 weeks’ gestation, and the onset of PG production was delayed by 1 to 1½ weeks in the diabetic pregnancies.⁵⁹ The increased risk of RDS despite a mature L/S ratio and the delayed appearance of PG could result in part from increased levels of myoinositol with hyperglycemia,⁶⁰ because myoinositol enhances PI production to the detriment of PG synthesis.⁶¹

The major factor that influences pulmonary maturation in diabetic progeny appears to be blood glucose control, because those with good control do not have delayed maturation.^{62,63} PG appears later in poorly controlled diabetic pregnancies.^{64,65} The presence of PG, however, is reliable in prediction of fetal pulmonary maturity.⁶⁶ Women with more advanced diabetes (White class D, R, or F) may demonstrate accelerated fetal maturation,⁵⁶ possibly related to uteroplacental dysfunction leading to fetal growth restriction. The S/A ratio, with a cutoff of 70 mg/g, is a reliable predictor of pulmonary maturity in women with diabetes, as is a mature LBC.^{23,67} In a comparison of LBC with PG and L/S ratio in 90 diabetic pregnancies at term,⁶⁸ a centrifuged LBC count greater than 37,000/μL was consistent with fetal pulmonary maturity based on PG and L/S ratio testing. Because the potential impact of delayed fetal pulmonary maturation with diabetes is resolved by 38 weeks’ gestation, well-dated pregnancies with good blood glucose control generally do not require assessment of fetal pulmonary maturity after 38 completed weeks.⁶⁹ When a term infant of a diabetic mother suffers RDS, other possible causes, such as hypertrophic cardiomyopathy, cardiac malformations, and isolated ventricular septal hypertrophy, should be considered.

TABLE 23-1 SELECTED ANTENATAL TESTS FOR ASSESSMENT OF FETAL PULMONARY MATURITY: TECHNIQUE, PREDICTIVE VALUES, AND PREDICTED RELIABILITY BASED ON CONTAMINATION AND SOURCE

Test	Author and Year (Ref. No.)	Technique	Cutoff	Impact of Contamination		Vaginal Pool Collection	Comments
				Blood	Meconium		
L/S ratio	Gluck 1973 (56) Buhi 1975 (70) Cotton 1984 (71)	Thin-layer chromatography	2.0:1	Mature result valid	Not valid	Valid*	Blood decreases mature and increases immature result.
PG	Hallman 1976 (3) Hallman 1977 (4) Schumacher 1985 (5)	Thin-layer chromatography	Present	Valid	Valid	Valid [†]	—

LBC, uncentrifuged	Neerhof 2001 (23)	Cell counter	50,000/ μ L	Mature result valid	Reduces count	Valid [†]	Reliable if Hct <1%. Platelets initially increase count. Coagulation subsequently decreases count.
LBC, centrifuged	Fakhoury 1994 (25) Dalence 1995 (26)	Cell counter	30,000/ μ L	Mature result valid	Reduces count	Valid [†]	Reliable if Hct <1%. Platelets initially increase count. Coagulation subsequently decreases count.

*Free-flowing vaginal fluid may be valid if no blood or meconium is present.

[†]Heavy genital bacterial contamination may yield false mature result due to bacterial phospholipid production.

[‡]Vaginal fluid may be valid if no blood, meconium, or mucus is present.

FLM, fetal lung maturity; Hct, hematocrit; LBC, lamellar body count; L/S ratio, lecithin/sphingomyelin ratio; PG, phosphatidyl glycerol; S/A ratio, surfactant/albumin ratio.

Impact of Contaminants on Fetal Pulmonary Testing Results

Because of the presence of nonpulmonary phospholipids, contamination of amniotic fluid with blood can alter the results of nonspecific fetal pulmonary maturity tests for pulmonary phospholipids (Table 23-1). Maternal serum has been shown to have an intrinsic L/S ratio of between 1.3:1 and 1.9:1, raising the possibility that blood contamination could falsely lower a mature result.^{70,71} On the other hand, a mature result can be considered reassuring, because blood contamination could not be expected to increase an immature value to the level of a mature result. In one study, meconium contamination increased the L/S ratio by 0.1 to 0.2 in preterm infants and by as much as 0.5 after 35 weeks' gestation,⁷² leading the authors to recommend cutoffs of 2.2:1 and 2.5:1 for preterm and term pregnancies, respectively, when meconium staining is present.

The PG test is not affected by blood contamination. Blood contamination can falsely lower the TDx FLM II assay result, but a mature result reliably predicts fetal pulmonary maturity.⁷³ Because red blood cell phospholipids may interfere with the TDx FLM result, some elect not to perform a TDx FLM II assay if there is blood in the specimen.⁷⁴ Dubin suggested that the LBC is not affected by osmotically lysed blood.²¹ Others, however, have suggested that blood contamination may alter the LBC in a biphasic manner, initially increasing the count as a result of the presence of platelets and subsequently decreasing the count as a result of sequestration of lamellar bodies with coagulation.⁷⁵ As such, the LBC should be treated with caution if there is greater than 1% contamination with blood.

Assessment of Fetal Pulmonary Maturity from Vaginal Fluid Specimens

Clinical studies support a role for vaginally collected amniotic fluid specimens after preterm premature rupture of the membranes (pPROM). Shaver and coworkers obtained amniotic fluid by amniocentesis and from the vaginal pool of women admitted with pPROM.⁷⁶ There was a close correlation between L/S ratios obtained from vaginal pool specimens and those obtained from amniocentesis ($r = .88$), and there was an 89% concordance regarding fetal pulmonary maturity. The mean L/S ratio from vaginal pool specimens was not significantly higher than from amniocentesis (2.6 versus 2.3:1; $P = .06$). Similarly, the correlation coefficient for PG was 0.94, and all patients with a positive amniocentesis result also had PG present in the vaginal pool. In addition, PI, phosphatidylethanolamine, and phosphatidylserine levels were similar between amniocentesis and vaginal pool specimens. Other studies have found no evident lecithin or sphingomyelin in lavage fluid from the vagina⁷⁷ and no differences in the L/S ratio or in the amounts of lecithin between vaginal and amniocentesis specimens.⁷⁸

Although prolonged exposure to vaginal fluids has been suggested to yield inaccurate results because of bacterial degradation or phospholipid production, the L/S ratio, PG, and PI levels were similar when fluid was collected directly from the vagina or collected over a period of hours from perineal pads,⁷⁹ and RDS did not occur among infants delivered after a mature PG result from vaginal pool fluid.⁸⁰ In 447 women with PROM, PG determinations from vaginal fluid collected via perineal pads were highly predictive of fetal pulmonary maturity (97.8%), and they were similarly predictive of pulmonary immaturity when compared with specimens collected by amniocentesis (33.7%).⁸¹ In a study of 60 vaginally collected samples, no cases of RDS occurred after a mature L/S ratio, PG, or TDx FLM result greater than 50 mg/g was found.¹⁴ Regarding the vaginally collected fluid for TDx FLM II analysis, a mature S/A ratio (≥ 55 mg/g) had a predictive value of 97.6% in a study of 153 women with pPROM at 30 to 36 weeks, and 24.4% of infants with an immature result (< 40 mg/g) suffered RDS.⁸² The LBC can be falsely elevated by vaginal mucus, which also can block Coulter analyzer channels.⁷⁵

Because vaginally collected amniotic fluid samples yield results similar to those of amniocentesis specimens, it is reasonable to evaluate free-flowing vaginal fluid samples by L/S ratio, S/A ratio, PG determination, and the LBC, provided there is no evident blood, meconium, or mucus in the sample. Perineal collection appears appropriate for L/S ratio and PG determinations, but it is not known whether perineal pad collection is appropriate for TDx FLM II analysis or LBC. Blood and

meconium have the potential to alter testing results, as delineated in the foregoing discussion. Practically, if significant blood or meconium is present in a vaginal pool specimen, consideration should be given to expeditious delivery for fetal indication rather than conservative management.

Induction of Fetal Pulmonary Maturity

The mainstay of efforts directed toward acceleration of fetal maturation is maternal administration of antenatal corticosteroids before preterm birth. Glucocorticoids act through reversible binding to the promoter region of genes that code for functional and structural proteins in various organs.^{83,84} In the lung, glucocorticoids induce lipogenic enzymes necessary for surfactant phospholipid synthesis and conversion of unsaturated to disaturated phosphatidylcholine, stimulate production of antioxidants and surfactant proteins (SP-A through SP-D), and induce enzymes responsible for sodium and potassium channel ion and fluid flux.⁸⁵ The physiologic effects of glucocorticoids on the lung include increased compliance and maximal lung volume, decreased vascular permeability, enhanced lung water clearance, parenchymal structural maturation, and improved respiratory function, in addition to an enhanced response to postnatal surfactant treatment. In addition, glucocorticoids have demonstrated maturational effects in the brain, heart, skin, digestive system, and kidney through cytodifferentiation, enzyme induction, and protein synthesis.

Betamethasone and dexamethasone are long-acting synthetic corticosteroids with similar glucocorticoid potency and negligible mineralocorticoid effects (Table 23-2).⁸⁴ Because of differences in albumin binding, placental transfer, and glucocorticoid receptor affinity, substantially higher doses of cortisol, cortisone, hydrocortisone, prednisone, and prednisolone are required to reach dose equivalency to betamethasone and dexamethasone in the fetus. Women receiving corticosteroids other than betamethasone or dexamethasone should not be considered to have received an adequate dose to stimulate fetal pulmonary maturation.

Prolactin, ambroxol, aminophylline, Intralipid, and β -adrenergic agents, among others, have also been evaluated as potential treatments to enhance fetal pulmonary maturation but have not been consistently effective. Thyroxine has been shown to act directly on the type II pneumocyte to induce surfactant synthesis in animal and human models, but, because thyroxine crosses the placenta poorly, intra-

TABLE 23-2 RELATIVE GLUCOCORTICOID AND MINERALOCORTICOID ACTIVITIES AND EQUIVALENT DOSES OF NATURAL AND SYNTHETIC ADRENAL STEROIDS

amniotic thyroxine instillation with fetal ingestion would be necessary to achieve therapeutic fetal levels. Alternatively, thyrotropin-releasing hormone administered to the mother can cross the placenta to induce fetal thyroxine synthesis via production of thyroid-stimulating hormone. Despite early encouraging results, a meta-analysis of this approach failed to demonstrate benefit of concurrent antenatal maternal thyrotropin-releasing hormone and corticosteroid administration.⁸⁵ In one study, adverse neurologic outcomes—including delayed motor and sensory development as well as social delay—were seen with thyrotropin-releasing hormone exposure.⁸⁶

Antenatal Corticosteroids

Neonatal Outcomes

First demonstrated to reduce RDS and neonatal death by Liggins and Howie in 1972, antenatal corticosteroid administration is one of the most effective and cost-efficient prenatal interventions for preventing perinatal morbidity and mortality related to preterm birth.⁸⁷ Meta-analysis of 21 randomized clinical trials, including 4269 infants, confirmed that antenatal corticosteroids administered to women at risk for preterm birth significantly reduced the incidences of RDS (relative risk [RR], 0.66), IVH (RR, 0.54), necrotizing enterocolitis (RR, 0.46) and neonatal death (RR, 0.69), without increasing maternal or neonatal infection (Fig. 23-2).⁸⁸ Antenatal corticosteroid administration is effective regardless of infant gender or race.⁸⁹ The beneficial impact of antenatal corticosteroids on perinatal outcomes is similar when

pPROM occurs before the onset of treatment (Fig. 23-3).⁸⁸ Although Liggins' original trial suggested that corticosteroids might increase the risk of fetal death in the setting of maternal hypertension, this was not confirmed in subsequent studies.⁹⁰⁻⁹² It is generally believed that optimal corticosteroid effects are achieved when delivery occurs 24 hours or longer after initiation of therapy, but significant reductions in the rates of IVH (odds ratio [OR], 0.42), neonatal death (OR, 0.31), and need for vasopressors (OR, 0.35) have been observed when delivery occurs before the second dose of betamethasone is administered.⁹³

It has been suggested that the immunosuppressive effects of corticosteroids could predispose to maternal or neonatal infection. In a retrospective evaluation of 1260 infants weighing less than 1750 g at birth, administration of antenatal corticosteroids was found to reduce the incidence of RDS, IVH, periventricular leukomalacia, and neonatal death without increasing neonatal sepsis when delivery occurred in the presence of histologic chorioamnionitis.⁹⁴ A retrospective evaluation of 457 pregnancies delivering at 23 to 32 weeks' gestation found no increases in neonatal morbidities after corticosteroid exposure when intrauterine infection or inflammation was evident, and fetal systemic inflammatory response syndrome was less common in this setting if the fetus was exposed to corticosteroid treatment before birth.⁹⁵

Although several studies have suggested that betamethasone is more protective against periventricular leukomalacia than dexamethasone, review of published trials reveals no apparent difference in efficacy with either agent regarding prevention of RDS, IVH, or neonatal

death (Fig. 23-4).^{88,96-98} In 2007, a randomized, controlled trial that directly compared betamethasone and dexamethasone in 299 pregnancies found similar neonatal outcomes between the two treatments, with the exception of IVH, which was more common after betamethasone (17.0 versus 5.7%; $P = .02$). Further study to clarify the relative benefits and risks of these two agents is needed.⁹⁹ Despite a pharmacokinetic profile similar to that of intramuscular injection, oral administration of dexamethasone is not recommended because it has been associated with an increased risk of neonatal IVH and sepsis when compared with intramuscular injection.^{100,101} Because placental transfer of betamethasone and dexamethasone is rapid, there is no rationale for direct fetal administration.

The potential benefit of antenatal corticosteroids varies according to the a priori risk of fetal morbidity due to prematurity (Fig. 23-5).¹⁰² The most recent meta-analysis evaluated the benefits of antenatal corticosteroids across the spectrum of gestational age and found evident benefit with corticosteroid administration up to 34 weeks and 6 days of gestation (see Fig. 23-2).⁸⁸ Although significant benefit was not demonstrated at 35 to 36 weeks' gestation, the relative risk of RDS after antenatal corticosteroid exposure (0.66) was similar to that at earlier gestations. The Collaborative Group on Antenatal Steroid Therapy

permitted enrollment of women beyond 34 weeks if an L/S ratio yielded an immature result and excluded those with a mature result at any gestational age.⁹¹ Infants born after an immature L/S ratio had a significant reduction in RDS with antenatal dexamethasone exposure (8.7% versus 17.3%; $P = .03$). Amniotic fluid testing for fetal pulmonary maturity identifies women with fetuses at higher risk for RDS and also those who will not benefit from antenatal corticosteroids. Antenatal corticosteroid administration may therefore be considered when an immature fetal pulmonary maturity result is identified between 34 and 36 completed weeks of gestation.

Other Fetal and Neonatal Effects

A number of investigators have evaluated the impact of antenatal corticosteroid exposure on fetal biophysical and heart rate activity. These studies have found that betamethasone and dexamethasone reduce fetal breathing and body movements, with inconsistent findings regarding elevation of the baseline fetal heart rate.¹⁰³⁻¹⁰⁹ Although it is unclear whether antenatal corticosteroids reduce the frequency of non-reactive fetal heart rate patterns, a decrease in the frequency of accelerations after corticosteroid administration has been reported.¹⁰⁷⁻¹⁰⁹ Overall, the fetal biophysical effects of betamethasone appear to be

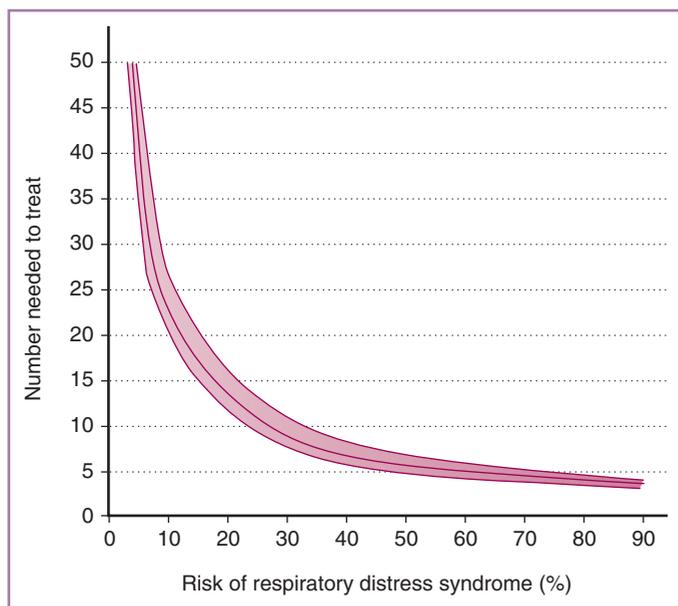

FIGURE 23-5 Number of women who must be treated with antenatal corticosteroids to prevent one case of neonatal respiratory distress syndrome based on the a priori risk of respiratory distress. Shaded zone shows 95% confidence limits. more pronounced than those of dexamethasone and resolve within 3 to 7 days after administration.^{104,106-109}

Neonatal white blood cell counts are generally not affected by maternal glucocorticoid administration.¹¹⁰ Sporadic case reports of neonatal Cushing syndrome and adrenal dysfunction have been reported with prolonged antenatal exposure to steroids.^{111,112} However, Terrone and coworkers found no significant decrease in cortisol levels with increasing antenatal corticosteroid exposure after controlling for other variables,¹¹³ and several studies have found normal neonatal responsiveness to adrenocorticotropic hormone (ACTH) stimulation after exposure to antenatal corticosteroids.¹¹⁴⁻¹¹⁷ Isolated cases of neonatal hypertrophic cardiomyopathy, a known complication in infants of diabetic mothers and with postnatal corticosteroid exposure, have also been reported after antenatal corticosteroid exposure in the absence of significant maternal glucose intolerance.¹¹⁷ A direct cause-effect relationship and the biologic mechanism of this finding remain to be elucidated.

Maternal Consequences

Antenatal corticosteroid administration has been associated with a transient increase in maternal white blood cell count that becomes evident within 24 hours.¹¹⁸ The maternal leukocyte count increases by 4.4×10^3 cells/mL on average but is not expected to rise above $20,000 \times 10^3$ cells/mL. Glucose intolerance can occur, with transient maternal hyperglycemia in nondiabetic women and increasing insulin requirements in diabetic women.^{119,120} Assessment for gestational diabetes is best delayed at least 1 week after corticosteroid administration. Mathiesen and colleagues found that daily insulin requirements increased by 6%, 38%, 36%, 27%, and 17%, respectively, on days 1 through 5 after corticosteroid administration and suggested an algorithm of increasing

insulin doses on those days by 25%, 40%, 40%, 20%, and 10% to 20%, respectively, to compensate for this need.¹²¹ In Liggins' original trial, betamethasone transiently reduced plasma cortisol; levels returned to normal by the fourth day after administration.⁸⁷ In addition to a reduction in basal maternal cortisol (1.9 versus 26.5 $\mu\text{g/mL}$; $P < .001$), McKenna and colleagues demonstrated a decreased maternal response to corticotropin stimulation with antenatal corticosteroids.¹²² Although betamethasone and dexamethasone have virtually no mineralocorticoid effects, it has been suggested that antenatal corticosteroid administration could predispose pregnant women to pulmonary edema. This issue is confounded by concurrent administration of fluid boluses, administration of tocolytics, and coexisting infection as a cause of preterm labor, all of which can lead to pulmonary edema. Current data do not support an independent role for antenatal treatment with either betamethasone or dexamethasone in the pathogenesis of maternal pulmonary edema.

Repeated Courses

Review of published research in animals reveals a consistent improvement in lung function at the expense of decreased fetal growth and adverse effects on brain development with repeated courses of antenatal corticosteroids.¹²³ Jobe and coworkers found that both a single course and three weekly courses of antenatal betamethasone caused a dose-dependent reduction in birth weight in preterm and term lambs, as well as decreased head size in term lambs.¹²⁴ Reduced brain growth, nerve growth, and myelination have been demonstrated after exposure to antenatal corticosteroids, particularly with repeated courses.¹²⁵⁻¹²⁸ A review of eight trials demonstrated a consistent pattern of neurologic abnormalities, including altered optic nerve myelination, decreased eye diameter and retinal thickening, altered sciatic nerve development, reduced brain volume, neuronal degeneration in sheep and monkeys.¹²³ Growth restriction, low body weight, low blood pressure at 3 months, and a persistent decrease in brain weight at 3.5 years were noted in a randomized, controlled trial of repeated corticosteroids in sheep.¹²⁹ Postnatal cortisol exposure in rats was associated with reduced total body weight (50%) and brain weight (30%), with a proportional reduction in cerebral (30%) and cerebellar (20%) cell number, suggesting a reduction in cell division during the first 2 weeks of life.¹³⁰

Retrospective and observational studies in humans have revealed similar effects on fetal pulmonary function and brain growth with multiple courses of antenatal corticosteroids. Infants exposed to more than one course of antenatal steroids had smaller head circumferences (28.1 versus 28.4 cm; $P = .01$) and a lower incidence of RDS (34.9% versus 45.2%; $P = .005$).¹³¹ In an observational study of 447 infants born before 33 weeks' gestation, a dose-dependent reduction in birth weight (122 g; $P = .01$) and head circumference (1.02 cm; $P = .002$) occurred after three or more courses of antenatal corticosteroids.¹³² In a post hoc analysis of 710 fetuses exposed to various doses of antenatal corticosteroids in a trial of antenatal thyrotropin-releasing hormone, exposure to more than one course of antenatal corticosteroids was associated with a 32-g decrease in birth weight for infants born before 32 weeks' gestation and an 80-g reduction for infants born after 32 weeks' gestation.¹³³ A review of retrospective and nonrandomized observational studies of antenatal corticosteroids in humans found that multiple courses were associated with significantly reduced RDS (OR, 0.79) and patent ductus arteriosus (OR, 0.56) but no differences in mortality, IVH, bronchopulmonary dysplasia, or necrotizing enterocolitis when compared with a single course.¹³⁴ Overall, these studies revealed no consistent increase in the risk of neonatal sepsis or amnio-

nitis with multiple courses despite an increased rate of endometritis (OR, 3.22).

No significant differences in functional residual capacity, respiratory compliance, head circumference, or birth weight were found in a recent study between infants delivered within 7 days after at least two courses of antenatal betamethasone, infants delivered more than 7 days after a single course, and untreated controls.¹³⁵ Although postnatal systemic corticosteroid administration has been shown to reduce chronic lung disease and ventilatory requirements, short-term peripartum treatment of preterm infants is also associated with hyperglycemia, hypertension, hypertrophic cardiomyopathy, and growth failure.¹³⁶

Long-term data regarding the effects of antenatal corticosteroid exposure in humans are limited. The Collaborative Group on Antenatal Steroid Therapy monitored infants exposed antenatally to dexamethasone for 3 years.⁹¹ Steroid-exposed infants were slightly heavier and taller (3%; $P = .05$); the placebo group had more respiratory complications (3.5% versus 0.5%; $P = .02$) and heart murmurs (11.2% versus 5.6%; $P = .04$). Head circumferences and neurologic outcomes were similar in the placebo and steroid groups. Infants evaluated 10 to 12 years after participating in a randomized, placebo-controlled trial of antenatal betamethasone demonstrated more admissions for infections during the first years of life but no differences in weight, height, head circumference, neurologic development, pulmonary function, or visual acuity.¹³⁷ Long-term evaluation of the preterm infants revealed catch-up growth after exposure to multiple courses of antenatal corticosteroids, with no differences in infant weight, length, or head circumference at 3 years.¹³²

Data are available from several prospective, randomized clinical trials of repeated antenatal corticosteroids in humans. In a study of 502 women randomized to receive either weekly betamethasone to 34 weeks or no further treatment after an initial course of antenatal corticosteroids, repeated antenatal corticosteroids did not significantly reduce composite morbidity (severe RDS, bronchopulmonary dysplasia, severe IVH, periventricular leukomalacia, sepsis, necrotizing

enterocolitis, or death; 22.5% versus 28.0%; $P = .16$).¹³⁸ However, severe RDS (15.3% versus 24.1%; $P = .01$) and composite morbidity were decreased if delivery occurred between 24 and 27 weeks (77.4% versus 96.4%; $P = .03$) after repeated doses. The relative risk of composite morbidity after repeated corticosteroids declined with increasing gestational age at birth. There was no significant relationship between birth weight and repeated steroids (2009 versus 2139 g; $P = .10$), but the effect size was similar to that previously described.^{132,133} The National Institute of Child Health and Human Development Maternal-Fetal Medicine Units (NICHD-MFMU) Network study randomly assigned 495 women at 23 to 32 weeks' gestation to receive either weekly betamethasone or placebo 7 to 10 days after an initial course and found no significant reduction in the composite primary morbidity outcome (8.0% versus 9.1%; $P = .67$) with repeated corticosteroid treatments.¹³⁹ However, repeated treatment was associated with less frequent neonatal surfactant administration ($P = .02$), mechanical ventilation ($P = .004$), continuous positive airway pressure ($P = .05$), and pneumothoraces ($P = .03$). The group receiving repeated corticosteroids had more neonates weighing less than the 10th percentile (23.7% versus 15.3%; $P = .02$), and those receiving four or more courses were significantly smaller.

Crowther and colleagues randomly assigned 982 women at risk for preterm birth at less than 32 weeks' gestation after a single course of antenatal corticosteroids to receive repeated weekly betamethasone or placebo weekly.¹⁴⁰ Repeated corticosteroid treatment led to less frequent RDS (33% versus 41%; $P = .01$) and severe lung disease (12% versus 20%; $P = .0003$), as well as less frequent oxygen therapy and shorter duration of mechanical ventilation. In the only reported trial to evaluate rescue corticosteroid treatments, Mercer and associates randomly allocated women at risk for preterm birth to weekly betamethasone through 34 weeks or rescue therapy if needed.¹⁴¹ Those assigned to repeated weekly corticosteroids were twice as likely to receive corticosteroids within 1 week of birth before 35 weeks; only 37% of those assigned to rescue therapy receiving corticosteroids in a timely fashion before early preterm birth ($P = .001$). As in the NICHD-

TABLE 23-3 SUMMARY OF THE 1994 AND 2000 NATIONAL INSTITUTES OF HEALTH CONSENSUS PANEL GUIDELINES REGARDING ANTENATAL CORTICOSTEROIDS FOR FETAL MATURATION

The benefits of antenatal administration of corticosteroids to fetuses at risk of preterm delivery vastly outweigh the potential risks. These benefits include not only a reduction in the risk of RDS but also a substantial reduction in mortality and IVH. Optimal benefit begins 24 hours after initiation of therapy and lasts at least 7 to 14 days.

All pregnant women between 24 and 34 weeks' gestation who are at risk of preterm delivery within 7 days should be considered candidates for antenatal treatment with a single course of corticosteroids.

Treatment consists of two doses of betamethasone, 12 mg given IM 24 hours apart, or four doses of dexamethasone, 6 mg given IM 12 hours apart. There is no proof of efficacy for any other regimen.

Because treatment with corticosteroids for less than 24 hours is still associated with significant reductions in neonatal mortality, RDS, and IVH, antenatal corticosteroids should be given unless immediate delivery is anticipated.

The decision to use antenatal corticosteroids should not be altered by fetal race or gender or by the availability of surfactant replacement therapy. Patients who are eligible for therapy with tocolytics should also be eligible for treatment with antenatal corticosteroids.

In complicated pregnancies where delivery before 34 weeks' gestation is likely, antenatal corticosteroid use is recommended unless there is evidence that corticosteroids will have an adverse effect on the mother or delivery is imminent.

In preterm premature rupture of the membranes at less than 30 to 32 weeks' gestation in the absence of clinical chorioamnionitis, antenatal corticosteroid use is recommended because of the high risk of IVH at these early gestational ages.

Because of insufficient scientific data from randomized clinical trials regarding efficacy and safety, repeated courses of corticosteroids should not be used routinely. In general, repeated courses should be reserved for patients enrolled in randomized, controlled trials.

IVH, intraventricular hemorrhage; RDS, respiratory distress syndrome.

MFMU trial, multivariate analysis revealed a dose-dependent reduction in birth weight ($P < .02$) with increasing exposure to antenatal corticosteroids.¹⁴² Further study is needed to determine the optimal approach to achieve timely antenatal corticosteroid treatment while minimizing fetal exposure.

National Institutes of Health Consensus Panel on Antenatal Steroids

In 1994, a National Institutes of Health (NIH) consensus panel reviewed the available literature and published guidelines regarding antenatal corticosteroid administration.¹⁴³ In response to the rapid adoption into clinical practice of repeated antenatal corticosteroid administration to women at high risk for preterm birth and the accumulating data suggesting potential risks associated with this approach, the consensus panel was reconvened to review the available literature regarding repeated corticosteroid administration in August, 2000.¹⁴⁴ This review reaffirmed the benefits of antenatal corticosteroid administration and recommended against routine administration of repeated courses of corticosteroids. The recommendations of these two conferences are summarized in Table 23-3.

Summary

The induction of fetal maturation through timely antenatal administration of betamethasone or dexamethasone is one of the most effective prenatal interventions available for reduction of perinatal morbidity and mortality related to preterm birth. Like many medications with strong effects, antenatal corticosteroids have the potential for significant side effects. The optimal timing and dosage of antenatal steroids before anticipated preterm birth is the subject of important ongoing research. In the meantime, unless delivery is imminent, a single course of antenatal corticosteroids should be considered when preterm birth before 34 completed weeks is anticipated, and repeated courses should not be administered routinely outside the setting of randomized clinical trials. Alternative techniques to promote fetal pulmonary maturation are not recommended. Fetal pulmonary maturity testing through amniotic fluid analysis can be helpful in determining the relative risks of neonatal complications. If amniotic fluid testing indicates fetal pulmonary maturity, aggressive attempts at pregnancy prolongation for infant benefit may not be worthwhile, but an immature result can identify those who may benefit from pregnancy prolongation for antenatal corticosteroid administration. In any case, delivery should not be delayed for the purpose of fetal maturation in the setting of nonreassuring fetal testing, suspected intrauterine infection, or worsening maternal or fetal condition that places the mother or fetus in imminent jeopardy.

Chapter 24

Invasive Fetal Therapy

Jan A. Depreest, MD, PhD, Eduardo Gratacos, MD, PhD, and Liesbeth Lewi, MD, PhD

The availability of high-resolution ultrasound imaging and screening programs has made the unborn child a true patient. When fetal malformations, genetic diseases, or in utero acquired conditions are suspected, patients are referred to tertiary care units with more specialized skills, technical equipment, experience, and multidisciplinary counselors to define potential options. In some cases, intervention before birth may be desirable, which often does not require direct access to the fetus—for example, transplacental administration of pharmacologic agents for cardiac arrhythmias or antibiotics in case of fetal infection. Other conditions can be treated only by invasive access to fetus. In utero transfusion of a hydropic fetus to treat the anemia of Rh isoimmunization, first described in 1961, was probably the first successful invasive therapeutic procedure. Today, blood transfusion through the umbilical cord, intrahepatic vein, or (exceptionally) directly into the fetal heart is widely offered, with good fetal and long-term outcome when procedures are done by experienced operators.

Some conditions are amenable to surgical correction, and in the majority of cases this is best done after birth. Occasionally, prenatal surgery is required to save the life of the fetus, or to prevent permanent organ damage. This can be achieved by correcting the malformation, by arresting the progression of the disease, or by treating some of the immediately life-threatening effects of the condition, delaying more definitive repair until after birth. Because of the potential complications, risks and benefits of the intervention must be weighed against each other. Table 24-1 summarizes the indications and rationale for in utero surgery on the fetus, placenta, cord, or membranes.

A consensus, endorsed by the International Fetal Medicine and Surgery Society (IFMSS), has been reached on the criteria and indications for fetal surgery (Table 24-2).¹ In the 1980s to 1990s, only a few conditions met these criteria, and surgical intervention required maternal laparotomy, partial exteriorization of the fetus through a stapled hysterotomy. These “open” procedures were initially associated with high fetal-maternal morbidity, raising the question for some of the value of claimed benefits.

The growing availability of videoendoscopic surgery in the 1990s, combined with earlier experience with fetoscopy, paved the way for the concept of *endoscopic fetal surgery*. The rationale was that minimally invasive access to the amniotic cavity would reduce the frequency of preterm labor and diminish maternal morbidity. Investigators at the Centre for Surgical Technologies (CST) in Leuven, Belgium, have helped advance the application of these techniques by first establishing an ovine model for endoscopic fetal surgery.² That experience laid the basis for the first successful umbilical cord ligation in Europe,³ almost simultaneously with, but independently from, a successful pro-

cedure done by Quintero a few months earlier. The Leuven group subsequently set up the Eurofoetus consortium supported by the European Commission (E.C.), acting as liaison between selected European fetal medicine units and an endoscopic instrument maker to design new endoscopes and instruments to improve management of specific conditions.^{4,5} The later execution of a successful randomized trial on laser coagulation of twin-twin transfusion syndrome (TTTS) prompted in Europe wide clinical acceptance of fetoscopy.

Progress in the practice of fetal surgery has been slowed by the paucity of randomized trials, by patient and practitioner reluctance, by availability of local operator expertise, and even by the lack of regulatory approval of novel surgical instrumentation. For example, open fetal surgery can now be performed with significantly improved outcomes and fewer side effects compared with a decade ago. Despite that, such procedures are rarely done in Europe, with the exception of operations on placental support.⁶ In the United States, slow regulatory acceptance of new fetoscopic instruments has contributed to the controversy regarding the place of fetoscopic treatment of TTTS,^{7,8} together with a historically stronger preference for open procedures, including even for nonethical conditions. Indeed, in utero repair of myelomeningocele (MMC) is currently being performed in the MOMS trial (see Outcome of Antenatal Neural Tube Defect Repair, later), sponsored by the National Institutes of Health, which tests the hypothesis that antenatal repair will reduce morbidity in survivors compared with postnatal repair. Should the results of the MOMS trial be positive, undoubtedly European centers will have to reconsider the issue of open surgery, just as increasing experience and more encouraging long-term results of fetoscopic procedures from Europe have spurred the spread of minimally invasive procedures throughout the United States.

Open Fetal Surgery

Open fetal surgery is a complex enterprise that should be undertaken only in centers staffed with skilled personnel. Because of the high incidence of preterm labor, prophylactic tocolysis is essential, using for instance indomethacin or nifedipine. Large-bore venous access is established, but fluid administration is conservative and meticulously managed to reduce the risk for pulmonary edema that frequently occurs with certain tocolytics. Open surgical procedures are typically performed using general endotracheal anesthesia, taking advantage of the myorelaxant and uterine contraction suppression qualities of halogenated anesthetic gases. The uterus is exposed by a large laparotomy and opened with specially designed, resorbable lactomer surgical staples

TABLE 24-1 INDICATIONS AND RATIONALE FOR IN UTERO SURGERY ON THE FETUS, PLACENTA, CORD, OR MEMBRANES

	Pathophysiology	Rationale for In Utero Intervention
Surgery on the Fetus		
1. Congenital diaphragmatic hernia	Pulmonary hypoplasia and anatomic substrate for pulmonary hypertension	Reverse pulmonary hypoplasia and reduce degree of pulmonary hypertension; repair of actual defect delayed until after birth
2. Lower urinary tract obstruction	Progressive renal damage by obstructive uropathy Pulmonary hypoplasia by oligohydramnios	Prevention of renal failure and pulmonary hypoplasia by anatomic correction or urinary deviation
3. Sacrococcygeal teratoma	High-output cardiac failure by arteriovenous shunting and/or bleeding Direct anatomic effects of the tumoral mass	Reduction of functional impact of the tumor by its ablation or (part of) its vasculature Reduction of anatomic effects by draining cysts or bladder
4. Thoracic space-occupying lesions	Polyhydramnios-related preterm labor Pulmonary hypoplasia (space-occupying mass) Hydrops by impaired venous return (mediastinal compression)	Amnioreduction preventing obstetric complications Creating space for lung development Reverse process of cardiac failure
5. Neural tube defects	Damage to exposed neural tube Chronic cerebrospinal fluid leak, leading to Arnold-Chiari malformation and hydrocephalus	Prevention of exposure of the spinal cord to amniotic fluid; restoration of CSF pressure, correcting Arnold-Chiari malformation
6. Cardiac malformations	Critical lesions causing irreversible hypoplasia or damage to developing heart	Reverse process by anatomic correction of restrictive pathology
Surgery on the Placenta, Cord, or Membranes		
7. Chorioangioma	High-output cardiac failure by arteriovenous shunting Effects of polyhydramnios	Reverse process of cardiac failure and hydrops fetoplacentalis by ablation or reduction of flow
8. Amniotic bands	Progressive constrictions causing irreversible neurologic or vascular damage	Prevention of amniotic band syndrome leading to deformities and function loss
9. Abnormal monochorionic twinning: twin-to-twin transfusion	Intertwin transfusion leads to oligopolyhydramnios sequence, hemodynamic changes; preterm labor and rupture of the membranes; in utero damage to brain, heart, or other organs In utero fetal death may cause damage to co-twin	Arrest intertwin transfusion, prevent or reverse cardiac failure and/or neurologic damage, including at the time of in utero death Prolongation of gestation
Fetus acardiacus and discordant anomalies	Cardiac failure of pump twin and consequences of polyhydramnios Serious anomaly raises question for termination of pregnancy or selective feticide	Selective feticide: to arrest parasitic relationship, to prevent consequences of in utero fetal death To avoid termination of the entire pregnancy

Historically, in utero treatment of hydrocephalus was attempted but abandoned. In the late 1990s, indications 5 and 6 were added; 7 to 9 were typical results of the introduction of obstetric endoscopy in fetal surgery programs.

TABLE 24-2 CRITERIA FOR FETAL SURGERY

1. Accurate diagnosis and staging is possible, with exclusion of associated anomalies
2. Natural history of the disease is documented, and prognosis established.
3. Currently no effective postnatal therapy.
4. In utero surgery proven feasible in animal models, reversing deleterious effects of the condition.
5. Interventions performed in specialized multidisciplinary fetal treatment centers with strict protocols and approval of the local ethics committee, and with informed consent of the mother or parents.

Adapted from Harrison MR, Adzick NS: The fetus as a patient: Surgical considerations. *Ann Surg* 213:279-291; discussion, 277-278, 1991.

(Premium Poly CS 57, US Surgical, Norwalk, CT) to prevent intraoperative maternal hemorrhage. Location of the uterine incision largely depends on placental position, as determined by sterile ultrasound.

The fetus is partially exposed, and sometimes exteriorized, and monitored while the procedure is performed, using ultrasound, pulse-oximetry, or direct fetal electrocardiography.⁹ Additional analgesics, atropine, and pancuronium or vecuronium are given to the fetus to suppress the fetal stress response, bradycardia, as well as to immobilize it. The fetus is kept warm through the use of intrauterine infusion of Ringer's lactate at body temperature, and intrauterine volume and pressure are maintained as close as possible to physiologic levels. After completion of the fetal portion of the procedure, the uterus is closed in two layers with resorbable sutures, amniotic fluid volume is restored, and intra-amniotic antibiotics are administered. The hysterotomy is covered with an omental flap. Postoperatively, the patient is managed

in intensive care while receiving aggressive tocolysis with magnesium sulfate and, when required, additional agents.

Complications of open fetal surgery include preterm contractions, maternal morbidity from tocolysis, rupture of membranes, and fetal distress. Postoperative uterine contractions are the Achilles' heel of open fetal surgery, but new tocolytic regimens have improved tocolytic efficacy while limiting maternal side effects. Amniotic fluid leakage through the hysterotomy site (or, more commonly, vaginally because of membrane rupture) can occur. With significant postoperative oligohydramnios, delivery may be necessary because of fetal distress. In recent case series on myelomeningocele repair, patients left the hospital within a few days, a much shorter interval than previously.^{10,11} Delivery by cesarean section is mandatory to prevent uterine rupture.

The EXIT Procedure

The EXIT (ex utero intrapartum treatment) procedure is increasingly used for selected fetal conditions and is an example of open fetal surgery—in this instance, to establish functional and reliable fetal airway control while keeping the fetus attached to the uteroplacental circulation by delivering only a portion of the fetus through a hysterotomy incision. EXIT is done under maximal uterine relaxation, so the maternal risks of this procedure are mainly hemorrhagic. Because of the complex interactions necessary between the anesthesia, obstetric, and pediatric personnel, EXIT procedures require significant advance preparation and preassignment of the roles for the many physicians and nurses involved. The indications for EXIT include congenital airway obstruction from laryngeal atresia, large head and neck tumors, and malformations of the face and jaw. For more information on EXIT, please refer to the Online Edition of this chapter.

Fetoscopy

Instrumentation

Fetoscopic procedures are minimally invasive interventions that can be considered a cross between ultrasound-guided and formal surgical procedures. Fetoscopy must be organized so that the surgical team can see simultaneously both the ultrasound and the fetoscopic image. Specifically designed fetoscopes typically have deported eyepieces to reduce weight and facilitate precise movements. Nearly all are flexible

fiber-endoscopes rather than conventional rod lens scopes, and as the number of pixels has increased, image quality has improved markedly. Working length must be sufficient to reach all regions of the intrauterine space. Amniotic access is facilitated by thin-walled, semiflexible disposable, or larger-diameter reusable metal cannulas, so that instrument changes are possible. Once inside the amniotic cavity, the obturator is replaced by the fetoscope. Technical handbooks provide details of use of these instruments and a discussion of distention media.^{3,4} Instrument insertion is facilitated with local or locoregional anesthesia, which is injected along the anticipated track of the cannula down to the myometrium.

Despite the minimally invasive nature of fetoscopy, it continues to be associated with iatrogenic preterm premature rupture of membranes (pPROM) (Table 24-3). Initiatives that have been evaluated to treat or prevent this condition¹² include attempts to repair defects with various tissue sealants applied either intracervically or intra-amniotically. These efforts have met with limited success, because fetal membranes have limited ability to heal.¹³ The use of amniopatch as a treatment modality for symptomatic iatrogenic pPROM was first described by Quintero in 1996,¹⁴ and since then a number of case series have been published¹⁵ for iatrogenic membrane rupture after amniocentesis, fetoscopy, or chorionic villus sampling.¹⁶ Chorionic membrane separation, without obvious amniorrhexis, is another complication that may be treated with amniopatch.¹⁷

Fetal Pain Relief during Procedures

Pain is a subjective experience occurring in response to impending or actual tissue damage. The subjective experience of pain requires nociception and an emotional reaction. Nociception requires an intact sensory system, whereas an emotional reaction requires some form of consciousness. It is difficult to know the extent to which the fetus experiences pain. However, several indirect methods have suggested that the fetus at least *can* feel pain. Anand and colleagues and Fisk and coworkers demonstrated that premature infants and fetuses display several stress responses during invasive procedures.¹⁸⁻²⁰ These data indicate that the mid-gestational fetus responds to noxious stimuli by mounting a distinct stress response as evidenced by an outpouring of catecholamines and other stress hormones as well as hemodynamic changes. Consequently, management of fetal pain and associated stress response in utero during invasive fetal interventions is important.²⁰

TABLE 24-3 RISK FOR PRETERM PREMATURE RUPTURE OF MEMBRANES (pPROM) AFTER FETOSCOPIC PROCEDURES

Procedure	Risk for pPROM (At Assessment)	Diameter Instrument	Reference
Amniocentesis	1%-1.7%	22 ga (0.7 mm)	Tabor et al, 1986; Eddleman et al, 2006
Amniodrainage	1% per tap	18 ga (1.2 mm)	Umur et al, 2001 Mari et al, 2000
Cordocentesis	3.7% (<37 wks)	20 ga (0.9 mm)	Tsongsong et al, 2001
Shunt	15% (thorax) 32% (bladder)	7 Fr (2.3 mm)	Picone et al, 2004 (thorax) Freedman, 1996 (bladder)
Fetoscopic laser	7% (<1 wk)	10 Fr (3.3 mm)	Yamamoto and Ville, 2005
(twins: 6%)	45% (<37 wks)		Lewi et al, 2006
Cord occlusion	10% (<4 wks)	10 Fr (3.3 mm)	Robyr et al, 2005
FETO	20% (<32 wks)	10 Fr (3.3 mm)	Jani et al, 2006

FETO, fetal endoscopic tracheal occlusion.

Fetal Therapy for Complicated Monochorionic Twin Pregnancies

Monochorionic twins constitute about 30% of all twin pregnancies²¹ and by definition share a single placenta and nearly always have vascular anastomoses interconnecting their circulations.²² Because of often unequal placental circulatory districts as well as cross-connecting placental vessels, monochorionic twins have substantially greater morbidity and mortality than their dichorionic counterparts.²³ These result from complications such as TTTS, twin reversed arterial perfusion (TRAP) sequence, and, in the event of single intrauterine fetal demise (IUFD), acute exsanguination of the surviving twin into the vascular space of the demised twin.²⁴

Twin-Twin Transfusion Syndrome

TTTS occurs in 8% to 9% of monochorionic twin pregnancies and represents the most important cause of mortality. The complication typically becomes clinically evident between 16 and 26 weeks of gestation.^{25,26} The pathology is usually explained by unbalanced circulatory sharing between the twins across placental vascular anastomoses. These anastomoses are denoted as arterioarterial (AA), venovenous (VV) or arteriovenous (AV).²⁷ AA and VV anastomoses are bidirectional anastomoses, whereas AV anastomoses are unidirectional and hence may create imbalance in interfetal circulation, leading to TTTS. The artery and vein of an AV anastomosis can be visualized on the placental surface as an unpaired artery and vein that pierce the chorionic plate at close proximity. Bidirectional AA anastomoses are believed to protect against the development of TTTS, as most non-TTTS monochorionic placentas (84%) have AA anastomoses in contrast to TTTS placentas (24%). Although vascular anastomoses are an anatomic prerequisite for the development of TTTS, the pathogenesis of TTTS is probably more complex,²⁸ involving vasoactive mediators produced by both donor and recipient.²⁹

Diagnosis

The diagnosis of TTTS is based on stringent sonographic criteria of amniotic fluid and bladder filling discordance. In the donor, there is

oliguric oligohydramnios, with the deepest vertical pocket (DVP) being 2 cm, while the recipient twin presents with polyuric polyhydramnios (DVP cutoff of 8 cm before 20 weeks' gestation and 10 cm after 20 weeks).⁷ Although growth restriction is often present in the donor twin, it is not essential for the diagnosis of TTTS. In severe cases of TTTS, ultrasound signs of congestive cardiac failure resulting from fluid overload in the recipient include a negative or reverse a-wave in the ductus venosus, pulsatile flow in the umbilical vein, tricuspid regurgitation, and signs of hypovolemia or increased vascular resistance in the donor, with absent or reversed flow in the umbilical artery.

The differential diagnosis includes monoamnioticity, discordant growth, isolated polyhydramnios or oligohydramnios, and severe intertwin hemoglobin differences at the time of birth. TTTS does occur in monoamniotic pregnancies and is characterized by polyhydramnios of the common amniotic cavity with discordant bladder sizes. However, monoamniotic twins can move freely and usually their umbilical cords are entangled, whereas in diamniotic twins with TTTS, the donor is usually stuck against the uterine wall. Severe discordant growth is also often confused with TTTS, as the growth restricted twin may appear stuck because of oligohydramnios, but the appropriately grown twin invariably has normal amniotic fluid or only a mild degree of polyhydramnios that does not fulfill the criteria of TTTS.

Staging

TTTS is currently staged according to the Quintero staging system,³⁰ which is based on relative amniotic fluid volume, Doppler waveforms, and the bladder status in the donor (Table 24-4). Although the Quintero staging system predicts outcome, it better reflects manifestations of disease rather than a time sequence, as it is clear that cases can progress directly from stage I to stage V, and TTTS can appear as stage III. Attempts are now being made to improve the current staging system by incorporating a cardiac function score with echocardiographic features.^{31,32} However, its additional value for predicting outcome or the choice of treatment remains to be demonstrated.³³

Treatment

The mortality of untreated mid-trimester TTTS is more than 80% because of extreme prematurity with labor or pPROM with polyhydramnios, or as a result of fetal demise of one or both twins from cardiac failure in the recipient or poor perfusion in the donor. In view of the poor outcome, the general consensus is that treatment should

TABLE 24-4 QUINTERO STAGING SYSTEM

Time in Pregnancy	DVP Recipient		DVP of Donor	
<20 weeks*	≥8 cm		<2 cm	
≥20 weeks*	≥10 cm*		<2 cm	
With Either				
Stage I	Stage II	Stage III	Stage IV	Stage V
Bladder filling in donor	Absent bladder filling in donor	Abnormal Doppler findings: Absent/reversed EDF umbilical artery (donor); Reversed a-wave ductus venosus (recipient)	Hydrops fetalis	Intra-uterine fetal death

DVP, deepest vertical amniotic fluid pocket; EDF, end-diastolic flow.

Twin-twin transfusion syndrome cases should have a deepest pool of 8 cm on the recipient side and a deepest pool of less than 2 cm on the donor side. Classification is further made by the filling status of the bladder in the donor (Stages I and II). Additional (Doppler) ultrasound features upgrade stage.

*In European centers, most use a cutoff of 10 cm for gestation over 20 weeks. For earlier presentations than 18 weeks, cutoffs have not been agreed upon.

be offered. Unfortunately, even with the latest treatment modalities, the risk for adverse outcome remains significant and the pregnancy must be followed carefully regardless. The option of pregnancy termination should be part of patient counseling.

AMNIOREDUCTION

Serial amnioreduction was the first procedure offered to reduce polyhydramnios and intrauterine pressure in the hopes of alleviating contractions and prolonging the pregnancy. Theoretically, amnioreduction might also improve fetal hemodynamics by reducing the amniotic fluid pressure on the placental vessels. Amnioreduction is a relatively simple procedure involving aspiration of amniotic fluid via an 18-gauge needle under local anesthesia until restoration of normal amniotic fluid volume can be measured sonographically. The main shortcoming of amnioreduction is its failure to address the cause of the disease, because the vascular anastomoses remain patent. Furthermore, even if amnioreduction can resolve or stabilize stage I or II disease, it fails in one third of cases,³³ and, after failed amnioreduction, subsequent laser coagulation may be hampered by intra-amniotic bleeding, membrane separation, or unintentional septostomy.

SEPTOSTOMY

Intentional puncturing of the intertwin septum (i.e., septostomy), with or without amnioreduction, has been suggested to have beneficial effects largely based on the rarity of TTTS in monoamniotic twins. It is proposed that the donor may be able to restore blood volume and improve perfusion by swallowing amniotic fluid. A randomized trial comparing septostomy with amnioreduction found similar rates of survival of at least one twin. However, patients undergoing septostomy were more likely to require only a single procedure.³⁴ Nevertheless, septostomy brings with it the potential risks of cord entanglement resulting from an iatrogenic monoamniotic state, and it makes laser coagulation of the vascular anastomoses for progressive disease technically much more challenging.

SELECTIVE FETICIDE

This procedure is usually performed by umbilical cord coagulation with laser or bipolar energy and is associated with an overall survival rate of the remaining twin of about 70% to 80%.^{8,9} The most important drawback of this approach is its maximum survival rate of 50%. Also, it may be unacceptable for many parents to sacrifice one twin without obvious structural pathology, and it may not be easy to determine which twin has the highest risk for adverse outcome. Therefore, this technique should be reserved for cases with severe discordant anomalies, with an inaccessible vascular equator, with pPROM of one sac, or with imminent IUFD.

FETOSCOPIC LASER COAGULATION

Laser coagulation of the vascular anastomoses was first reported in 1990 by De Lia and colleagues,³⁵ who described nonselective coagulation of all vessels crossing the intertwin membrane, thus arresting the transfusion of blood and vascular mediators from donor to recipient and functionally making the placenta dichorionic. However, nonselective coagulation of all vessels along the intertwin membrane causes significant parenchymal placental damage and probably increases the procedure-related fetal loss. Most fetoscopic laser centers therefore avoid coagulation of nonanastomosing vessels and instead perform selective coagulation of all visible anastomosing vessels along the vascular equator.

Fetoscopic laser coagulation is usually performed between 16 and 26 weeks of gestation. Before 16 weeks, the amniotic membrane may

still be separated from the chorion, hampering amniotic access and making the degree of oligohydramnios or polyhydramnios difficult to measure. After 26 weeks, fetoscopic laser coagulation remains a valid treatment option and appears to be associated with less major neonatal morbidity than repeated amnioreduction.³⁶ From 32 weeks onward, elective preterm delivery should be considered if lung maturation can be documented.

Preoperatively, a detailed ultrasound scan is performed for disease staging and to exclude discordant anomalies. Prophylactic antibiotics and prophylactic tocolytics are used. Fetoscopy is performed percutaneously through a 3- to 4-mm incision under local or regional anesthesia. High-quality videoendoscopic hardware with an excellent light source, video camera, and monitor, and with specifically designed 20- to 30-cm fiberoptic or rod lens fetoscopes with a diameter of 1 to 3 mm, is used. For laser coagulation, a neodymium-yttrium aluminum garnet (Nd-YAG) laser (minimal power requirements, 60 to 100 W) or a diode laser (30 to 60 W) with fibers of 400 to 600 μm provide optimal efficacy.

Next, the positions of the fetuses, umbilical cord insertions, and placenta are mapped by ultrasound. Under ultrasound guidance, the cannula or fetoscopic sheath is inserted into the recipient's sac. Preferentially, the site of the trocar insertion is remote from the donor's sac to avoid the risk of unintentional septostomy, and the trocar is aimed to achieve a 90-degree angle with the vascular equator, as this provides the best opportunity for optimal coagulation. The vascular equator can usually not be visualized on ultrasound unless there is a marked difference in echogenicity between the two placental districts.³⁷ The trocar is therefore optimally inserted halfway along the imaginary line between the two cord insertions. Occasionally, vision is hampered by blood or debris, in which case amnioexchange with warmed Hartmann's solution (heated by a blood warmer or a special amnio-irrigator) can improve visibility.

A systematic inspection of the entire vascular equator is performed. The placental insertion of the intertwin septum is easily identified as a thin white line on the chorionic surface, and anastomosing vessels leaving the donor usually cross under the septum in the direction of the recipient. Anastomosing vessels can also be identified starting from the recipient's or donor's cord insertion. Arteries are distinguishable from veins, as they cross over the veins and have a darker color because of their lower oxygen saturation.³⁸ Not uncommonly, it may be impossible, because of the position of the intertwin septum, placenta, fetus, or other physical limitations, to determine whether vessels anastomose. In these instances, these vessels are coagulated as well, as the aim is to separate the two fetal circulations completely.

Coagulation is performed at a distance of approximately 1 cm and ideally at a 90-degree angle, using a nontouch technique (Fig. 24-1), starting at one placental border and finishing at the other end. Recently the sequential approach selecting A-V anastomoses first has been advocated.³⁹ Sections of 1 to 2 cm are coagulated with shots of about 3 to 4 seconds, according to the tissue response. The use of excessive laser power levels should be avoided, as this may cause vessel perforation and fetal hemorrhage. Once all vessels are coagulated, the vascular equator is inspected once more to ascertain that all anastomoses have been fully coagulated and that flow has not resumed. The procedure is completed by amnioreduction until normal amniotic fluid volume (DVP, 5 to 6 μm) is measured by ultrasound.

With an anterior placenta, the recipient's sac as well as the anastomosing vessels may be much more difficult to access. Instruments for anterior placentas have been developed, but it is still unclear whether these improve performance. Nonflexible rod lens telescopes have been fabricated with angles of inclination up to 30 degrees, or with an associ-

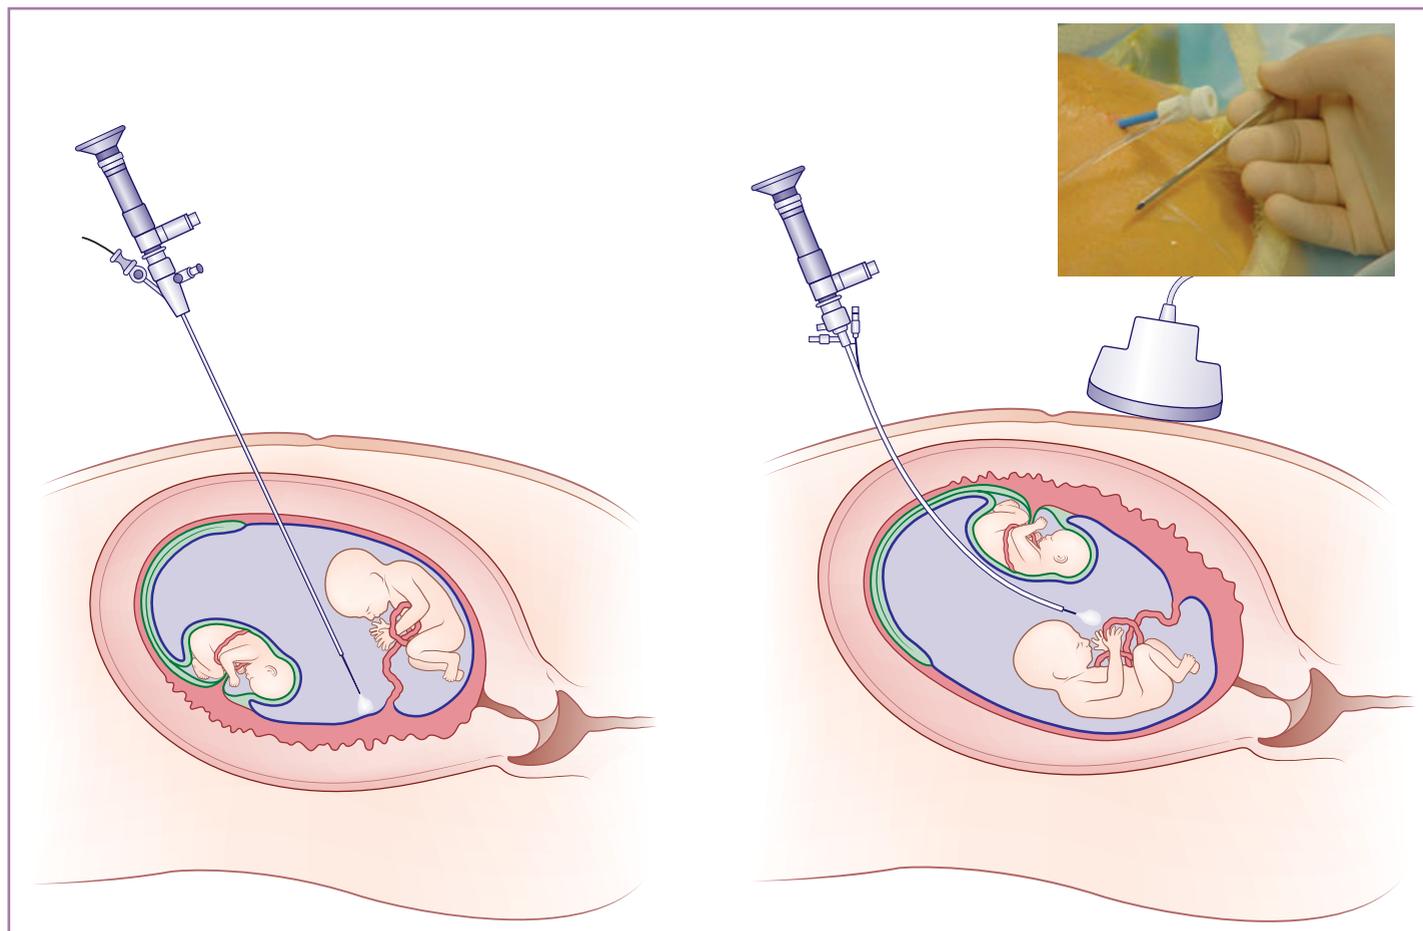

FIGURE 24-1 Schematic drawing of fetoscopic laser coagulation. When the placenta is posterior, the scope can be directly inserted through the sheath without using a cannula (*left*). When the placenta is anterior (*right*), a curved sheath and a flexible cannula (*inset*) can be used. This allows a change of instruments. (Drawing by K. Dalkowski, and modified with permission of Endopress Karl Storz.)

ated deflecting mechanism for the laser fiber.⁴⁰ Thus far, similar outcomes have been reported for anterior and posterior placentas.⁷

Postoperatively, the patient should remain in the hospital for 1 to 2 days while daily ultrasound scans are performed to document fetal viability, amniotic fluid volume, and changes in the phenotypic features of TTTS, particularly bladder filling and Doppler parameters. Postoperative transient hydropic changes and absent or reversed a-wave in the ductus venosus may occur in the donor twin.^{41,42} For fetuses with absent end-diastolic flow preoperatively, reappearance of end-diastolic flow is observed in 53%.⁴³ Laser coagulation may equalize previously discordant umbilical venous blood flow between donor and recipient.^{44,45} Catch-up fetal growth has also been described.

Fetal complications after laser treatment include fetal demise, isolated severe intertwin hemoglobin discordance, and persistent TTTS. Postoperative single IUID occurs in about 33% and double IUID in 4% of pregnancies. Single IUID seems to affect donor and recipient equally,⁴⁶ and approximately 60% are diagnosed within 24 hours and 75% within 1 week. Persistent TTTS complicates up to 14% of pregnancies with two surviving fetuses 1 week after laser treatment⁴⁷ and appears to be related to missed, large, unidirectional anastomoses.⁴⁸ Possible treatment options include repeat laser with backup cord coagulation, amnioreduction, and elective delivery. A number of other, rarer complications have been described, most of them occurring after amnioreduction as well. Please also refer to the Online Edition of this chapter.

AMNIOREDUCTION VERSUS LASER COAGULATION

The Eurofoetus trial,⁷ with 142 enrolled patients with stage I to IV disease diagnosed between 15 and 26 weeks of gestation, demonstrated that fetoscopic laser coagulation is currently the best available treatment option for TTTS (Table 24-5). Compared with amnioreduction, use of the laser was associated with a significantly higher likelihood of the survival of at least one twin to 28 days of life (76% versus 56%). Also, the median gestational age at delivery was higher in the laser than in the amnioreduction group (33.3 weeks versus 29.0 weeks' gestation), with 42% and 69% women, respectively, delivering at less than 32 weeks. Also, infants in the laser group had a lower incidence of cystic periventricular leukomalacia (laser 6% versus amnioreduction 14%). Importantly, the Eurofoetus trial demonstrated that more than half of severe cerebral lesions identified postnatally appear to have had an antenatal origin.^{24,49} A recent systematic review of the Eurofoetus randomized controlled trial and two other observational studies confirmed that laser coagulation appears to be more effective in the treatment of TTTS, with less perinatal neurologic morbidity and mortality.⁵⁰

Huber and coworkers⁵¹ similarly demonstrated, in a consecutive series of 200 pregnancies, a significant trend toward reduced survival after fetoscopic laser treatment with increasing stage. Survival of both twins was 75.9% for stage I, 60.5% for stage II, 53.8% for stage III, and 50% for stage IV. At least one twin survived in 93.1% of pairs at stage

TABLE 24-5 LASER COAGULATION VERSUS AMNIOREDUCTION

Baseline characteristics according to group. Results reported as number of pregnancies [n (%)]. AFV, amniotic fluid valve.

*Two patients had two laser procedures.

[†]With number of fetuses as denominator (P value adjusted for clustering).

[‡]Severe intraventricular hemorrhage was defined as ventricular bleeding with dilation of the cerebral ventricles (grade III) or parenchymal hemorrhage (grade IV).

[§]Cystic periventricular leukomalacia was defined as periventricular densities evolving into extensive cystic lesions (grade III) or extending into the deep white matter evolving into cystic lesions (grade IV).

I, 82.7% at stage II, 82.5% at stage III, and 70% at stage IV. The survival rate of donors (70.5%) was similar to that of recipients (72.5%). Hecher and associates demonstrated the importance of the learning curve in laser photocoagulation, with increased experience leading to improved survival,⁵² later gestational age at delivery, and a decrease in neurodevelopmental impairment.⁵³

With regard to long-term follow-up, a study of surviving infants (aged 14 to 44 months) from a laser photocoagulation series laser demonstrated neurologic problems in 22% of survivors,⁵⁴ of which 11% were mild and 11% were severe. In a later series by the same group, 7% of infants showed minor and 6% showed major neurologic abnormalities.⁵³ The reduced neurologic impairment in the second report may be explained by increased operator experience. These results are significantly better than the 16% minor and 26% major abnormalities in a cohort treated with amnioreduction.⁵⁵

Selective feticide may be indicated for cases with a severe discordant structural or chromosomal anomaly, with severe discordant growth and a high risk for IUFD, or with TRAP sequence, and it may be indicated for selected cases with TTTS. However, because monochorionic

multiple fetuses share a single placenta with multiple vascular anastomoses, selective feticide by intravascular injection of potassium chloride may embolize the healthy fetus. Fetoscopic umbilical cord ligation has been largely abandoned because it is a cumbersome and lengthy procedure, although it achieved an immediate and complete cord occlusion.⁵⁶

Selective Feticide for Other Complications

For fetuses with TRAP sequence, needle-based coagulation techniques using laser, monopolar, and radiofrequency energy⁵⁷⁻⁵⁹ have been adopted, involving the insertion of a 14- to 17-gauge needle into the acardiac twin's abdomen under ultrasound guidance, and aiming for the intra-abdominal rather than umbilical vessels. The largest series, of 29 monochorionic multiple pregnancies treated with radiofrequency energy between 18 and 24 weeks, reported a survival rate of 86%.⁵⁹ Median gestational age at delivery was 38 weeks (range, 24 to 40 weeks). In another recent smaller series⁶⁰ of 13 cases treated with radiofre-

quency energy between 17 and 24 weeks, the survival rate was 94%. All patients delivered after 32 weeks, except for one patient complicated by pPROM at 26 weeks.

Umbilical Cord Occlusion

At present, laser or bipolar coagulation of the umbilical cord is our preferred approach and can be used for all indications from 16 weeks onward.^{48,61} Early on, a double-needle loaded with a 1-mm fetoscope and a 400- μ m laser fiber is used.⁶² Lasering of the cord allows optimal visual control but may fail beyond 20 weeks because of the increasing size of the umbilical cord vessels.^{63,64} Ultrasound-guided bipolar cord coagulation was therefore introduced for later gestational ages.

Bipolar coagulation is performed with a 2.4- or 3-mm reusable or disposable forceps. Under ultrasound guidance, a portion of the umbilical cord is grasped at a convenient location and coagulation current is applied in progressive increments until the appearance of turbulence and steam bubbles indicates tissue coagulation. Confirmation of arrest of flow distal to the occlusion is performed by color Doppler. Even if there is no longer any visible flow, two additional cord segments (preferably at a site more proximal to the target fetus) are coagulated. After completion of the coagulation procedure, amnioreduction of excessive fluid is carried out before removal of the cannula. The survival rates of umbilical cord coagulation in monozygotic twins is approximately 80%. In dichorionic and monozygotic triplets, the technique resulted in similar survival rates of 79%. About half of the losses are attributable to intrauterine demise of the healthy co-twin and about half to postnatal losses related to the very preterm birth, mostly related to pPROM.^{47,48}

Twin Reversed Arterial Perfusion Sequence

An extreme manifestation of TTTS is the TRAP sequence, which complicates about 1% of monozygotic twin pregnancies. In the TRAP sequence, blood flows from an umbilical artery of the pump twin in a reversed direction into the umbilical artery of the perfused twin, via an AA anastomosis. The perfused twin's blood supply is by definition deoxygenated and results in variable degrees of deficient development of the head, heart, and upper limb structures. Two criteria are necessary for the development of a TRAP sequence: an AA anastomosis and a discordant development⁶⁵ or intrauterine death of one twin,⁶⁶ allowing reversal of blood flow.

The increased burden to perfuse the parasitic twin puts the pump twin at risk for congestive heart failure and hydrops.⁶⁷ Because of the rarity of the disorder, the natural history of antenatally diagnosed cases is still poorly documented, with reported survival rates for the pump twin varying between 14%⁶⁸ and 90%.⁶⁹ Data on long-term outcome are not available, although the risk for cardiac and neurodevelopmental sequelae may be high as a result of vascular imbalances in utero.^{70,71} Several factors have been suggested to indicate a poor prognosis, such as a high ratio of the weight of the acardiac twin to that of the pump twin,⁷² a rapid increase in the acardiac mass,⁷³ and small differences in the umbilical artery Doppler values.^{74,75} These parameters were, however, mostly studied in the late second and third trimesters and do not necessarily apply in the early second trimester, where spontaneous resolution as well as sudden death of the pump twin remain unpredictable. Early intervention is an option, as the diagnosis is now usually made at an early stage in pregnancy, although the pump twin may survive without any intervention in at least half of cases. For later procedures, umbilical cord coagulation as well as needle-based intrafetal coagulation techniques are both suitable treatment options. The largest experience with fetoscopic laser coagulation for this indication

was reported by Hecher and coworkers ($N = 60$) with an 80% survival rate.⁷⁶

More discussion of the techniques of management of TTTS, together with figures, tables, and references, can be found in the Online Edition of this chapter.

Isolated Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) occurs sporadically, with an incidence of 1 in 2500 to 1 in 5000 newborns. The term *congenital diaphragmatic hernia* designates a range of lesions, and outcomes are accordingly diverse.⁷⁷ Ultimately, all the phenotypes of CDH arise from genetic mutations in one or several developmental pathways common for tissues of the fetal diaphragm and adjacent organs.

Eighty-four percent of lesions are left-sided, 13% are right-sided, and 2% are bilateral. Complete diaphragmatic agenesis, with herniation of the central tendinous portion and eventration, are other rare manifestations. Associated anomalies are present in 40% of cases, which confers an increased risk for neonatal death, and less than 15% of infants in this group survive.^{78,79} In the majority, however, CDH is an isolated defect. Although CDH is in essence a defect in the diaphragm, the abnormal lung development that ensues confers its clinical impact. CDH lungs have a reduced number of alveoli, thickened alveolar walls, increased interstitial tissue, and markedly diminished alveolar air space and gas-exchange surface area. The conducting airways and associated blood vessels are diminished as well. Both lungs are typically affected, the ipsilateral more than the contralateral. There may be other anatomic aberrations present in the diaphragm and in the upper gastrointestinal tract, such as the position of the liver, lower esophagus, and stomach.

Prenatal Diagnosis of Congenital Diaphragmatic Hernia

The diagnosis of CDH is usually made in the prenatal period when cystic masses are visualized in the chest or when cardiac deviation is noted in the axial view of the thorax (Fig. 24-2). Left-sided CDH typically appears with rightward shift of the heart and the echolucent stomach and intestines in the left chest. Right-sided CDH is more difficult to diagnose because the echogenicity of liver is similar to that of the mid-trimester fetal lung. The diagnosis is suggested when the fetal heart is shifted farther into the left chest, or when color Doppler interrogation of the umbilical vein and hepatic vessels are shown to cross the diaphragmatic boundary. The differential diagnosis includes cystic or mixed masses (cystic adenomatoid malformation, bronchogenic, enteric and neuroenteric cysts, mediastinal teratoma, and thymic cysts), bronchopulmonary sequestration, and bronchial atresia. In these conditions, abdominal organs are not displaced into the chest.

When CDH is suspected, the patient should be examined for associated cardiac, renal, central nervous system, and gastrointestinal anomalies.⁸⁰ Chromosomal anomalies are increased in CDH, so amniocentesis and genetic consultation are mandatory. For management, patients should be referred to tertiary centers accustomed to managing complex congenital anomalies, in prenatal and in postnatal periods, to optimize the necessary comprehensive diagnostic and prognostic assessments, provide counseling on which parents can base further decisions, and eventually offer timed delivery followed by optimal postnatal care.

Echogenicity has changed. **C**, Herniation of the liver. **D**, Visualization of the major vessels helps identify the liver position.

Prognostic Indicators for Congenital Diaphragmatic Hernia

Multiple prognostic measures have been proposed, including proportions of the cardiac ventricles, amniotic fluid volume, degree of mediastinal shift, and position of the stomach. However, most have not been shown to reliably provide clinically useful correlations. Because the most critical problems of the neonate with CDH are lung hypoplasia and pulmonary hypertension, quantitation of relative pulmonary mass using a variety of imaging techniques has been most successful.⁸¹

The best validated measurement is the ratio of lung area (assessed by two-dimensional ultrasound through the contralateral lung) to head circumference (LHR).⁸² Although different methods for measuring the LHR have been proposed, the most reproducible and accurate involves tracing the lung contours (see Fig. 24-2).⁸³ The predictive value of LHR was validated in 184 consecutive cases of isolated left-sided CDH; the fetuses were examined at 22 to 28 weeks of gestation and were born live beyond 30 weeks at 10 centers (Table 24-6).⁸³⁻⁸⁵ Liver herniation has also been shown to be an independent predictor

of outcome.⁸⁶ Because the echogenicity of liver is comparable to that of the lung, Doppler interrogation of the umbilical vein and hepatic vessels helps in determining its position above or below the diaphragm.

From 12 to 32 weeks, lung area in the fetus increases four times faster than head circumference, so the LHR must be referenced to gestational age.³⁵ The gestational effect on LHR can be accommodated by expressing the observed LHR as a ratio of the expected mean for gestation. A study from the CDH antenatal registry (354 fetuses) with unilateral isolated CDH evaluated these measures between 18 and 38 weeks.⁸⁵ Observed-to-expected (O/E) LHR predicted outcome well, regardless of the gestational age at measurement, and also correlates with short-term morbidity indicators (Fig. 24-3).⁸⁷

Prediction of Pulmonary Arterial Hypertension

In utero assessment of lung vasculature can be obtained by measuring the number of branches and vessel diameters, and by performing mea-

surements of flow and resistance with two- or three-dimensional techniques. The Toronto group demonstrated that the diameter of the ipsilateral branch of the main pulmonary artery is related to the severity of hypoplasia in the prenatal as well as in the postnatal period, where it is also a significant predictor of morbidity.⁸⁸⁻⁹⁰ Recently, Ruano and colleagues established nomograms for main pulmonary artery branch diameters, which will allow proper validation of this concept.⁹¹ They also proposed three-dimensional power Doppler to assess the entire lung vasculature, and to predict neonatal survival and the occurrence of pulmonary hypoplasia.⁹²

Postnatal Management of Congenital Diaphragmatic Hernia

The ill development of the fetal lung leads to variable degrees of respiratory insufficiency and pulmonary hypertension after birth. The aberrant vasculature is also more sensitive to hypoxic vasoconstriction, leading to pulmonary hypertension and further increasing right-to-left shunt. This creates a vicious cycle that prevents gas exchange of the shunted blood and increases acidosis and hypoxia. Pulmonary hypertension is increasingly being treated by inhaled nitric oxide.⁹³ Administration of prostaglandin E₁ has been advocated to keep the ductus arteriosus patent in cases with severe secondary left ventricular cardiac dysfunction.^{94,95} Survival statistics for postnatally managed CDH are optimized in specialized centers: in France, referral centers have higher survival rates (41% to 66%; $P = .03$)⁹⁶; in Canada, high-volume centers (>12 CDH admissions over the 22-month period) with centralized management report a 13% higher survival rate than low-volume centers.⁹⁷

Antenatal Management for Congenital Diaphragmatic Hernia

Meticulous preparation for a possible antenatal surgical procedure for CDH is critical. Informed consent requires counseling that includes describing the typical postnatal course of a newborn with CDH, together with the range of expected morbidities that might be encountered. Counseling should also include individualized information derived from the imaging assessments (O/E LHR < 25%). In mild or

moderate cases, the predicted survival rate is more than 60%, so planned delivery at a referral center is appropriate. In more severe cases, especially with associated anomalies, other options should be discussed, including termination of pregnancy.

The patients with a poorer prognosis are also candidates for an antenatal intervention that could reduce the likelihood of lethal pulmonary hypoplasia. Previously, antenatal therapy consisting of in utero anatomic repair using hysterotomy and direct fetal surgery was advocated, but this has been abandoned because of poor results. Subsequently, Di Fiore and colleagues revived the concept of triggering lung growth by tracheal occlusion,⁹⁸ based on the observation that fetuses with congenital high airway obstruction syndrome (CHAOS) display impressive lung growth, probably because of the lung-distending pressure of the trapped pulmonary secretions. However, lung growth alone is not adequate for postnatal pulmonary function, as lung epithelial maturation is also necessary. Under normal circumstances, fetal breathing movements promote fluid flow out of the airways, creating cycles of tissue stretch and relaxation. It is now clear that breathing movements are important for an appropriate balance between growth and differentiation.⁹⁹

Temporary tracheal occlusion takes advantage of this principle, its beneficial effects being a function of the timing and duration of the occlusion. When sustained until birth, lung growth is vigorous but airway epithelial maturation is compromised. Experimental models, now confirmed with clinical experience, demonstrate that in utero placement, then reversal of occlusion (plug-unplug sequence) achieves improved lung volume and maturation.¹⁰⁰ Antenatal tracheal occlusion is clinically applied at 26 to 28 weeks under locoregional anesthesia using fetoscopy to insert a balloon into the fetal trachea. The occlusion is reversed by removing the balloon fetoscopically at 34 weeks to allow fetal breathing and epithelial maturation.^{101,102} If preterm labor precludes fetoscopic removal, emergency peripartum removal by laryngo-tracheoscopy or an EXIT procedure may be required.¹⁰³

A recent report of a randomized controlled trial by Harrison and coworkers showed that prenatal tracheal occlusion did not increase survival.¹⁰⁴ In that study, however, fetuses with O/E LHR up to 36% (LHR = 1.4) were offered fetal therapy. It is therefore not surprising that postnatal management yielded results equivalent to those of antenatal surgery. There were not enough cases with extreme or severe

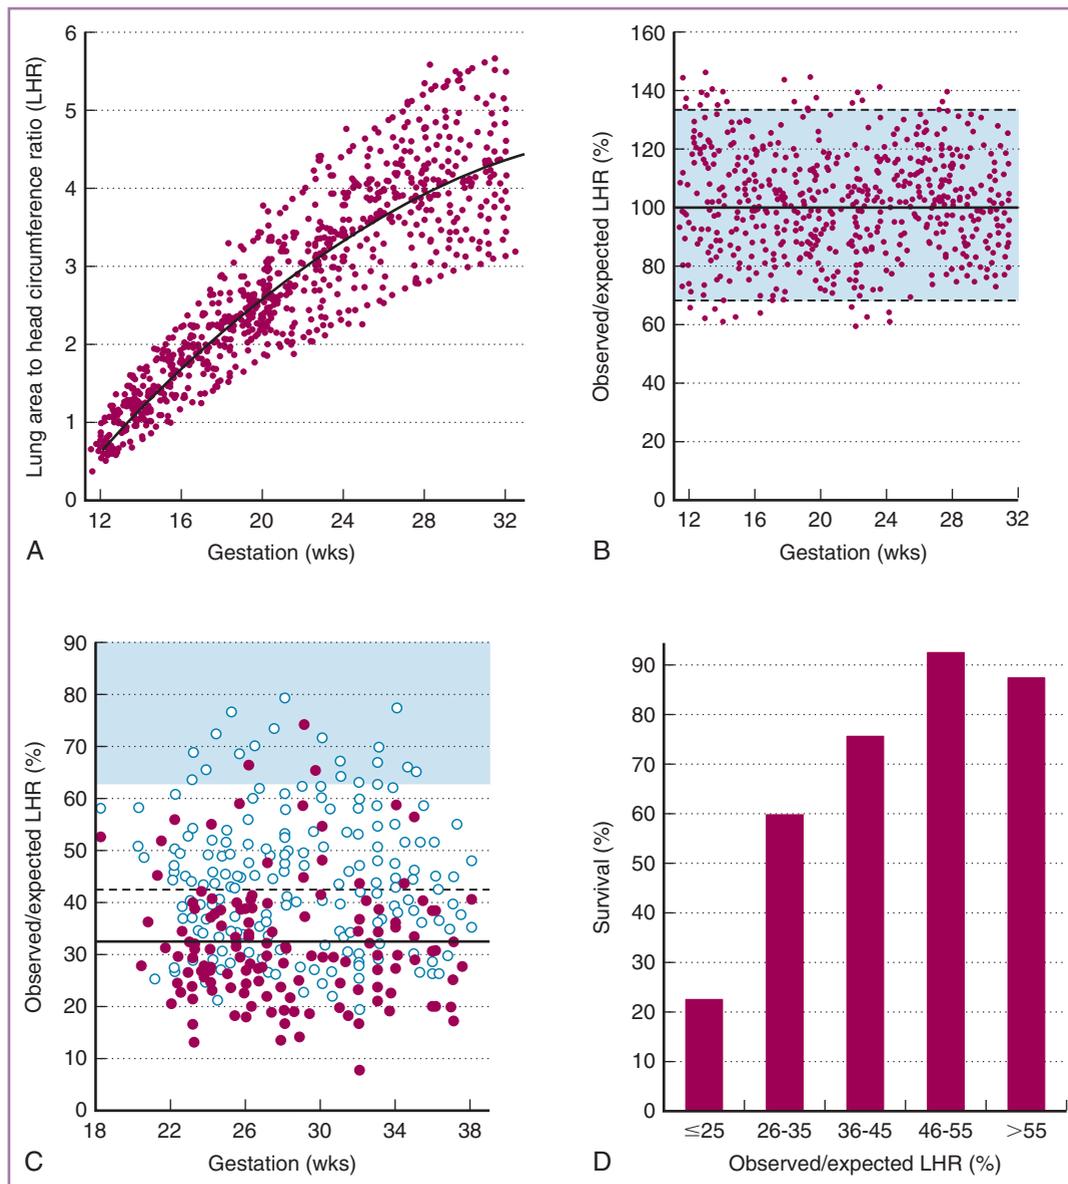

FIGURE 24-3 Ratio of lung area to head circumference (LHR). **A**, Measurements of right LHR in normal fetuses throughout pregnancy. The curve shows LHR as a function of gestational age. **B**, Plot of the observed-to-expected (O/E) LHR with the mean and the 95th and 5th percentiles in normal fetuses. **C**, Right O/E LHR in fetuses with isolated left-sided diaphragmatic hernia. The shaded area depicts the lower part of the normal range. *Closed circles* (observations), *solid line* (mean), *nonsurvivors*; *open circles* (observations), *dotted line* (mean), *survivors*. **D**, Survival rates according to the O/E LHR in fetuses with isolated left-sided diaphragmatic hernia and liver herniation ($N = 161$). (**A** and **B** from Peralta CF, Cavoretto P, Csapo B, et al: Assessment of lung area in normal fetuses at 12-32 weeks. *Ultrasound Obstet Gynecol* 26:718-724, 2005; **C** and **D** modified from Jani J, Nicolaides KH, Keller RL, et al: Observed to expected lung area to head circumference ratio in the prediction of survival in fetuses with isolated diaphragmatic hernia. *Ultrasound Obstet Gynecol* 30:67-71, 2007.)

hypoplasia. These are the subjects who are offered fetal endoscopic tracheal occlusion (FETO) in the current European programs, where the presence of liver herniation and O/E LHR < 27% to 28% (corresponding to LHR < 1.0 in the early third trimester) are strict criteria today.

The European FETO task force has reported a survival rate of 50% to 57% in this group of fetuses with otherwise poor predicted survival.¹⁰⁵ Iatrogenic pPROM remains a major complication. In such

cases, patients are managed expectantly in the hospital so that the tracheal balloon can be promptly removed once labor or chorioamnionitis occurs. Thus far, more than 75% of patients have delivered beyond 34 weeks (mean gestational age at birth, 36 weeks), significantly later than the 31 weeks observed by Harrison and colleagues.¹⁰⁴ Neonatal survival rate is higher with prenatal than with perinatal balloon retrieval (83.3% versus 33.3%; $P = .013$), a trend persisting until discharge (67% versus 33%; NS). Major predictors of survival are gesta-

tional age at delivery and lung size prior to FETO.⁷⁴ Similarly, the increase in lung area or volume after FETO is also an independent predictor of survival.^{106,107} Trials are currently under design in Europe.

Congenital Cystic Adenomatoid Malformation

Congenital cystic adenomatoid malformation (CCAM) is a common pulmonary malformation estimated to occur in approximately 1 in 3000 to 5000 pregnancies. CCAM is a dysplastic or hamartomatous tumor with overgrowth of terminal bronchioles and reduction in number of alveoli. Patients usually present with a thoracic mass involving only one pulmonary lobe. In approximately 40%, the CCAM may have a systemic vascular supply, similar to bronchopulmonary sequestration (BPS), and these forms are defined as hybrid CCAM-BPS. The classic pathologic classification as proposed by Stocker established three types.¹⁰⁸ Chapter 18 gives details of diagnosis and prognosis.

When the CCAM is larger, there is an increased risk for pulmonary compression and hydrops. Use of the ratio of the mass area to head circumference (CCAM volume ratio [CVR]) has been proposed as a gestational-age-independent prognostic measure.¹⁰⁹ CCAM volume (in milliliters) is measured using the formula for an ellipse (length \times height \times width \times 0.52). When CVR is higher than 1.6, an 80% risk for fetal hydrops is predicted. When the CVR is high but fetal age is greater than 34 weeks, respiratory distress should be anticipated, and the EXIT procedure with lobectomy in a tertiary care center should be considered.¹¹⁰ Hydrops after viability should prompt delivery. In the previable period, fetal intervention can be lifesaving, but no large series is available to judge among options. Percutaneous puncture and thoracoamniotic shunting of macrocystic masses has been reported and has the advantage of minimal invasiveness.¹¹¹ Wilson recently reviewed experience with 23 shunted cases at a mean gestational age of 21 to 22 weeks.¹¹² The mean CVR in this group was 2.4, which fell to 0.7 after shunting. The mean interval from shunt to delivery was 11.8 weeks (36.3 weeks at birth). The overall survival was 74%, with one fetal and five neonatal deaths, correlating with a shorter shunt-to-delivery interval. A recent systematic review concluded that CCAM cyst drainage improves perinatal survival among hydropic fetuses.¹¹³

For solid lesions, lobectomy via open fetal surgery can be considered. In a series of 22 cases receiving surgery between 21 and 31 weeks, there were 11 long-term survivors who were developmentally normal (up to 12 years of age).¹¹⁴ Hydrops resolved in 1 to 2 weeks, followed by normalization of the mediastinum, and the remaining lung underwent impressive catch-up growth. Causes of fetal death despite fetal surgery were termination of pregnancy for Ballentyne syndrome (one patient), preterm labor and/or chorioamnionitis (two patients), and fetal hemodynamic compromise leading to intraoperative death in six fetuses and postoperative death in another two.

Other Thoracic Lesions

Pleural effusion or fetal hydrothorax is a typical symptom of other pathology. Pleural effusions have the potential to cause mediastinal shift, abnormal venous return and secondary lung compression, hydrops, and intrauterine demise. Most primary effusions are lymphatic in origin, but they may be associated with other anomalies (25%), including aneuploidy (7%).¹¹⁵ Bilateral effusions are associated

with pulmonary lymphangiectasia, and the prognosis remains poor despite fetal treatment.

The principal indication for fetal intervention for pleural effusions is fetal hydrops, because the survival rate is 30%, compared with 80% when there are effusions without fetal hydrops.¹¹³ Thoracoamniotic shunting is performed using a double-pigtail catheter or via serial thoracentesis.¹¹⁶ There is no proof that serial puncture is better than shunting, and the complication rate of this procedure is about 15%. Iatrogenic pPROM¹¹⁷ and procedure-related fetal loss occurs in 5% to 10%. Shunt dislodgment has been described, but posterior insertion may prevent the fetus from pulling the shunt out. Preterm birth is common, with a mean gestational age of 34 to 35 weeks.

Lower Urinary Tract Obstruction

Pathophysiology

Congenital anomalies of the genitourinary tract are the most commonly identified during prenatal ultrasound screening, with an incidence of up to 0.4%. *Lower urinary tract obstruction* (LUTO) is a descriptive term for a heterogeneous group of relatively common conditions (1 in 5000 to 8000 male newborns). Posterior urethral valves is by far the most common cause (at least one third in autopsy series), but other conditions such as stenosis of the urethral meatus, anterior urethral valves, urethral atresia, ectopic insertion of a ureter, and (peri)vesical tumors are included.

LUTO leads to bladder distention with compensatory hypertrophy of the smooth muscle of the bladder wall. Over time, bladder compliance and elasticity decrease and may contribute to poor postnatal bladder function. Elevated bladder pressure inhibits urinary inflow from above, resulting in reflux hydronephrosis. Progressive pyelectasis and calyctasis compress the delicate renal parenchyma, leading to functional abnormalities in the medullary and eventually the cortical regions, leading eventually to renal insufficiency. Concurrently, amniotic fluid volume falls, and pulmonary hypoplasia evolves. This condition is reproducible in animal models, and more importantly, reversal of the obstruction both experimentally and clinically leads to reaccumulation of amniotic fluid.¹¹⁸

Case Selection

Because LUTO can result in neonatal lethal pulmonary hypoplasia and renal failure, careful selection of candidates for antenatal intervention is paramount, ensuring that procedures to relieve LUTO are offered only to fetuses with sufficient renal function.¹¹⁹ Because fetal renal function cannot be determined on a single urine sample, the best prediction is obtained by two or more sequential vesicocenteses several days apart.¹²⁰ The commonly recognized prognostic thresholds are shown in Table 24-7.

The prenatal evaluation of fetuses with the sonographic findings of LUTO must be comprehensive, and coexisting structural and chromosomal anomalies must be excluded before intervention can be considered.¹²¹ Female fetuses very often have more complex syndromes of cloacal malformations that may not benefit from in utero shunt therapy. Because of the presence of oligohydramnios or anhydramnios, it may be necessary to obtain karyotype by transabdominal chorionic villus or fetal blood sampling and thorough structural assessment of the fetus after amnioinfusion.

TABLE 24-7 FETAL URINE ANALYSIS PROGNOSTIC THRESHOLDS

Electrolytes	Good Prognosis	Poor Prognosis
Sodium	<90 mmol/L	>100 mmol/L
Chloride	<90 mmol/L	>100 mmol/L
Osmolality	<180 mOsm/L	>200 mOsm/L
Total protein	<20 mg/dL	>40 mg/dL
β_2 -microglobulin	<6 mg/L	>10 mg/L

Outcomes for Antenatal Therapy of Lower Urinary Tract Obstruction

Vesicoamniotic shunts bypass the urethral obstruction, diverting the urine into the amniotic space and allowing drainage of the upper urinary tract and prevention of pulmonary hypoplasia by restoration of amniotic fluid volume. Initial experience showed good outcomes.¹²² In the largest and longest-term documented experience from Biard and coworkers,¹²³ postnatal diagnosis of the type of urinary obstruction was highly predictive of long-term renal outcome. Fetuses with posterior urethral valves had better outcomes than those with urethral atresia or the prune belly syndrome. Most children were developmentally normal, but pulmonary problems may persist. Among 18 survivors, six had acceptable renal function, four had mild insufficiency, and six required dialysis and transplantation.

Other case series have had similar results, suggesting that even with favorable pre-procedure urine profiles, up to half of survivors have chronic renal insufficiency in childhood.^{124,125} The systematic review by Clark and coworkers¹²⁴ indicated that there was a lack of high-quality evidence to reliably support the clinical practice of vesicoamniotic shunting despite an improvement in perinatal survival (odds ratio [OR], 2.5; 95% confidence interval [CI], 1.0 to 5.9; $P < .03$). Subgroup analysis indicated that improved survival was most likely in fetuses with a defined poor prognosis (based on a combination of ultrasound appearance and fetal urinary analytes) (OR, 8.0; CI, 1.2 to 52.9; $P < .03$). It has now been proposed to evaluate this therapy in a multicenter randomized trial, referred to as a PLUTO trial.¹²²

Congenital Heart Defects

The first fetal cardiac intervention was an attempt by Carpenter and colleagues¹²⁶ at fetal pacing for complete heart block because of circulating anti-Ro/La antibodies. In 1991, Maxwell and coworkers¹²⁷ performed two percutaneous valvuloplasties, and since then, there has been an increase in experience with minimally invasive treatment for congenital heart defects. Still, most centers only have sporadic experience, and only a few, such as Children's Hospital in Boston, have achieved a wider experience.¹²⁸

Most congenital heart defects can be operated on postnatally with low (<5%) mortality and good quality of life in survivors. However, when this is not the case, and when the abnormal cardiac anatomy would lead to progressive myocardial and pulmonary damage during the pregnancy and would ultimately preclude effective postnatal treatment, timely fetal intervention can be lifesaving. Antenatal intervention theoretically reduces intraventricular pressure, improves coronary perfusion, reduces ischemic damage, allows ventricular growth, and avoids induction of myocardial fibroelastosis, thus enabling improved functional postnatal repair. However, the exact timing and selection

of patients for performing such interventions remains unclear. Furthermore, in utero fetal cardiac intervention is still frequently bound by technical limitations, the often late timing of diagnosis, and our current insufficient understanding of these diseases.

Antenatal Intervention for Congenital Heart Defects

Fetal valvuloplasty is the most frequent intrauterine intervention, with indications including management of critical aortic and pulmonary stenosis or atresia, atrial septostomy for highly restrictive foramen ovale with aortic stenosis, and hypoplastic left heart syndrome (HLHS). Table 24-8 summarizes experiences with conditions that are currently claimed to be candidates for prenatal intervention, as recently summarized by Matsui and Gardiner.¹²⁸

In utero valvuloplasty is typically done by a team of fetal medicine specialists familiar with intrauterine invasive procedures, and interventional pediatric cardiologists. Levine and Tworetzky recently reviewed their experience with this procedure.¹²⁹ External version is performed as required, and the fetus is positioned with the left chest facing anteriorly and the insertion track free of limbs or cord. Achieving these optimal but essential conditions sometimes requires a laparotomy. Fetal analgesia and immobilization are required; the mother can be sedated or more rarely is given general anesthesia. Bradycardia during the procedure occurs in 9% and hemopericardium in less than 1%, and the fetal loss rate has been reported as 3.8%.¹³⁰ Under ultrasound guidance, the valve is dilated with a balloon up to 1.2 to 1.5 times the size of the annulus.

HLHS is a particularly severe valvular abnormality amenable to prenatal intervention. The range of HLHS structural malformations includes critical aortic stenosis, unbalanced atrioventricular septal defects with hypoplasia of the left heart and aorta, severe aortic coarctation, and the association of atresia or hypoplasia of both the aortic and mitral valve. Currently, the only available neonatal treatment is staged palliative surgery (Norwood operation, followed by a Fontan procedure), with an overall 5-year survival of 70%. However, more than half will require further surgery before the age of 5 years.¹³¹

Balloon valvuloplasty for HLHS was first technically successful in 1991, and by 2000, 12 cases had been performed world-wide and compiled. However, technical problems were frequent, with a 50% balloon rupture rate and a 75% incidence of bradycardia. Only two patients survived, and one of them had a two-ventricle circulation after birth.¹³² However, the more extensive experience of the Boston group learns what can be achieved after the learning curve. From the initial 20 cases,¹³³ there were 13 successful procedures between 21 and 29 weeks. In their most recent series, 28 of 38 treated fetuses survived. Nevertheless, three died in utero after the procedure, one was born prematurely, and two patients opted for termination. Postprocedure assessments of the left heart showed growth of the ventricle, of the mitral and aortic valves, and of ascending aorta. Of the seven born live, three were surviving with biventricular circulation, and another had palliative surgery.

There are also other indications for in utero valvuloplasty and disruption of the atrial septum. More information on these indications and procedures for fetal cardiac diseases is available in the Online Edition of this chapter.

Myelomeningocele

Neural tube defects (NTD) are a major source of mortality and morbidity. The pathophysiology and details of diagnosis are discussed in

*Two procedures required on one fetus.

NA, not available; TOP, termination of pregnancy.

Reported experience with fetal valvuloplasty as summarized in Matsui H, Gardiner H: Fetal intervention for cardiac disease: The cutting edge of perinatal care. *Semin Fetal Neonatal Med* 12:482-489, 2007.

Chapter 18. The 5-year mortality of patients with neonatally repaired spina bifida is 79 in 1000 births. Mortality can be as high as 35% among patients with symptoms of brainstem dysfunction, and 81% of children have hydrocephalus requiring treatment. More than 70% of NTD survivors have an IQ above 80 but only 37% can live independently as adults. The vast majority have anal sphincteric dysfunction and lower extremity paralysis.¹³⁴

The technique of closure of the NTD in the fetus is identical to that of the postnatal surgical procedure. The fringe of full-thickness skin is incised circumferentially down to the fascia and the sac is mobilized medially. It is then excised from the placode, removing all epithelial tissue to avoid inclusion cysts later on. Because the spinal cord in the fetus is extremely frail, no attempt is made to re-neurulate the placode. The defect is then closed with dura or undermined fascia, or both. The skin is closed primarily, at times requiring lateral relaxing incisions or even dermal graft material.

Outcome of Antenatal Neural Tube Defect Repair

Preliminary experience at Vanderbilt¹³⁵ and Children's Hospital of Philadelphia¹³⁶ did demonstrate improvement in outcome with intra-uterine microsurgical closure of myelomeningocele compared with postnatal repair. These centers noted a decreased requirement for ventriculoperitoneal (V-P) shunting, attributed in part to reversal of cerebellar herniation. The other potential outcomes such as thinning of the corpus callosum and polymicrogyria were not affected by in utero surgery. Fetal head size, typically lower after postnatal repair, has also been shown to increase, which is believed to be the result of restoration of cerebrospinal volume.

Although the relatively decreased need for shunting among babies repaired in utero diminishes with passing time, a number of them never require shunts. The combined experience suggests an overall incidence of approximately 30% (hence a lower incidence) of V-P

shunting. This is clinically important, because the placing of a shunt increases the possibility of surgical complications and infection, thus affecting cognitive functioning in later life. Another important co-determinant of long-term outcome is the upper level of the lesion.¹³⁵ For each increase in vertebral level, the risk of receiving a shunt increases accordingly. A final determinant of outcome quality is the gestational age at repair: shunt rate drops significantly (from 71% to 39%) when fetal surgery is done before or after 25 weeks, respectively.

Improvement in lower extremity function or urinary continence with in utero NTD repair has been more difficult to demonstrate. However, although postnatally repaired patients have neurologic function that corresponds with the bony level of the defect, prenatally repaired patients, who have maintained leg function in the prenatal period and had an early repair, have in the majority (57%) of cases a "better than predicted" leg function when evaluated over the short term.¹¹ However, a major cognitive improvement in prenatally repaired fetuses is not expected.¹³⁷ An interesting observation is that in utero repairs showed a surprisingly impressive cosmetic result, confirming that fetal epithelial wound healing is more favorable.

These data were taken into account when planning the Management of Myelomeningocele study (MOMS) on in utero closure of fetal MMC (available at www.spinabifidamoms.com, accessed March 9, 2008). Selection criteria for this trial were gestation less than 26 weeks, normal karyotype, structural examination confirming normal leg movement and absence of talipes, a maximum lateral ventricle diameter of less than 17 mm, and grade III (severe) Chiari type II malformation. The MOMS trial is a nonblinded randomized study requiring 200 patients offered either in utero repair at 28 to 25 weeks or postnatal repair at one of the three participating institutions. In the United States, no fetal MMC repair is offered outside the trial. By the beginning of 2007, recruitment efforts had enrolled just over half of the required subjects. The primary outcome measure is placement of a V-P shunt at the age of 1 year, with predefined shunting criteria. Secondary

TABLE 24-9 OBSTETRIC AND SHORT-TERM OUTCOMES ON MYELOMENINGOCELE REPAIR

	Children's Hospital of Philadelphia (N = 51)	Vanderbilt (N = 178)
Gestation at surgery (wks and days)	23 + 0 (20 + 0 to 25 + 4)	(19-30); later <26 wks
Gestation at delivery (wks and days)	34 + 4 (25 + 4 to 37)*	33 + 5 (25-38)
Chiari malformation	14%/86%	7%/0%
Before (moderate/severe)	100%/0%	
After		
Postnatal shunt (postnatal age)	46% (21 wks)	46% (12 wks)
Perinatal losses	3/51 (prematurity)	5/178 (2.8%) (not specified)
Length of hospital stay	4 days	3.3 days (3-7)
Oligohydramnios		25% early on with 30% readmission rate
Delivery <30 wks	5/47 (10.6%) [†]	11.8%
Delivery >32 wks	40/47 (85%) [†]	(not specified)
Maternal complications	None reported, including dehiscence or rupture; one amniotic fluid leak through hysterotomy	9 (5.1%) mild pulmonary edema 1 bowel obstruction 4 (2.2%) dehiscence, asymptomatic in 3

*Includes all patients.

[†]Denominator is survivors only.

Children's Hospital of Philadelphia data from Johnson MP, Sutton LN, Rintoul N, et al: Fetal myelomeningocele repair: Short-term clinical outcomes. *Am J Obstet Gynecol* 189:482-487, 2003.

Vanderbilt data from Bruner J, Tulipan N: Intra-uterine repair of spina bifida. *Clin Obstet Gynecol* 48:942-955, 2005.

end points include neurologic function, cognitive outcome, and maternal morbidity.

Table 24-9 summarizes important outcome variables from the earlier published experience on MMC repair. From these data, it appears that open fetal surgery has a significant but possibly acceptable maternal risk given the debilitating nature of MMC for the fetus. Maternal pulmonary edema after aggressive tocolytic therapy has been initially frequent, but this is potentially reducible by improved tocolytic regimens. Transfusions are uncommon (2.2% in the Vanderbilt experience), and maternal bowel obstruction happened in a single case. Preterm birth before 30 weeks occurs in approximately 10% to 15% despite aggressive tocolysis. Postoperative oligohydramnios is not uncommon but is usually without significant clinical consequences, although occasional lethal fetal pulmonary hypoplasia has been observed. The risk for perinatal death at the time of surgery or associated with preterm delivery in the available studies was 3% to 6%.

Summary

In utero fetal therapy is an evolving science significantly hampered by the lack of adequately studied animal models and practice in a wide variety of perinatal centers with a generally uncontrolled range of interventions. Nevertheless, laser photocoagulation for TTTS has been shown via randomized trials to be beneficial. The judgment regarding efficacy for antenatal treatment of congenital diaphragmatic hernia, urinary tract obstruction, and congenital cardiac lesions is yet incomplete.

Chapter 25

Multiple Gestation

Clinical Characteristics and Management

Fergal D. Malone, MD, and Mary E. D'Alton, MD

The incidence of multiple gestation continues to increase, and multiple gestations now account for more than 3% of all live births in the United States.¹ Over the last several decades, the rate of twin births in the United States has increased every year, to a current rate of 32.2 per 1000 total births. In the decade from 1995 to 2004, the number of twin births increased by 37% (Table 25-1). The two major factors accounting for these increases are the widespread availability of assisted reproductive technologies and increasing maternal age at childbirth. The number of triplet, quadruplet, and higher-order multiple births has peaked or dropped slightly, most likely due to voluntary limits imposed by many assisted reproduction centers in the number of embryos transferred and to the availability and acceptance of multifetal pregnancy reduction (MFPR) procedures.² Because perinatal and maternal morbidity and mortality are increased in multiple gestation, contemporary data about pregnancy outcome and management options are essential. Congenital abnormalities are also increased in multiple gestation, making management decisions more complex, because the fates of sibling fetuses are necessarily linked. For these reasons, women with complicated multiple gestation are increasingly cared for under the supervision of an appropriately trained specialist.^{3,4}

Perinatal Mortality and Morbidity

Prematurity, monochorionicity, and growth restriction pose the main risks to fetuses and neonates in multiple gestations. Perinatal deaths have decreased, but the risk of prematurity has not changed significantly. The mean duration of pregnancy is 35 weeks for twin gestations, 32 weeks for triplets, and 29 weeks for quadruplets.¹ The mean gestational age at delivery in multiple pregnancies can be misleading because it does not reveal the true incidence of extreme prematurity, which has greater clinical significance. Although the incidence of very premature delivery (before 32 weeks) for singletons in the United States is 1.6%, that incidence increases to 12% for twin and 36% for triplet gestations.¹ The perinatal mortality rate for twins is at least threefold higher than for singletons. In a Swedish population database of more than 2.2 million births, the fetal and infant mortality rates for singletons were 4.1 and 5.0 per 1000 births, respectively; the rates for twins were 12.0

and 16.0 per 1000 births.⁵ Mortality rates are significantly higher among same-gender twins compared with discordant-gender twins. It therefore appears that the two most important factors explaining increased mortality in twin gestations are increased rates of prematurity and complications of monochorionicity. The risk that twins will weigh less than 1500 g at birth is 10 times the risk for singletons. These increased risks are more pronounced in male-male pairs, in black infants, and in infants of younger mothers.⁶

Most published data on perinatal outcome for higher-order multiple gestations (triplets or greater) are limited by (1) noncontemporary study periods, (2) small sample size, (3) long duration of sample collection, (4) lack of control groups for comparison, and (5) accumulation of data from multiple centers with differing management practices. These limitations are even more pronounced for pregnancies with four or more fetuses. In one recent population study, stillbirth rates were noted to increase from 6.8 per 1000 for singletons to 16.1 for twins and 21.5 for triplets, and infant mortality rates increased from 5 to 23.4 and 51.2 per 1000 births, respectively⁷ (Figs. 25-1 and 25-2). Two recent, large studies summarized perinatal outcome of triplet pregnancies. One suggested an incidence of preterm delivery before 28 weeks of 14%, with a perinatal mortality rate of 103 per 1000, and the second showed an incidence of preterm delivery before 30 weeks of 24%, with a perinatal mortality rate of 150 per 1000.^{8,9} Perinatal mortality in triplet gestations is significantly worse in dichorionic compared with trichorionic pregnancies.⁹ In addition, the rate of spontaneous loss before 24 weeks for triplet pregnancies with confirmed cardiac activity may be as high as 20%.¹⁰ Once cardiac activity is confirmed at 10 to 14 weeks in a triplet pregnancy, the risk of miscarriage before 24 weeks is 4.4%.¹¹ Some quadruplet pregnancy series have suggested perinatal mortality rates ranging from 0 to 67 per 1000 quadruplet births.^{12,13} However, caution is needed when interpreting studies of higher-order multiple gestations, because often only pregnancies reaching “viability” are included, producing an overly positive view of perinatal outcome.

Perinatal morbidity is also more likely in multiple gestations. Although multiple gestation accounts for only 3% of all births in the United States, infants of multiple gestations comprise almost one quarter of very-low-birth-weight infants.¹⁴ The incidence of severe handicap among neonatal survivors of multiple gestation is also increased: 34.0 and 57.5 per 1000 twin and triplet survivors, respec-

TABLE 25-1 INCIDENCE OF MULTIPLE BIRTHS IN THE UNITED STATES

Year	Twins	Triplets	Quadruplets	Quintuplets and Higher Order
2004	132,219	6,750	439	86
2003	128,665	7,110	468	85
2002	125,134	6,898	434	69
2001	121,246	6,885	501	85

1997	104,137	6,148	510	79
1996	100,750	5,298	560	81
1995	96,736	4,551	365	57

From Martin JA, Hamilton BE, Sutton PD, et al: Births: Final Data for 2004. Natl Vital Stat Rep 55(1):80-81, 2006.

tively, compared with 19.7 per 1000 singleton survivors.¹⁵ Twins account for 5% to 10% of all cases of cerebral palsy in the United States.¹⁶ The risk of producing at least one infant with cerebral palsy from one pregnancy has been reported to be 1.5% for twin, 8.0% for triplet, and 42.9% for quadruplet gestations.¹⁷

In the United States, mean birth weight is significantly lower for twin neonates (2333 g) and triplet neonates (1700 g), compared with singletons (3316 g).¹ However, there is no evidence that twin or triplet neonates have outcomes different from those of gestational age-matched singletons. When matched by gestational age at delivery, singleton, twin, and triplet neonates have similar birth weights and similar rates of morbidity and mortality.¹⁸

Maternal Mortality and Morbidity

Given the low rate of maternal mortality in developed countries and the small sample sizes in published series, it is difficult to determine the incidence of maternal death in contemporarily managed multiple gestations. However, maternal morbidity is significantly increased in mothers with multiple gestations and is apparently related to the number of fetuses. Twin pregnancies are associated with significantly higher risks of hypertension (2.5-fold), abruption (3-fold), anemia (2.5-fold), and urinary tract infections (1.5-fold) than singleton pregnancies.¹⁹

The risk of significant maternal morbidity is also increased in triplet pregnancies. In a comparison of maternal morbidity among twin, triplet, and quadruplet pregnancies, the risks of gestational hypertension, eclampsia, diabetes, placental abruption, and preterm premature rupture of membranes (pPROM) were all significantly increased.²⁰ In a study of 100 triplet pregnancies, almost all women had at least one antenatal complication and almost half developed postpartum complications.⁸ These risks include preterm labor (78%); preeclampsia (26%); hemolysis, elevated liver enzymes, or low platelets (HELLP) syndrome (9%); anemia (24%); pPROM (24%); gestational diabetes (14%); acute fatty liver (4%); chorioendometritis (16%); and postpartum hemorrhage (9%). No differences in the frequency of complications were noted between spontaneous triplets and those arising from ovulation induction or in vitro fertilization. Preterm labor occurs in nearly all quadruplet pregnancies, and the risk of gestational hypertension ranges from 32% to 90%.^{12,13} In addition, preeclampsia

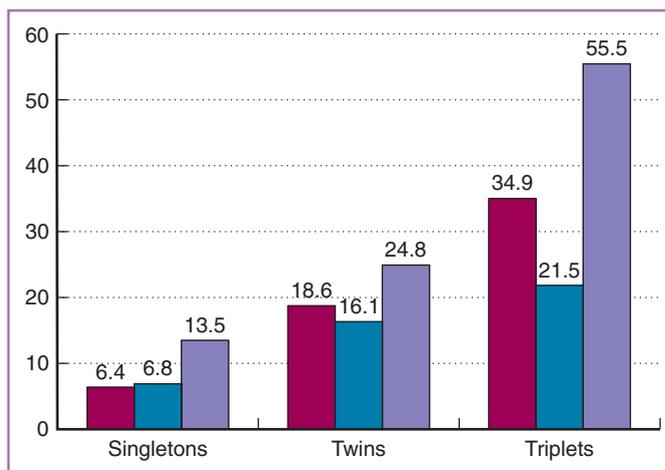

FIGURE 25-1 Rates of stillbirth in the United States. Crude stillbirth rates for singletons, twins, and triplets by race/ethnicity. Purple bars, blacks; blue bars, whites; red bars, Hispanics. (Modified from Salihu HM, Garces IC, Sharma PP, et al: Stillbirth and infant mortality among Hispanic singletons, twins, and triplets in the United States. *Obstet Gynecol* 106:789-796, 2005.)

in higher-order multiple gestations occurs at an earlier gestational age, is more severe, and more likely to have an atypical clinical presentation than preeclampsia in singleton gestations.^{8,21}

Maternal Adaptations

The normal maternal physiologic adaptations seen in singleton pregnancy are exaggerated in multiple gestation. These physiologic responses consist of both observed changes and expected changes extrapolated from singleton pregnancy physiology.^{22,23} Serum levels of progesterone, estradiol, estriol, human placental lactogen, human chorionic gonadotropin (hCG), and α -fetoprotein (AFP) are all significantly higher in multiple than in singleton gestations.

Heart rate and stroke volume are significantly increased in gravidas with twins during the third trimester, leading to a significant increase in cardiac output and cardiac index compared with singleton pregnancies.²⁴ In one study of 119 twin pregnancies, stroke volume was increased by 15%, heart rate by 4%, and cardiac output by 20%, compared with singletons.²⁵ These increases most likely occur secondary to increased myocardial contractility and blood volume in the setting of multiple gestation. Systolic and diastolic blood pressures mirror the changes seen during singleton pregnancy, with an even greater drop in pressures noted during the second trimester in twin pregnancy. However, by the time of delivery, mean maternal blood pressures are significantly higher in multiple compared with singleton pregnancies.²⁶ Depending on the number of fetuses, plasma volume increases by 50% to 100%, which may lead to dilutional anemia.

Uterine volume increases rapidly in multiple gestation. A 25-week twin-gestation uterus is equal in size to a term singleton uterus.²⁷ Uterine blood flow increases significantly in a twin pregnancy and is related to both increased cardiac output and decreased uterine artery resistance.²⁸ In multiple gestations, the normal increase in tidal volume and oxygen consumption is probably increased further, which may lead to an even more alkalotic arterial pH than that seen with singleton pregnancy. Similarly, the normal increase in glomerular filtration rate and size of the renal collecting system is probably more marked in women with multiple gestations.

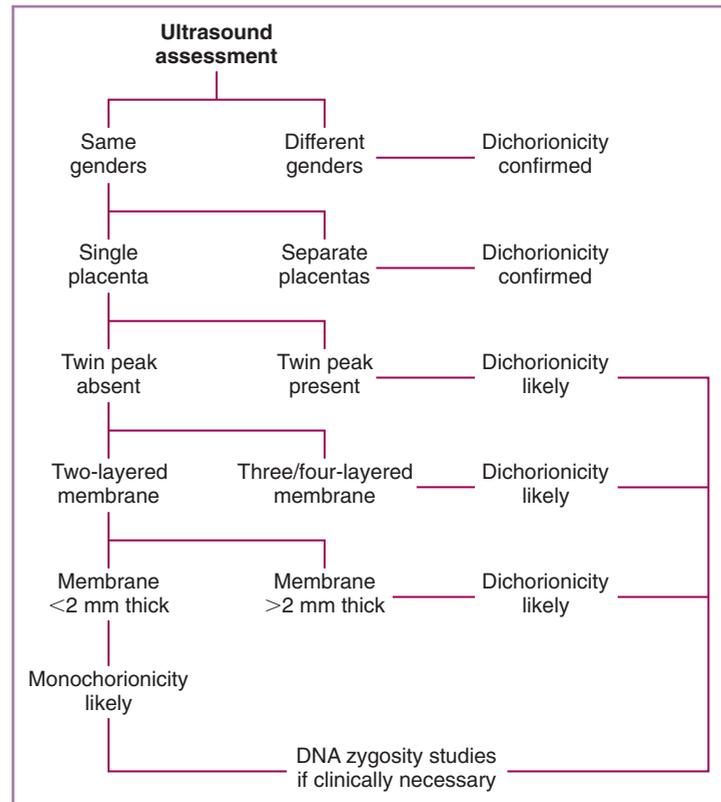

FIGURE 25-2 Determining chorionicity. Flow chart for determining chorionicity in multiple gestation.

It is recommended that daily caloric intake increase to 3000 to 4000 kcal (depending on whether the pregravid body mass index suggests underweight or overweight) in multiple gestations, compared with 2400 kcal/day in singleton gestations.²⁹ The recommended maternal weight gain for twin pregnancies is 1 to 1.5 pounds per week, for a total pregnancy weight gain of 35 to 45 pounds. An easy-to-remember recommendation of 24 pounds by 24 weeks' gestation has been suggested to achieve this goal.²⁹ Although specific recommendations have not been issued, ideal weight gain in higher-order multiple gestations is likely to be significantly greater than in twin gestations. Some have suggested that optimal fetal growth in higher-order multiple gestations can be achieved with maternal weight gain of at least 1.5 pounds per week during the first 24 weeks of pregnancy.³⁰

Ultrasonography

Routine prenatal ultrasonography has proved valuable for early detection of multiple gestation.³¹ It is only after diagnosis of a multiple gestation that steps can be taken to reduce the perinatal and maternal morbidity associated with the condition. Prenatal ultrasonography in multiple gestation is useful for the following:

- Confirming a diagnosis of multiple gestation
- Determining chorionicity
- Detecting fetal anomalies
- Guiding invasive procedures
- Evaluating fetal growth
- Measuring cervical length
- Confirming fetal well-being
- Assisting in delivery

Diagnosis of Multiple Gestation

Positive sonographic diagnosis of multiple gestation can be made by visualizing multiple gestational sacs with yolk sacs by 5 weeks of gestation and multiple embryos with cardiac activity by 6 weeks. If two gestational sacs are seen on early ultrasound studies, the chance of delivering twins is 57%, but this increases to 87% if two embryonic poles with cardiac activity are visualized.³² If three gestational sacs are seen on early ultrasound, the chance of delivering triplets is 20%, increasing to 68% if three embryonic poles with cardiac activity are visualized. In addition to twins, the early sonographic visualization of two intrauterine fluid collections may represent a singleton in a bicornuate uterus, a singleton with a subchorionic hemorrhage, or a vanishing twin, which can occur in 20% to 50% of cases of early multiple gestation diagnoses.³³

Chorionicity

Because 20% of twins are monozygotic and such pregnancies are associated with a perinatal mortality risk of up to 26%, accurate determination of chorionicity is essential for clinical management.^{34,35} In most women, sonographic assessment can determine chorionicity (see Fig. 25-2). Sonographic determination of chorionicity should be attempted in all multiple gestations and is best performed in the first trimester. Before 8 weeks' gestation, obvious separate gestational sacs, each surrounded by a thick echogenic ring, is suggestive of dichorionicity.³⁶ If separate echogenic rings are not visible, monozygosity is likely. In such situations, counting the number of yolk sacs may assist in establishing amnionicity. Two fetal poles with two yolk sacs in a monozygotic gestation suggests diamnionicity, whereas the presence of two fetal poles with only one yolk sac suggests a monoamniotic

TABLE 25-2 STATISTICAL ACCURACY OF ANTENATAL PREDICTION OF MONOCHORIONICITY

	Sensitivity (%)	Specificity (%)	Predictive Value (%)	
			Positive	Negative
Overall	88.9	97.7	92.6	96.5
1st trimester	89.8	99.5	97.8	97.5
2nd trimester	88	94.7	88	94.7

From Lee YM, Cleary-Goldman J, Thaker HM, et al: Antenatal sonographic prediction of twin chorionicity. *Am J Obstet Gynecol* 195:863, 2006 (Table 1).

gestation.³⁷ However, the specificity of this finding for monoamnioticity is uncertain.^{38,39} The sensitivity of first- and second-trimester ultrasound for predicting monochorionicity is approximately 90%; the specificity falls from 99% for first-trimester sonography to 95% in the second trimester (Table 25-2).⁴⁰ Later in gestation, if the fetuses are discordant for gender or two distinct placentas are seen, a dichorionic gestation can be confirmed with confidence (Fig. 25-3). In the absence of these findings, monochorionicity is possible, and other sonographic features should be assessed.

The visualization of only one placental mass has a positive predictive value for monochorionicity of only 42%, because many dichorionic gestations develop apparent fusion of separate placentas as pregnancy progresses.⁴¹ Counting the number of layers in the dividing membrane, near its insertion into the placenta, is 100% predictive of dichorionicity but is not as reliable in predicting monochorionicity.^{42,43} When this method is used, it is assumed that the placentation is monochorionic if only two layers are present; the presence of three or four layers suggests dichorionicity. The use of a membrane thickness cutoff value of 2 mm has also been reported to correctly assign chorionicity in more than 90% of cases, but the reproducibility of this measurement has been questioned.⁴⁴ Visualization of a triangular projection of pla-

centa between the layers of the dividing membrane (known as the *twin-peak* or *lambda* sign) is also useful in diagnosis of dichorionicity, but its absence is not as reliable to predict monochorionicity. Although each of these sonographic features individually has a poor positive predictive value for monochorionicity, use of a composite sonographic approach (i.e., one placenta, gender concordance, thin dividing membrane, and absence of the twin-peak sign) may yield a positive predictive value for monochorionicity of 92%.⁴¹

The use of transvaginal sonography in the first trimester, together with this composite approach, produces correct assignment of chorionicity and amnioticity in almost 100% of cases.³⁸ If the initial ultrasound examination is not performed until the second trimester, its precision in assigning chorionicity declines.⁴⁵ Although the sensitivity is not perfect, the specificity for monochorionicity is almost 100% when this approach is used in the first trimester, falling to 95% in the second trimester.⁴⁰ In certain clinical situations, such as the presence of fetal anomalies or of twins discordant for growth, management requires the reliable exclusion of monochorionicity. If monochorionicity cannot be reliably excluded, invasive testing to assign chorionicity by DNA zygosity studies on amniocytes can be performed if clinically indicated.⁴⁶

Detection of Fetal Anomalies

Careful sonographic surveys of fetal anatomy are indicated in multifetal pregnancies, because the risk of congenital anomalies is increased. The accuracy of ultrasonography to detect congenital fetal anomalies in multiple gestations has not been adequately studied in large series. Smaller, single-center series have tried to establish the predictive value of prenatal ultrasound for the detection of anomalies in multiple gestations. In a series of 24 anomalous fetuses in twin gestations, serial ultrasonography at a specialist center achieved an 88% detection rate, with 100% specificity, for the prenatal diagnosis of anomalies.⁴⁷ An 83% rate of detecting fetuses with Down syndrome in twin pregnancies was achieved by combining risks derived from maternal age and nuchal translucency thickness measurement at 10 to 14 weeks' gestation, with a 5% false-positive rate.⁴⁸ The finding of increased nuchal translucency in one fetus of a monochorionic pair may also presage the development of twin-twin transfusion syndrome (TTTS).

Evaluation of Fetal Growth

Serial ultrasonography is the most accurate method to assess fetal growth in multiple gestation. Intrauterine growth of twins is similar to that of singletons until 30 to 32 weeks' gestation, when the abdominal circumference measurements of twins begin to lag behind those of singletons.⁴⁹ Composite assessments of fetal weight appear to be superior to individual biometric parameters (e.g., abdominal circumference, femur length) for predicting growth discordance.⁵⁰ Although the predictive value of all biometric assessments to identify growth discordance has been questioned, no other sonographic markers for discordance have yet been validated.⁵¹

Although individual growth curves for twin and triplet gestations have been described, singleton fetal weight standards are still commonly used to assess growth in multiple gestation. A prospective study of serial biometric measurements in twins found no significant differences in fetal growth between twin and singleton gestations.⁵² Because growth restriction is a dynamic process and sibling fetuses are immediately available for comparison, we consider it reasonable to assess growth in multiple gestation with serial evaluations, based on singleton growth curves, using as many biometric parameters as possible and

comparing sibling estimated fetal weights for discordance. Typically, a 20% to 25% difference in estimated fetal weight between sibling fetuses, expressed as a percentage of the larger fetal weight, suggests clinically significant growth discordance.^{38,53} In a study of 460 twin pregnancies, weight discordance of 25% or more was associated with a 6.5-fold increase in the rate of stillbirth, compared with nondiscordant twins, and an overall perinatal death rate of 9.7%.⁵⁴ In another study of 1370 twin pregnancies in which weight discordance was stratified in 5% increments, a statistically significant increase in fetal death occurred only with weight discordance greater than 30%.⁵⁵ Growth discordance greater than 20% has also been shown to be an important predictor for adverse perinatal outcomes, even in situations where individual fetal size is appropriate for gestational age.⁵⁶

Much of the increased mortality associated with growth discordance is likely related to monochorionicity. In one study, birth weight discordance of at least 15% was associated with highest risk of perinatal mortality among same-gender twins, but discordance of at least 30% was required for significant perinatal mortality among gender-discordant twins.⁵⁷ It is unclear whether adverse outcomes seen with significant weight discordance are related to continuation of pregnancy within a hostile intrauterine environment or to iatrogenic prematurity. In general, we use the finding of significant weight discordance as an indication for close fetal surveillance rather than an indication for immediate delivery. Decisions regarding delivery are then made based on the results of tests of fetal well-being, together with gestational age, rather than solely on the basis of significant weight discordance.

Measurement of Cervical Length

Ultrasound surveillance of cervical length in multiple gestation can identify those at increased risk of preterm delivery. The Maternal-Fetal Medicine Units Network of the National Institute of Child Health and Human Development (NICHD) performed a Preterm Prediction Study of risk factors for preterm birth in twins. A transvaginal sonographic measurement of cervical length of 2.5 cm or less at 24 weeks' gestation was associated with a 6.9-fold increased risk of delivery before 32 weeks' gestation,⁵⁸ but a short cervix at 28 weeks' gestation was no longer predictive of preterm birth. A study of cervical length in 215 twin gestations reported that the sensitivity of a cervical length of 2.5 cm or less at 23 weeks' gestation was 100% for preterm delivery at or before 28 weeks, 80% for delivery at or before 30 weeks, and 47% for delivery at or before 32 weeks.⁵⁹ Approximately 11% to 17% of all twin gestations can be expected to have cervical lengths less than or equal to 2.5 cm.^{58,59} In a study of 66 triplet gestations, a cervical length cutoff of 2 cm at 24 weeks' gestation was significantly associated with preterm delivery.⁶⁰

When evaluating cervical length with ultrasound, the maternal bladder should first be emptied. Transvaginal sonography is the preferred approach. Care must be taken to avoid pressure on the cervix from the ultrasound probe. A sagittal view should be obtained, with an echogenic endocervical mucosa visible along the length of the cervical canal. Measurements should be taken between the V-shaped notch at the internal os and the triangular echolucent area at the external os. The optimal interval at which to perform sonographic assessments of cervical length during gestation is unclear. Our practice has been to measure cervical length every 2 weeks from 16 to 24 weeks in selected cases of multiple gestation deemed to be at highest risk for preterm delivery (e.g., higher-order multiple gestations, history of preterm deliveries). For all other multiple gestations, we perform sonographic assessment of cervical length at the time of sonography for fetal anatomy or growth. Two studies found that cervical length measurement of

3.5 cm or greater at 24 weeks can identify twin pregnancies with a very low (3% to 4%) risk of preterm birth before 34 weeks.^{61,62} The major limitation of routine cervical length assessment for multiple gestations is the lack of a proven effective intervention when a short cervix is noted⁴ (see later discussion on prophylaxis of preterm birth).

Confirmation of Fetal Well-Being

Ultrasonography is useful to confirm fetal well-being in multiple pregnancies. Nonstress testing (NST) in multiple gestation is discussed later (see Fetal Surveillance). The biophysical profile may also be of benefit in multiple gestation if an NST is not reassuring or in cases of higher-order multiple gestation, in which an NST can be impractical to perform. There is no evidence that routine biophysical profile testing in the absence of specific additional high-risk factors has any benefit in multiple gestations.⁴

Doppler velocimetry may also be used to evaluate fetal well-being in multiple gestations. Umbilical artery systolic-to-diastolic ratios are similar in singleton and twin gestations. A deterioration in this ratio may occur before the sonographic detection of growth restriction. Normal Doppler velocimetry indices of other fetal vessels, such as the middle cerebral artery and the descending aorta, are similar between singleton, twin, and triplet fetuses.⁶³ An absolute difference of 0.4 (or 15%) or greater in umbilical artery systolic-to-diastolic ratios between sibling fetuses identifies growth discordance as accurately as a difference in estimated fetal weight, presumably because such differences represent unequal fetoplacental perfusion.³¹ We employ Doppler velocimetry whenever multiple gestation is complicated by significant growth restriction or discordance.

Sonographic measurement of amniotic fluid volume is an important tool to evaluate fetal well-being. In a dye-dilution study of diamniotic twin pregnancies, the amniotic fluid volume in each amniotic sac was noted to be independent of the volume in the neighboring sac and was similar to singleton fluid volumes.⁶⁴ There is no agreement on the optimal sonographic method to assess amniotic fluid volume in multiple gestations. Methods in use include the following^{65,66}:

- A single overall amniotic fluid index without reference to the dividing membrane
- Individual amniotic fluid indices for each sac
- Largest two-diameter pocket in each sac
- Subjective assessment of the relative distribution of fluid between sacs

No one method, however, has been shown to be optimal to predict perinatal outcome in multiple gestation.

Prenatal Diagnosis

Prenatal diagnosis and genetic counseling are important in the management of multiple gestation, inasmuch as such patients are at higher risk of fetal anomalies because of (1) the presence of a multiple gestation and (2) the positive association between twinning and maternal age.

In dizygotic twin pregnancies, each fetus has its own independent risk of aneuploidy; thus, the chance of at least one abnormal fetus is increased. In addition, both monozygotic and dizygotic pregnancies are at increased risk for many structural anomalies. Monozygotic twins may not necessarily be concordant for chromosomal abnormalities, because the phenomenon of postzygotic nondisjunction can result in

heterokaryotypic twins. Because of this phenomenon, and because the diagnosis of monochorionicity is rarely made with certainty, consideration should be given to sampling each gestation separately whenever prenatal diagnosis is indicated.

The role of ultrasonography to detect fetal anomalies in multiple gestations has been discussed previously.

Risks of Chromosomal Abnormalities

Risks for Down syndrome and other chromosomal aneuploidies have been calculated for twin gestations at various maternal ages.⁶⁷ In the population studied by Rodis and coworkers, the risk that one fetus in a twin pregnancy would have Down syndrome for a 33-year-old woman was similar to that for a 35-year-old woman with a singleton gestation. These specific risks do change, depending on the incidence of dizygotic twinning, which is dependent on the maternal age and race profiles of the study population. **After correction for different rates of dizygosity based on maternal age and race, it was suggested that invasive prenatal diagnosis should be offered to women in the United States with twin gestations who are 31 years of age or older** (Table 25-3).⁶⁸ **In a triplet gestation, the chance that a 28-year-old woman will have at least one fetus with Down syndrome may be similar to that of a 35-year-old woman with a single fetus.** These alterations in risk assessment for chromosomal abnormalities are important, because invasive prenatal diagnosis may be considered at an even earlier maternal age for gravidas with higher-order multiple gestations. However, recent advances in multiple-marker screening have led to decreased use of maternal age alone as a threshold for offering invasive testing of fetal karyotype. For this reason, a policy of offering chorionic villus sampling (CVS) or amniocentesis to all patients with twin pregnancy who are 31 or 33 years of age or older is difficult to justify.⁶⁹ All women,

regardless of age, should be made aware of the relative advantages and disadvantages of screening versus diagnostic tests for fetal aneuploidy. Women with multiple gestations who are concerned about aneuploidy risk should be counseled and supported to make their own personal decision whether to choose a screening test, a diagnostic test, or no testing at all.⁶⁹

Serum Screening for Down Syndrome

Screening for Down syndrome using maternal serum levels of AFP, hCG, unconjugated estriol, and inhibin-A, together with maternal age, is commonly performed in the United States during the second trimester for singleton pregnancies. In twin pregnancies, experience with such screening is limited. **Average levels of AFP, hCG, and unconjugated estriol are increased 2.04-fold, 1.93-fold, and 1.64-fold, respectively, in twin compared with singleton pregnancies.**⁷⁰ In one prospective evaluation of screening with multiple serum markers in twins, the screen-positive rate remained at 5%, but no cases of Down syndrome were detected in the study population.⁷¹ Using statistical modeling and maintaining a 5% false-positive rate, the authors estimated that 73% of monozygotic twins and 43% of dizygotic twins with Down syndrome would be detected. In another series of 420 twin pregnancies, AFP and hCG levels were twice the levels seen in singletons.⁷² The authors postulated that risk prediction from singletons could be extrapolated to twin gestations using a twin correction method in which the multiple of the median (MoM) value is divided by the mean MoM of the twin population. This process with AFP and hCG screening was predicted to yield a 51% detection rate for Down syndrome, with a 5% rate of false-positive results.⁷² Although second trimester serum screening for Down syndrome represents an improvement over the use of maternal age alone, it is also clear that the accuracy of such

TABLE 25-3 RISK OF AT LEAST ONE CHROMOSOMAL ABNORMALITY IN WHITE SINGLETON AND TWIN GESTATIONS BASED ON MATERNAL AGE AT THE TIME OF AMNIOCENTESIS

From Meyers C, Adam R, Dungan J, et al: Aneuploidy in twin gestations: When is maternal age advanced? *Obstet Gynecol* 89:248; 1997. Reprinted with permission from the American College of Obstetricians and Gynecologists.

an approach is considerably less than that of serum screening in singleton pregnancies.⁷³ Given the effective alternative of nuchal translucency sonography, we do not routinely offer serum marker evaluation for aneuploidy screening with multiple gestation.

First-Trimester Screening

With the availability of late first-trimester MFPR procedures in higher-order multiple gestations, there is now increasing interest in screening tests for fetal abnormalities in the first trimester. Although combined screening for Down syndrome with nuchal translucency, free β -hCG, and pregnancy-associated plasma protein A (PAPP-A) has been reported in singletons, less is known about the performance of first-trimester screening in multiples.⁶⁹ Similar to second-trimester serum markers, first-trimester free β -hCG and PAPP-A levels are about twice as high in twin compared with singleton pregnancies.⁷³ In studies of normal twin pregnancies, average first-trimester free β -hCG levels were 1.86 MoM and PAPP-A levels were 2.10 MoM.^{73,74}

At present, we use only increased nuchal translucency thickness to screen for aneuploidies in multiple gestations in the first trimester, given the limitations of interpreting serum marker results in the setting of multiple gestation. In one study of 448 twin gestations, this form of screening delivered an 88% detection rate for Down syndrome, with a 7.3% screen-positive rate.⁷⁵ In another series of 24 multiple gestations and 79 singleton control subjects, the distribution of nuchal translucency measurements, including 95th percentile values, was similar in all cases, implying that this form of screening could be implemented using established normative data from singleton populations.⁷⁶ If MFPR is being planned, we incorporate the nuchal translucency measurement into consideration in deciding which fetus or fetuses to target for reduction.

Screening for Neural Tube Defects

A second-trimester maternal serum AFP level greater than 2.0 or 2.5 MoM has been used to screen for neural tube defects in singleton gestations. Because the maternal serum AFP level is approximately doubled in normal twin pregnancy, different cutoff values are needed to interpret this test if it is used in multiple gestations. If a 2.5 MoM cutoff in twin pregnancy is used, 99% of cases of anencephaly and 89% of open neural tube defects are detected but at the expense of generating a 30% false-positive rate.⁷⁷ Raising the twin cutoff value to 5.0 MoM decreases the false-positive rate to 3% but also decreases the detection of anencephaly to 83% and that of open neural tube defects to 39%.

The most commonly used cutoff for neural tube defect screening is 4.5 MoM, which has a detection rate of 50% to 85%, based on a 5% false-positive rate.⁷⁰ Amniotic fluid AFP and acetylcholinesterase levels in different amniotic sacs are independent of each other in dichorionic twins but are interdependent in monochorionic twins.⁷⁸ Because serum screening for fetal abnormalities in multiple gestation will always be limited by the inability to confirm which fetus is affected, many centers do not offer serum screening in multiple gestation, even for neural tube defects. Sonographic evaluation alone may be more efficient to screen for fetal neural tube defects in multiple gestations. Use of this approach relies on identifying either the neural tube defect along the fetal spine or the secondary intracranial effects (e.g., Chiari malformation). These sonographic features include the “lemon” sign, representing scalloping of the frontal bones, and the “banana” sign, representing downward displacement of the cerebellum toward the foramen magnum.

Genetic Amniocentesis

Genetic amniocentesis in twins is most commonly performed with an ultrasound-guided double-needle approach.⁷⁰ After the first sac has been entered and amniotic fluid aspirated, several milliliters of the blue dye indigo carmine are instilled and the needle is removed. A new needle is then placed into the second sac, and aspiration of clear fluid confirms successful sampling of two separate sacs. Methylene blue dye should not be used because of the risks of fetal hemolytic anemia, small-intestine atresia, and fetal demise. This procedure can be extended sequentially to perform triplet and quadruplet genetic amniocenteses.⁷⁹

Careful sonographic mapping of placentas and sacs is mandatory to assist in future management plans when karyotype results return, which may be as long as 2 weeks later if rapid diagnostic techniques such as polymerase chain reaction (PCR) or fluorescence in situ hybridization (FISH) are not utilized. The rate of pregnancy loss after genetic amniocentesis in twins has been considered similar to that observed with singletons,⁸⁰ but a comparison of pregnancy outcomes after amniocentesis in 476 twin pregnancies with a similar number of control twins and singleton pregnancies suggested a 2% increased risk of loss in women with twins.⁸¹ A higher loss rate after amniocentesis in twins may reflect the higher spontaneous loss rate seen in twins.⁷⁰ No data exist on loss rates for amniocentesis with higher-order multiple gestation or on loss rates for early amniocentesis (<14 weeks) with multiple gestations. However, early amniocentesis is no longer recommended in singleton or multiple gestations, because its safety compares unfavorably with that of CVS.⁷⁹

Chorionic Villus Sampling

CVS is usually performed in twin gestations at 10 to 13 weeks. It is considered to be an equally safe alternative to amniocentesis in twins.⁸² The needle tip must be kept under constant sonographic visualization to ensure that both chorion frondosum sites have been separately sampled. If monochorionicity has been confirmed, then a single-placenta sampling procedure is reasonable. A combination of transabdominal and transcervical approaches to the two placentas of a dichorionic pregnancy may ensure that separate placental sites have indeed been sampled.⁷⁹ Because as many as 2% to 4% of samples show evidence of twin-twin contamination, the cytogenetic laboratory should be made aware that a twin CVS has been performed.^{70,79} As with twin amniocentesis, careful sonographic mapping of placentas and sacs is mandatory to assist in future management plans after karyotype results become available. Although data on the safety of twin or triplet CVS are limited, at least one series of 208 procedures at a single center demonstrated very low pregnancy loss rates.⁸³

Antepartum Management

The incidence and range of maternal and fetal complications in multiple gestation suggest that these pregnancies should be managed under the supervision of an appropriately trained specialist.^{3,4,84} In a nonrandomized study comparing the outcome of 67 triplet gestations managed by maternal-fetal medicine specialists with 24 triplet gestations managed by generalist physicians, significant increases in gestational age at delivery and birth weight were observed for cases managed by specialists,⁸⁴ as well as significant reductions in neonatal intensive care unit length of stay and cost.

Interventions to improve outcome cannot reasonably be expected to work unless an early diagnosis of multiple gestation has been made. This supports our practice of offering routine ultrasonography to all pregnant patients. If ultrasound diagnosis is not offered, vigilance should be maintained for early clinical signs of multiple gestation, such as size greater than dates, excessive maternal weight gain, auscultation of more than one fetal heart rate, elevated maternal serum AFP levels, or unexplained severe anemia.

Preterm Labor and Delivery

Preterm birth occurs in more than 40% of twin and 75% of triplet gestations.^{8,85} Although patient education regarding the early signs of preterm labor in multiple gestations is important, surveillance for cervical change may also be helpful in predicting premature delivery. Other parameters used to predict preterm delivery in multiple gestations include sonographic assessment of cervical length and cervicovaginal assays for fetal fibronectin. As described previously, these factors were evaluated in large prospective studies of twin gestations.^{58,59} In women with twins who are screened at 24 weeks, a cervical length of less than 25 mm is significantly associated with preterm delivery before 32 weeks (odds ratio, 6.9), as well as a 27% rate of spontaneous preterm birth before 32 weeks, compared with 5% in twin gestations with a longer cervical length. A positive cervicovaginal fetal fibronectin assay at 28 weeks is also significantly associated with preterm delivery before 32 weeks, with an odds ratio of 9.4 and a spontaneous preterm birth rate (<32 weeks) of 29%, compared with 4% for a twin gestation with negative fetal fibronectin. The main value of a single negative fetal fibronectin test for twin pregnancy is in its very high negative predictive value for subsequent preterm delivery.^{4,58} No other risk factors were significantly associated with preterm delivery of twins in the NICHD study.⁵⁸

Interventions to prevent preterm labor and prolong pregnancy in multiple gestations have been disappointing. There is no evidence that prophylactic cervical cerclage or prophylactic tocolytic agents are beneficial.^{86,87} An observational study of 128 twin pregnancies with cervical length less than 2.5 mm at 18 to 26 weeks' gestation revealed no benefit for any outcome measure after cerclage placement.⁸⁸ There are no randomized trials indicating a benefit to cerclage for a shortened cervix in multiple gestations. In a comparison of 16 triplet gestations treated by prophylactic cervical cerclage and 52 triplet gestations without cerclage, the mean gestational age at delivery was 34 weeks in both groups, and the perinatal mortality rates were 104 per 1000 births with cerclage versus 71 per 1000 with no cerclage.⁸⁹ In another observational study of 59 triplet gestations, 20 received prophylactic cervical cerclage, and the remaining 39 were expectantly managed.⁹⁰ Although the authors reported fewer infants with extremely low birth weight in the cerclage group, there were no significant differences in mean gestational age at delivery or any other measure of neonatal outcome. We reserve cervical cerclage in multiple gestation for women who also meet historical criteria for cervical insufficiency (see Chapter 30).

Cerclage placement has been considered in women with multiple gestation when sonographic surveillance of cervical length demonstrates progressive cervical shortening, but a meta-analysis of data from four prospective trials found a twofold increase in preterm birth in women with twins and short cervix who received a cerclage.⁸⁷ Current data are insufficient to exclude or confirm a benefit of cerclage in multiple gestation.^{4,87,91}

Based on studies showing reduced rates of preterm birth after treatment with progesterone compounds in singleton gestations at risk of preterm birth,^{92,93} prophylactic progesterone was investigated in a ran-

domized, placebo-controlled trial of 661 twin pregnancies. Weekly intramuscular injections of 17 α -hydroxyprogesterone caproate (17P) had no effect on outcome. Forty-two percent of treated women delivered before 35 weeks, compared with 37% in those who received placebo injections.⁹⁴

Long-term maintenance administration of tocolytic drugs (e.g., oral terbutaline or nifedipine, rectal indomethacin, subcutaneous infusion of terbutaline) does not prolong pregnancy or prevent prematurity in multiple gestation. Caution is advised when tocolytic agents are given to women with multiple gestation because of the significant potential for maternal cardiovascular and pulmonary morbidity. The combination of one or more tocolytic agents, corticosteroids, and intravenous fluid replacement in the setting of the increased blood volume of multiple gestation leads to a significant risk of pulmonary edema. We suggest that acute tocolysis be reserved for women with documented preterm labor, to delay delivery and allow transport to an appropriate medical center and antenatal treatment with betamethasone. Betamethasone (12 mg IM, two doses, 24 hours apart) is given whenever there is a high risk of delivery between 24 and 34 weeks of gestation. Use of repeated courses of antenatal corticosteroids is discussed in Chapter 23.

Bed rest, at home or in hospital, is not effective in prolonging pregnancy or preventing preterm labor or delivery.^{4,95} Retrospective studies suggested that hospitalization and bed rest might improve outcome in multiple gestation, but subsequent prospective trials and meta-analyses have not supported this intervention. A review of six randomized trials involving more than 600 multiple gestations noted a trend toward a decrease in low-birth-weight infants with inpatient bed rest.⁹⁶ However, there was no decrease in very-low-birth-weight infants, and inpatient bed rest was actually associated with an increased risk of delivery before 34 weeks' gestation in women with uncomplicated twin pregnancies. There have been no recent prospective trials evaluating the role of bed rest at home for patients with multiple gestation. Because it is extremely difficult to standardize home bed rest and, consequently, difficult to refute the possibility of potential benefit, we advise modified rest at home for women with higher-order multiple gestations, starting at approximately 20 weeks of gestation.³ For example, one suggested care algorithm for triplet gestation recommends lateral recumbent rest for 4 to 6 hr/day beginning at 16 weeks' gestation, increasing to 6 to 8 hr/day by 20 weeks and extending to rest for most of the day by 24 weeks.⁹⁷ Others omit a recommendation for bed rest in women with multiple gestation if cervical sonography indicates a length greater than 35 mm at 24 weeks' gestation.^{61,62}

Outpatient uterine activity monitoring does not prolong pregnancy or prevent preterm labor and delivery in either singleton or multiple gestations.^{98,99} A meta-analysis of six randomized trials showed no significant benefit of home uterine activity monitoring to reduce the risk of preterm birth in twin gestations.¹⁰⁰ A randomized trial of weekly nurse contact, daily nurse contact, or daily nurse contact plus home uterine activity monitoring conducted in 2422 women at risk of preterm birth found no differences in frequency of birth before 35 weeks' gestation overall and, specifically, no benefit in the 844 women with twin gestations.⁹⁸ Outpatient uterine activity monitoring has not been studied in women who have undergone fetal reduction procedures in higher-order multiple gestation or in utero fetal surgery.

Preeclampsia

Pregnancy-related hypertension, including gestational hypertension and preeclampsia, is increased in multifetal gestations, ranging from 10% to 20% in twin, 25% to 60% in triplet, and up to 90% in quadru-

plet pregnancies.^{8,13,19,21,85} The incidence of preeclampsia may be further increased in multiple pregnancies that follow assisted reproductive technologies, but it does not appear to be related to zygosity.^{101,102} When preeclampsia occurs in higher-order multiple gestations, it more often occurs earlier, is more severe, and is atypical.^{4,8,21} A multicenter study of 87 twin and 143 singleton gestations with preeclampsia demonstrated lower gestational age at delivery, lower birth weight, and a higher rate of cesarean delivery among the twin gestations.¹⁰³ These data emphasize the importance of specialist supervision of multiple gestations and regular monitoring for early signs and symptoms of preeclampsia. To date, however, no prophylactic interventions (e.g., low-dose aspirin, calcium supplementation) have been found to prevent or reduce the incidence of preeclampsia in these high-risk pregnancies. In one study in which 688 women with multiple gestation were randomized to receive low-dose aspirin or placebo between 13 and 26 weeks' gestation, the incidence of preeclampsia was 12% with aspirin and 16% with placebo, a difference that was not significant (relative risk, 0.7; 95% confidence interval, 0.5 to 1.1).¹⁰⁴

Other Maternal Complications

Daily supplementation with at least 60 mg of elemental iron and 1 mg of folic acid is recommended because of the increased risk of iron- and folate-deficiency anemia in multiple gestation. Surveillance for other potential maternal complications of higher-order multiple gestations, including acute fatty liver of pregnancy, gestational diabetes, urinary tract infections, and intervertebral disk disease, is important as well.^{4,8} Although there are no data to guide timing or frequency of screening for gestational diabetes in multiple gestations, it may be reasonable to perform glucose challenge testing at 20 to 24 weeks' gestation, followed by a repeat screen at 28 to 32 weeks' gestation. In particular, multiple gestation is a risk factor for the development of acute fatty liver of pregnancy, perhaps because of the increase in placental mass.¹⁰⁵ Acute fatty liver should be carefully considered in the differential diagnosis if hepatic dysfunction is found in a woman with multiple gestation.

Fetal Surveillance

As described earlier, serial sonographic assessment of fetal growth is recommended for multiple gestations. We evaluate fetal weight and growth discordance every 3 to 4 weeks from approximately 18 weeks' gestation, or every 2 weeks if growth restriction or growth discordance (>20%) is discovered. Although some obstetricians routinely monitor all multiple gestations using weekly NST or biophysical profiles beginning at 34 weeks, this practice has not been validated by prospective studies.⁴ Surveillance with NST or biophysical profile is reserved for multiple pregnancies with the following indications:

- Significant growth restriction in either fetus
- Growth discordance
- Oligohydramnios
- Decreased fetal movement
- Maternal medical complications

Fetal testing for monoamniotic twins, TTTS, demise of one fetus, and anomalous twins is discussed later (see Special Considerations in Management).

As soon as the diagnosis of significant growth discordance is confirmed, fetal testing should begin intensively. In our practice, this consists of twice-weekly NST supplemented by biophysical profiles and umbilical artery Doppler velocimetry. If absent or reversed end-

diastolic flow is discovered, delivery should be considered if gestational age is sufficiently advanced that the healthy twin would not be significantly compromised by delivery. Selecting the appropriate time for delivery is extremely difficult in such cases, because an effort that is intended to save a twin that may already be significantly compromised may lead to iatrogenic morbidity in the healthy twin. Daily, or twice-daily, fetal testing should be performed in cases of absent or reversed end-diastolic flow until delivery is accomplished.

Determination of fetal lung maturity is sometimes helpful if multiple gestation is complicated by preterm labor, ruptured membranes, diabetes mellitus, growth restriction, or growth discordance. In most instances, only one sac is sampled, because lung maturity studies are usually similar.¹⁰⁶ In the case of discordant twins, it is difficult to predict which fetus will have higher lung maturity indices. In one series, 9 of 15 discordant twin pairs showed higher lung maturity indices in the larger twin, whereas theoretically the growth-restricted fetus would be predicted to have more advanced lung maturity owing to stress responses.¹⁰⁷ Therefore, we believe each amniotic sac should be sampled in selected cases if the results of lung maturity testing will affect management.⁴

Intrapartum Management

Preparations

The nadir of perinatal mortality for dichorionic twin pregnancies occurs at approximately 38 weeks, and for triplets at about 35 weeks.^{4,108} All twin fetuses should therefore be delivered by 39 weeks of gestation because of the rising perinatal morbidity and mortality beyond that date. The rate of stillbirth in multiple gestations at 39 weeks surpassed the risk for singleton gestations at greater than 42 weeks' gestation in one study.¹⁰⁹ A retrospective review of 5594 twin pregnancies demonstrated an increase in the rate of stillbirth beyond 36 weeks' gestation.¹¹⁰ The lowest rate of perinatal morbidity and mortality occurred at 37 weeks' gestation. Whether elective delivery at this gestational age for all twins will optimize outcomes is unclear and is the subject of ongoing study.¹¹⁰ Until more data are available, it is reasonable to consider delivery of uncomplicated dichorionic twins by 37 or 38 weeks' gestation.¹¹¹ For uncomplicated monochorionic twins, even in the setting of intensive fetal surveillance, the risk of sudden death after 32 weeks' gestation is significant, reaching 5%.¹¹² For this reason, and given the unique challenges of monochorionicity together with the relatively low risk of serious neonatal morbidity, we believe that it is reasonable to consider elective delivery of uncomplicated monochorionic twins by 34 to 35 weeks' gestation.

The use of prostaglandins for induction and oxytocin for induction or augmentation of labor is acceptable in twin gestation. An attempt at vaginal birth after a previous low transverse cesarean delivery is considered by some to be an acceptable alternative to elective repeated cesarean section in twin gestation.¹¹³ However, it should be noted that no randomized studies are available to confirm the safety of vaginal birth after cesarean (VBAC) in the setting of multiple gestation. A multicenter registry of 186 attempts at VBAC in twin pregnancies demonstrated a 65% success rate.¹¹⁴ In 30 of the 66 patients in whom a trial of labor failed, the first twin was successfully delivered vaginally, and a cesarean delivery was required for the second twin. Maternal and perinatal morbidity and mortality rates were similar in women with twins who attempted VBAC and those who delivered by repeat cesarean delivery¹¹⁴ in this observational study. However, such studies to date have lacked power to address the safety of this approach.

Intrapartum management of the parturient with a multiple gestation requires multidisciplinary cooperation. Adequate obstetric and nursing staff, together with an anesthesiologist and at least one neonatologist or pediatrician, should be present for delivery. Intravenous access and prompt availability of blood products should be ensured.¹¹¹

As soon as possible after admission to the delivery unit, ultrasonography should be performed to determine fetal presentations and size before choosing the mode of delivery. **Electronic fetal heart monitoring should be available; this is usually best achieved by placing a fetal scalp electrode for the first twin and using an external monitor for the second twin. If a trial of labor is elected, continuous lumbar epidural anesthesia should be strongly recommended, because it allows a full range of obstetric interventions to be performed rapidly if needed.** Vaginal deliveries should be performed in an operating room, because emergent cesarean section may be required for the second twin in a significant number of cases.¹¹⁵ Before vaginal delivery of a second twin, prompt availability of ultrasonography in the operating room may be very helpful in confirming presentation and fetal well-being.

Vertex-Vertex Twins

The vertex-vertex presentation occurs in 40% to 45% of all twin pregnancies. In the absence of obstetric indications for cesarean delivery, vaginal birth should be planned regardless of gestational age.^{111,115} **Routine cesarean delivery for all vertex-vertex twins is not supported by the literature; no improvement in perinatal outcome has been found.**¹¹⁶

After delivery of the first twin, the cord should be clamped. No blood samples should be obtained until after delivery of the second twin. Unless the presentation is obviously vertex by clinical examination, ultrasonography should be performed to confirm presentation of the second twin and to exclude a funis presentation. With the availability of continuous electronic fetal heart monitoring, there is no absolute indication to deliver the second twin within a specified time limit. **However, active intervention to complete the delivery (amniotomy, if safe, and oxytocin augmentation) is encouraged by studies that link length of delivery interval to fetal acid-base status.** In one series of 118 cases of twin deliveries, significant negative correlations were noted between the length of the delivery interval and umbilical cord pH and base excess.¹¹⁷ The rate of umbilical arterial pH of 7.00 or less was zero when the delivery interval was less than 15 minutes, increasing to 6% for an interval of 16 to 30 minutes, and to 27% for intervals longer than 30 minutes. Undue delay may also allow time for the fully dilated cervix to contract, thereby limiting the range of options for urgent delivery of the second twin should a problem develop. **The cesarean section rate for the second twin also increases with increasing delivery interval.**¹¹⁵

Vertex-Nonvertex Twins

Vertex-breech or vertex-transverse presentation occurs in 35% to 40% of all twin pregnancies. Selection of mode of delivery depends on (1) the size of the second twin; (2) the presence of growth discordance (estimated weight of second twin at least 25% greater than first twin); and (3) the availability of obstetric staff skilled in assisted breech delivery, internal podalic version, and total breech extraction. In the absence of an appropriately skilled obstetrician, or if the second twin is significantly larger than the first, cesarean delivery is recommended.

Another option is external cephalic version of the second twin immediately after delivery of the first. This method is successful in up to 70% of cases of vertex-nonvertex twins.¹¹⁸ **Vaginal delivery is not always possible after successful external version of the second twin and may be associated with complications, such as cord prolapse and placental abruption, that require emergent cesarean delivery of the second twin. For these reasons, breech extraction may be a better alternative, with success rates of more than 95%.**¹¹⁹ It has also been suggested that external cephalic version should no longer be attempted for a second twin because of the very high rate of emergency cesarean delivery required for the second twin.^{111,119,120}

Vaginal breech delivery of the second twin appears to be reasonable in appropriately selected cases. The adverse perinatal outcome associated with breech second twins is more often related to prematurity or growth restriction rather than mode of delivery.¹¹⁵ A liberal cesarean delivery policy for the nonvertex second twin has not significantly improved perinatal outcome. **For fetuses with birth weights of 1500 g or more, there is no apparent benefit to cesarean delivery over vaginal breech delivery for the nonvertex second twin.**¹¹⁵ Data for fetuses with estimated birth weights less than 1500 g are insufficient to make such a firm conclusion, but vaginal breech delivery of such fetuses is not absolutely contraindicated. In a series of 141 twin deliveries in which the second twin was nonvertex, including 35 cases of vaginal delivery, there was no evidence of benefit from cesarean delivery when gestational age was greater than 24 weeks and the birth weight exceeded 1500 g.¹²¹ It seems reasonable to offer vaginal breech delivery for the nonvertex second twin with an estimated birth weight between 1500 and 3500 g, provided it is not significantly larger than the first twin and the head is not hyperextended. An estimated fetal weight of 2000 g as a lower threshold of fetal size allows for the imprecision of fetal ultrasound in accurately predicting birth weight.

If a vaginal breech delivery is planned for the second twin, the delivery of the presenting vertex twin is performed as previously described. If the second twin is in a frank or complete breech presentation and the fetal heart tracing is reassuring, membranes may be left intact until engagement of the presenting part, and an assisted breech delivery can be performed.

If the second twin is in a transverse lie or a footling breech presentation, or if fetal testing is not reassuring, membranes should be left intact until the feet can be secured in the pelvis, after which immediate amniotomy and total breech extraction should be performed.¹¹⁵ Whenever total breech extraction is indicated, it should be performed as soon as possible after delivery of the first twin, while the cervix is still fully dilated.¹¹¹

Nonvertex First Twin

Breech-vertex or breech-breech presentation occurs in 15% to 20% of all twin pregnancies. Such cases are almost always managed by cesarean delivery. Historically, this was practiced because of concern about interlocking fetal heads in breech-vertex twins. However, this complication is so rare that some centers offer vaginal delivery when the breech twin of a breech-vertex pair meets the selection criteria for singleton vaginal breech deliveries. Among 239 vaginal deliveries in which the first twin was breech, there was no evidence of depressed Apgar scores or increased neonatal deaths when the first twin's weight was greater than 1500 g.¹²² However, Apgar scores and neonatal deaths were significantly increased for first twins weighing less than 1500 g who were delivered vaginally from breech presentation. External cephalic version of a breech-presenting twin has also been described.¹²³ In the absence of prospective studies validating these approaches,

cesarean section for the nonvertex first twin is likely to be the optimal mode of delivery.

Higher-Order Multiple Gestations

Although case series of successful vaginal delivery of triplets exist, there are no prospective series large enough to establish the safety of vaginal delivery over cesarean delivery.¹²⁴⁻¹²⁶ One center described a protocol for vaginal delivery in selected cases of triplet gestation and reported that 8 of 11 women who were eligible successfully underwent vaginal delivery.¹²⁷ No increase in maternal or neonatal morbidity was noted in this small series. Another review suggested that there was a sixfold increased risk of stillbirth and a threefold increased risk of neonatal death when vaginal delivery of viable triplets was attempted.¹²⁸ Because of practical difficulties in adequately monitoring three or more fetuses in labor and through delivery, we recommend cesarean delivery under regional anesthesia for all patients with three or more live fetuses that are of a viable gestational age. There is no conclusive evidence to recommend one type of uterine incision over another in higher-order multiple gestation.

Asynchronous Delivery

Asynchronous delivery, or delayed interval delivery, refers to delivery of one fetus in a multiple gestation that is not followed promptly by delivery of the remaining fetus or fetuses. This extremely rare scenario is acceptable only in the management of extreme prematurity, when the remaining fetus is either previsible or would be at very high risk for severe complications of prematurity if delivered. Clinical conditions that typically contraindicate asynchronous delivery include monochorionicity, intra-amniotic infection, placental abruption, and the coexistence of preeclampsia. Successful outcomes have been reported in carefully selected cases.¹²⁹ In a report of 24 twins and triplets managed with delayed interval delivery, a protocol of amniocentesis of the remaining sac to exclude infection, ligation of the cord of the delivered fetus with absorbable suture near the placenta, aggressive tocolysis, placement of a cerclage, broad-spectrum antibiotics for up to 7 days, bed rest, and close surveillance were instituted.¹³⁰ The mean latency interval was 36 days; the range was 3 to 123 days. In 16 of the 24 cases, the gestational age was 24 weeks or less at the time of presentation; 10 (63%) of these reached 24 weeks, and 8 (44%) of the 18 remaining infants survived. Given the limitations of these data, it is essential that careful counseling be provided and informed consent be obtained from the mother regarding risks to her health before such management is attempted. Eligible women should be monitored closely for the development of chorioamnionitis or maternal sepsis. Cervical cerclage and tocolytic agents should be used with extreme caution and only after excluding chorioamnionitis. Data are insufficient to comment on the role of prophylactic antibiotics or amniocentesis in this setting.

Special Considerations in Management

Twin-Twin Transfusion Syndrome

Background and Pathogenesis

TTTS occurs because of an imbalance in blood flow through vascular communications in the placenta which leads to overperfusion of one twin and underperfusion of its co-twin (Fig. 25-4). It occurs exclusively

FIGURE 25-4 Twin-twin transfusion syndrome. Twin-twin transfusion syndrome resulted in pregnancy loss at 22 weeks' gestation; the plethoric recipient twin is on the left and the anemic donor twin on the right. (Courtesy of Steven Ralston, MD, New England Medical Center, Boston, MA.)

in monozygotic twin pregnancies and is estimated to occur in at least 15% of such pregnancies.^{131,132} Theoretically, TTTS should not occur in dichorionic twin pregnancies, but it has been demonstrated at least once in a fused dichorionic twin gestation.¹³³ The precise incidence of TTTS is extremely difficult to define, because the syndrome is associated with a wide spectrum of clinical presentations, ranging from the vanishing-twin phenomenon in the first trimester to unexplained fetal demise in the third trimester. There is even disagreement on terminology defining the syndrome. Some authors suggest that "twin oligohydramnios-polyhydramnios sequence" is a more precise term.^{134,135}

The precise cause of TTTS is unknown. Initial theories suggested that pregnancies affected by TTTS demonstrate significantly fewer placental anastomoses, and the few anastomoses present are more likely to be deep than superficial.¹³⁶ This theory implies that TTTS is likely to be the result of a paucity of placental anastomoses, which interferes with the placenta's ability to regulate blood flow equally between the twins. More recent work has demonstrated that it is the anatomic type of placental anastomoses, rather than simply their number, that underlies the pathophysiology of TTTS. Arteriovenous (AV) anastomoses have been described on the placental surface as a single unpaired artery

carrying blood from the donor twin to a placental cotyledon, together with a single unpaired vein carrying blood from that cotyledon back to the recipient twin.¹³⁷ Although these vessels run along the surface of the placenta separately, they enter the same placental cotyledon. It is theorized that these AV anastomoses result in net transfusion of blood from the donor to the recipient fetus. However, such AV anastomoses are present in up to 70% of monochorionic placentas, whereas the clinical syndrome of TTTS is far less common (15%).¹³⁸ Therefore, a protective mechanism must be in place that prevents TTTS from developing in the majority of monochorionic pregnancies. It has been suggested that arterioarterial anastomoses are bidirectional and that the presence of a large number of such anastomoses in a monochorionic placenta may compensate for unidirectional AV anastomotic flow, thereby preventing the appearance of TTTS.^{138,139} This theory is consistent with earlier studies suggesting that a lack of superficial placental anastomoses (presumably arterioarterial), together with the existence of a number of deep placental anastomoses (presumably AV), explains the pathophysiology of TTTS.^{136,139,140}

Clinical and Sonographic Features

The clinical features of TTTS can be explained by the placental architecture findings just described. The donor fetus is relatively hypoperfused, demonstrating signs of intrauterine growth restriction and oligohydramnios. Eventually, anhydramnios develops, and this fetus attains the typical “stuck twin” appearance because of inability to visualize the dividing membrane separate from the fetal body. Fetal blood sampling studies have demonstrated that this donor fetus has a significantly lower hematocrit than the recipient fetus (36% versus 47%).¹⁴¹ Echocardiographic studies have not shown any specific pattern of abnormal findings among donor fetuses.^{142,143} By contrast, the recipient fetus is relatively hyperperfused, becomes hypertensive, and produces increasing amounts of atrial and brain natriuretic peptides in an effort to handle its larger blood volume.¹⁴⁴ Recipient fetuses demonstrate biventricular hypertrophy and diastolic dysfunction, which tends to be progressive without definitive therapy.¹⁴⁵ This results in significant polyhydramnios and increasing intrauterine pressure. Uterine overdistention and raised intrauterine pressure may then contribute to increased rates of preterm labor or pPROM, as well as exacerbating hypoperfusion of the donor fetus through compression effects. Echocardiographic features in the recipient twin include ventricular hypertrophy and dilation, tricuspid regurgitation, and cardiac failure.^{142,143} Additionally, acquired progressive right ventricular outflow tract obstruction, possibly leading to right ventricular outflow atresia, has been described in up to 9% of recipient fetuses.¹⁴⁶

Prenatal diagnosis of TTTS depends on a high degree of clinical suspicion in monochorionic pregnancies, together with the visualization of certain ultrasonographic criteria. These include the following³⁴

- Presence of a single placenta
- Gender concordance
- Significant growth discordance (usually >20%)
- Discrepancy in amniotic fluid volume between the two amniotic sacs (usually oligohydramnios and polyhydramnios)
- Discrepancy in size of the umbilical cords
- Presence of fetal hydrops or cardiac dysfunction
- Abnormal umbilical artery Doppler findings, such as absent end-diastolic flow in the donor fetus

Not all sonographic criteria need to be met to make the diagnosis of TTTS, and none of the criteria is specific for TTTS. For example, a

significant growth discrepancy between monochorionic fetuses is not required to make a diagnosis of TTTS, because acute TTTS is known to occur; it leads to marked inequality in amniotic fluid volume in each sac but with insufficient time for significant fetal size discordance to become apparent. The most important criterion appears to be discrepancy in amniotic fluid volume, with a maximum vertical pocket of less than 2 cm expected around the donor fetus and a maximum vertical pocket greater than 8 cm around the recipient fetus. An early sonographic marker of TTTS may be significant discrepancy in nuchal translucency measurements at 10 to 14 weeks' gestation in a monochorionic twin.¹⁴⁷ The differential diagnosis of significant growth discordance or stuck twin phenomenon includes uteroplacental insufficiency, structural or chromosomal fetal abnormalities, abnormal cord insertion, and intrauterine infection (e.g., cytomegalovirus infection). Although abnormal cord insertions can coexist with TTTS, it does not appear that this contributes to the incidence of TTTS. In one study of monochorionic twins with and without TTTS, the incidence of velamentous cord insertion was approximately 15% in both groups.¹⁴⁸

Other methods of prenatal diagnosis of TTTS have included (1) fetal blood sampling to detect a difference in hemoglobin concentration between twins and (2) transfusion of adult rhesus-negative red blood cells into the donor twin, followed by Kleihauer detection in the recipient twin. Although fetal blood sampling studies have demonstrated significantly lower hematocrit values in donor compared with recipient fetuses, only some cases of TTTS have sufficient hematocrit differences to be of diagnostic value.¹⁴¹ Neonatal diagnosis of TTTS also relies on significant birth-weight discordance and on the demonstration of a difference of at least 5 g/dL in initial neonatal hemoglobin levels. However, because weight and hemoglobin differences are common in most monochorionic gestations, with or without TTTS, it is difficult to use these criteria alone for diagnosis.¹⁴⁹ Because great clinical variability exists in the appearance of TTTS, sonographic criteria have been proposed to classify severity. The clinical value of scoring systems to improve fetal outcome has not yet been determined, but they may foster comparison of published treatment strategies. One system uses the following markers, with the stage being assigned based on the worst sonographic features documented¹⁵⁰:

- Stage I: Donor twin bladder still visible, fetal Doppler values normal
- Stage II: Donor twin bladder no longer visible, fetal Doppler values normal
- Stage III: Donor twin bladder no longer visible, fetal Doppler values critically abnormal
- Stage IV: Presence of hydrops
- Stage V: Intrauterine death of one or both fetuses

It should be noted that fetuses with TTTS may not show an orderly progression through these stages and that ultimate prognosis is likely determined by the final stage at the time of definitive therapy rather than the stage at initial diagnosis.

Management

Because the diagnosis of TTTS is essentially one of exclusion, management first involves excluding other causes of significant growth discordance or stuck twin phenomenon. This requires careful sonographic assessment of fetal anatomy (in particular, the presence of normal fetal kidneys), cardiac function, and placental cord insertions for both fetuses. Although consideration should be given to the performance of amniocentesis to exclude chromosomal anomaly or infection, this pro-

cedure may interfere with subsequent management if fetoscopic laser therapy is a possibility.¹⁵¹ It is preferable, therefore, to defer amniocentesis until the time of definitive fetal therapy. Expectant management is associated with high rates of perinatal mortality, as high as 80% to 100% if the diagnosis is made before 24 weeks' gestation.^{152,153} If only one twin dies, there is a significant risk (as high as 20%) of profound neurologic handicap in the surviving twin.¹⁵⁴ Medical management with maternal administration of digoxin has not been widely used, and administration of indomethacin is no longer practiced because of a high likelihood of intrauterine demise, presumably due to interference with fetal renal perfusion.¹⁵⁵

Three possible management approaches have been described for the treatment of TTTS: serial reduction amniocenteses, amniotic septostomy, and selective fetoscopic laser photocoagulation of placental anastomoses. Serial reduction amniocenteses have been suggested in an effort to equilibrate amniotic fluid volume across the dividing membrane and to reduce overall intrauterine pressure, although the precise mechanism of action is unclear. The main advantage of this approach is that it is simple to perform and is widely accessible to the vast majority of patients and obstetricians, with up to 20% of patients showing resolution of TTTS.¹⁵⁶ With this technique, aggressive decompression amniocentesis is performed under ultrasound guidance. An 18-gauge needle is used to drain off as much fluid as possible from around the recipient twin. The procedure is repeated as often as necessary to maintain near-normal amniotic fluid volume; in particular, it is repeated when the maximum pocket of fluid in the recipient sac increases again toward 10 cm. The rationale for amnioreduction is that a decrease in uterine distention leads to reduced risk of preterm labor and pPROM, thereby prolonging gestation and improving perinatal outcome. However, an improvement in fetal condition has also been noted after reduction amniocentesis, which suggests that this therapy may also provide direct benefit for the fetus. Because amnioreduction does not affect the placental anastomoses that are the basis of TTTS, the mechanism by which reduction amniocentesis improves the fetal condition is uncertain. A reduction in polyhydramnios and intrauterine pressure may improve circulation in superficial arterioarterial anastomotic placental vessels at the donor side, leading to increased fetal renal perfusion and formation of urine, and to increased amniotic fluid volume in the donor sac.

Perinatal survival rates when serial reduction amniocentesis is chosen as primary therapy for TTTS range from 37% to 83%.¹⁵⁷ The variability in reported performance of reduction amniocenteses may be the result of reporting bias, small study sizes, and variations in the timing and volume of fluid removed. An international registry of 223 twin pregnancies with TTTS detected before 28 weeks' gestation and managed with reduction amniocenteses reported an overall survival rate of 78%.¹⁵² The median number of amnioreduction procedures performed was two, with a median of 1400 mL of amniotic fluid removed per procedure. Predictors of poor outcome included earlier gestational age at diagnosis, absent end-diastolic umbilical arterial blood flow in the donor fetus, and the presence of hydrops. Survival at 4 weeks of age was 60%, and approximately 25% of survivors had abnormal intracranial ultrasound findings.¹⁵² However, the prevalence of long-term neurologic abnormality may be lower than is suggested by these sonographic data. In a series of 33 TTTS pregnancies in which surviving infants were monitored until 2 years of age, there were only two cases (4.9%) of cerebral palsy, one of which was an infant who survived after an intrauterine demise of its co-twin, and the other an infant who also had cardiac malformations.¹⁵⁸

Amniotic septostomy involves deliberate perforation of the dividing membrane.^{159,160} The mechanism of action for this approach is

unclear, but it may involve equalization of fluid across the dividing membrane that results in ingestion of a fluid bolus by the donor twin and resultant expansion in its intravascular volume. However, such a theory has not been proven and does not explain the finding of TTTS in up to 10% of monoamniotic twin pregnancies.¹⁶¹ In 12 twin pregnancies managed with amniotic septostomy, a survival rate of 83% was achieved.¹⁶² In another observational report of 14 cases, 7 managed with serial reduction amniocentesis and 7 with amniotic septostomy, there was no difference in overall survival, but there was significantly greater pregnancy prolongation with septostomy.¹⁶³ In another report of three cases of amniotic septostomy, all fetuses were lost within 5 days of the procedure.¹⁶⁴ A randomized trial of 73 patients comparing amniotic septostomy and reduction amniocentesis failed to demonstrate any difference in outcome between the two therapeutic approaches.¹⁶⁰ Septostomy has been criticized because it may result in an iatrogenic monoamniotic twin pregnancy, with all the negative implications of this condition. Additionally, creation of an undulating dividing membrane may limit the success of a subsequent fetoscopic laser procedure if one is required.¹⁵³ Some have advocated microseptostomy, in which a single needle perforation is made in the dividing membrane to reduce the likelihood of iatrogenic monoamnioticity. Comparison of amnioreduction and septostomy is difficult, because septostomy may inadvertently occur during amnioreduction and because many cases of septostomy are treated with amnioreduction as well.

Probably the most effective management option for TTTS is selective fetoscopic photocoagulation of the anastomotic vessels on the surface of the placenta, using a fetoscopically placed neodymium-yttrium aluminum garnet (neo-YAG) laser or diode laser. A 2- to 3-mm fetoscope is placed into the polyhydramniotic recipient twin's sac under ultrasound guidance, and the vessels on the surface of the placenta are inspected. AV anastomoses are easily identifiable as a single unpaired artery coming from the donor side and entering a foramen on the placental surface, together with a single unpaired vein exiting the same area on the placental surface with blood flowing toward the recipient twin. Selective photocoagulation involves placement of a 0.4-mm neo-YAG laser fiber through the fetoscope and ablating all visible anastomoses that communicate between the fetuses. Debate continues as to the benefit of ablating all anastomoses or just the AV anastomoses.^{138,165} It would appear to be preferable to ablate all vascular communications that connect the two fetal circulations, because this would prevent reverse fetal transfusion and neurologic injury if one fetus dies. Whereas the selective approach to laser ablation involves ablating all anastomoses that connect the two fetal circulations, it also involves leaving intact those vessels that drain an area of placenta both to and from one particular fetus. Amnioreduction is also performed as part of the same procedure. An apparent advantage of selective photocoagulation is that it is the only therapy that directly addresses the underlying pathophysiology of TTTS. By ablation of the AV anastomoses, the net transfusion of blood from donor to recipient can be reduced. Ablation of all placental anastomoses that connect the fetuses essentially makes the pregnancy dichorionic.

Overall survival rates of 55%, 69%, 65%, and 57% have been reported from series of 144, 93, 200, and 72 TTTS pregnancies, respectively.¹⁶⁶⁻¹⁶⁹ The mean survival rate for the 471 TTTS cases in these series was 62%, with a 5% incidence of neurologic injury among survivors. Comparing the outcome of survivors of TTTS cases managed by laser or reduction amniocentesis has been difficult. In one single-center study, of 137 survivors of TTTS therapy, death or severe cerebral injury was significantly more common after reduction amniocentesis than after laser therapy.¹⁷⁰ Additionally, the incidence of adverse

outcome was similar between survivors of laser therapy and gestational age–matched dichorionic twin controls.

A major advance in the debate on the comparative performance of reduction amniocenteses versus laser ablation for TTTS occurred in 2004 with the publication of the Eurofoetus Consortium randomized trial of these two approaches.¹⁷¹ This multicenter trial, based at centers of excellence for fetoscopy in Europe, randomized 142 patients with severe TTTS before 26 weeks' gestation to either serial reduction amniocenteses or fetoscopic laser ablation of placental vessels. The trial was stopped early because of the significance of the results in favor of laser therapy. Compared with the group undergoing amniocenteses, the laser ablation group had significantly prolonged median gestational age at delivery (33 versus 29 weeks), significantly more cases with at least one survivor at 6 months of age (76% versus 51%), and significantly fewer instances of major neurologic damage among surviving infants at 6 months of age (5% versus 10%). Overall, patients can be counseled based on such data that in about one third of cases both fetuses will die, in about one third one fetus will die, and in only one third of cases will both fetuses survive.^{156,171} The fact that two out of three patients with this condition will deliver a dead or neurologically impaired infant, despite optimal therapy, is sobering.

In another recent randomized trial of fetoscopic laser ablation and reduction amniocenteses for TTTS, no difference was found between the two approaches.¹⁷² However, the success rate of reduction amniocentesis appeared to be better than that found by the Eurofoetus investigators, whereas the efficacy of laser ablation appeared considerably worse than that seen by the Eurofoetus authors and other investigators. However, this trial, which was sponsored by the U.S. National Institutes of Health (NIH), differed significantly from the Eurofoetus trial and was significantly underpowered to make any conclusions regarding the relative efficacy of the two therapies. The NIH study randomized patients to either fetoscopic laser ablation of placental vessels or reduction amniocenteses only after patients first failed a trial of initial reduction amniocentesis. Power analysis suggested that 146 patients would need to be randomized, but the trial was stopped early, after only 42 patients had been enrolled over a study period of more than 5 years. The main reason for early cessation of the trial was difficulty encountered in recruiting patients. Therefore, it is hard to draw any meaningful conclusions regarding optimal therapy for TTTS from this trial.

Although these randomized trial data are of great utility in counseling patients with TTTS, there are still areas of uncertainty related to management. It is unclear whether fetoscopic laser surgery should be considered first-line therapy in all cases of TTTS, or whether it should be reserved for early and severe cases. Given that laser ablation is a significantly more invasive procedure and is available only at a limited number of centers, there will likely remain a role for reduction amniocentesis in certain situations. In any case, frequent sonographic follow-up is required after the initial therapy. Intensive fetal surveillance should be performed when viability is reached. Betamethasone administration is recommended because of the high likelihood of early delivery. Delivery should be based on usual obstetric indications, although cesarean section is likely. If complete laser separation of shared vessels within the placenta has been confidently achieved, and if TTTS features resolve, some experts believe that it is reasonable to maintain the pregnancy until 37 weeks. However, given the difficulty in confirming with certainty that all placental anastomoses have been ablated, it may also be reasonable to electively deliver TTTS cases at 34 weeks after successful earlier therapy. Two neonatal resuscitation teams should be present at delivery. Surviving infants are at increased risk for long-term morbidity, including cardiomyopathy and periventricular leukomalacia.

^{171,173} There have been no reports of recurrent TTTS in subsequent pregnancies.

Studies of long-term outcome after laser treatment for TTTS have also confirmed that a significant number of survivors have neurologic impairment. In one series reporting on 2 years' follow-up of 115 survivors after laser treatment for TTTS, 17% had neurodevelopmental impairment, mostly cerebral palsy or developmental delay.¹⁷⁴ In another study of 89 survivors of laser treatment for TTTS at a median age of 21 months, 11% had major neurologic deficits, and a further 11% had minor deficits.¹⁷⁵ However, it is likely that much of the neurologic injury seen in survivors of laser therapy for TTTS occurs antenatally. In a comparison of neurologic injury in survivors of laser-treated TTTS pregnancies versus survivors of monochorionic pregnancies without TTTS, severe cerebral lesions were diagnosed in 14% of the TTTS group and in only 6% of the control group, with two-thirds of these lesions being diagnosed antenatally.¹⁷⁶

Monoamniotic Twins

Monoamniotic twinning results in a single amniotic sac containing both twins and occurs in approximately 1% of monozygotic gestations.³⁴ Prenatal diagnosis is established when a dividing membrane cannot be identified by an experienced sonographer in a twin gestation. The diagnosis is also confirmed after sonographic identification of entangled umbilical cords (Fig. 25-5); this feature has been reported in 70% to 100% of cases.^{177,178} Cord entanglement has been diagnosed by color Doppler ultrasonography as early as 10 weeks' gestation.¹⁷⁹ It can be difficult to visualize the dividing membrane sonographically in certain situations, especially in the early first trimester. Other techniques used to diagnose monoamnicity include sonographic visualization of only one yolk sac in a twin gestation at less than 10 weeks' gestation and amniography with iopamidol or indigo carmine–air mixture.^{37,180,181} However, the specificity of the visualization of only one yolk sac for the diagnosis of monoamnicity is unclear.³⁹

Monoamniotic twins historically carried a higher risk of perinatal morbidity and mortality than diamniotic twins, with a perinatal mor-

FIGURE 25-5 Monoamniotic twins. Amplitude-based Doppler image of monoamniotic twins at 29 weeks' gestation demonstrates entangled umbilical cords of twins A and B. (Courtesy of Achilles Athanassiou, MD, New England Medical Center, Boston.)

tality rate greater than 50%.¹⁸² However, more recent series and reviews of prenatally diagnosed cases of monoamniotic twins suggest mortality rates ranging from 10% to 21%.^{178,183} This risk may be secondary to premature delivery, growth restriction, congenital anomalies, vascular anastomoses between twins, and umbilical cord entanglement or cord accidents. Because umbilical cord accidents (e.g., cord prolapse, cord compression between fetuses) seem to be the primary cause of fetal death, most management protocols for monoamniotic twins emphasize intensive fetal surveillance.¹⁸⁴ Such surveillance should occur from the time of fetal viability, because intrauterine fetal demise has been documented in monoamniotic twins throughout gestation.^{178,179,185,186} Additionally, surveillance must be repeated frequently, because fetal compromise and death have been documented despite twice-weekly fetal testing.¹⁷⁸ The only intervention proposed to reduce the likelihood of cord accidents in monoamniotic twins is maternal administration of sulindac, a prostaglandin inhibitor that results in decreased amniotic fluid volume, which may, in turn, stabilize fetal lie and theoretically reduce the risk of cord entanglement.¹⁸⁷ However, because of a lack of evidence to support its safety and efficacy, this approach must be considered to be experimental.

Because umbilical cord accidents are not predictable by current methods of fetal surveillance and continuous fetal heart monitoring throughout pregnancy is not feasible, we have managed monoamniotic twin gestations with daily NSTs beginning at 24 to 26 weeks' gestation to determine the frequency of variable decelerations.¹⁸⁴ If variable decelerations increase in frequency, we perform continuous fetal heart monitoring and intervene with cesarean delivery if fetal heart testing becomes nonreassuring.

In the absence of nonreassuring fetal heart testing, the timing and mode of delivery of monoamniotic twins are controversial. In two series of 44 sets of monoamniotic twins, Carr and colleagues¹⁸² and Tessen and Zlatnik¹⁸⁸ reported no fetal deaths after 32 weeks, suggesting that prophylactic early delivery was not indicated.^{182,188} In an addendum to the latter series, however, it was noted that a double fetal death occurred at 35 weeks' gestation in one monoamniotic twin set, calling into question the safety of expectant management of monoamniotic twins beyond a gestational age at which neonatal morbidity is likely to be low. In these two series, vaginal delivery was achieved in more than 70% of cases, although in the series by Carr and coauthors the diagnosis of monoamniotic twins was not known prenatally in 80% of cases. Although vaginal delivery of monoamniotic twins is clearly possible, the incidence of cesarean delivery is high when fetal testing is nonreassuring. In addition, case reports have described cutting of the nuchal cord of the second twin after delivery of the first twin's head.^{189,190}

Because of these concerns, we and others electively perform cesarean delivery at 32 to 34 weeks' gestation after maternal administration of betamethasone.^{111,184,191} It is difficult to recommend continuation of pregnancy beyond 34 weeks' gestation, given the ongoing risk of stillbirth and the high rates of infant survival beyond this gestational age.¹⁸⁵ Whereas the majority of recent studies have suggested elective cesarean section, vaginal delivery may be acceptable if the fetal heart rates are continuously monitored and the mother has been informed that an emergent cesarean delivery may be necessary.

Twin Reversed Arterial Perfusion Sequence

Twin reversed arterial perfusion (TRAP) sequence, or acardiac twinning, is a unique abnormality of monochorionic multiple gestations

in which one twin has an absent, rudimentary, or nonfunctioning heart. The incidence is estimated to occur in 1% of monozygotic twin pregnancies, with birth estimates ranging from 1 in 35,000 to 1 in 150,000 births.³⁴ The condition occurs because of early development of arterial-to-arterial anastomoses between the umbilical arteries of twin fetuses that share a fused placenta.¹⁹²

The donor, or "pump twin," provides circulation for itself and for the recipient, or "perfused twin," through a direct umbilical arterial-to-umbilical arterial anastomosis at the placental surface. There is reversal of blood flow in the umbilical artery of the acardiac twin, with the artery bringing deoxygenated blood from the co-twin to the acardiac twin. This perfusion is usually asymmetric in the recipient twin, with relative hypoperfusion of the upper part of the body, leading to significant structural anomalies. A bizarre range of anomalies can be seen in the acardiac twin, including anencephaly, holoprosencephaly, absent limbs, absent lungs or heart, intestinal atresias, abdominal wall defects, and absent liver, spleen, or kidneys.¹⁹² Up to one third of the fetuses also have an abnormal karyotype.¹⁹³

Prenatal diagnosis of TRAP is based on the recognition of one normal-appearing fetus and an additional, profoundly abnormal-appearing fetus or amorphous mass of tissue. The pregnancy should be clearly monochorionic, and two thirds of cases demonstrate a single umbilical artery. The acardiac fetus may be unrecognizable as a fetus or may have an abnormally appearing head or trunk with no obvious heart. Sonographic signs of cardiac failure may be visible in the pump twin, including polyhydramnios, cardiomegaly, and tricuspid regurgitation. The differential diagnosis of TRAP includes intrauterine fetal demise of one fetus and anencephaly. Doppler velocimetry of the umbilical cords demonstrating reversed direction of flow in the umbilical artery and vein may be helpful in confirming the diagnosis.¹⁹⁴

The goal of antepartum management of TRAP pregnancies is to maximize outcome for the structurally normal pump twin. The pump twin is at risk for development of hydrops or congestive cardiac failure. In one series of 49 cases of TRAP, the overall perinatal mortality rate for the pump twin was 55%, with polyhydramnios leading to prematurity being a major factor in prognosis.¹⁹⁵ Prediction of prognosis for the pump twin depends on the ratio of the weight of the perfused twin to the weight of the pump twin, with a 30% chance of congestive cardiac failure when the ratio is greater than 0.70, compared with 10% when the ratio is less than 0.70.¹⁹⁵ Other criteria that may suggest the need for intervention include an abdominal circumference measurement in the acardiac twin greater than or equal to that of the pump twin, polyhydramnios with maximum vertical fluid pocket greater than 8 cm, abnormal Doppler indices, hydrops in the pump twin, or TRAP in the setting of monoamniocity.¹⁹⁶

In the absence of such poor prognostic features, expectant management with serial sonographic evaluation may be reasonable.^{157,197,198} Serial weekly echocardiographic surveillance of the pump twin is recommended for early signs of cardiac failure, such as atrial or ventricular enlargement, tricuspid regurgitation, or decreased ventricular fractional shortening capacity. Rapid growth of the acardiac fetus may also be a sign of poor outcome.¹⁹⁹ Antenatal corticosteroid administration should be given if delivery is expected to occur between 24 and 34 weeks' gestation. Signs of cardiac decompensation after 32 to 34 weeks' gestation should prompt consideration for delivery. Antenatal intervention on behalf of the pump twin should be considered if poor prognostic criteria, as summarized earlier, are noted before 32 to 34 weeks' gestation.

Invasive management has included selective delivery by hysterotomy of the acardiac recipient fetus, as well as percutaneous injection of various sclerosants into the umbilical cord of the acardiac twin.^{200,201}

These options are now of only historical interest because of the availability of a range of less invasive and more effective percutaneous approaches to selective termination of the acardiac fetus. **Currently, percutaneous approaches for interrupting blood flow to the acardiac twin include fetoscopic cord ligation or laser ablation and radiofrequency thermablation of the acardiac twin's cord using a special needle device.**^{196,202} In 45 cases managed by fetoscopic cord ligation or laser ablation, 30 pump twins (67%) survived.¹⁹⁶ Twenty-five (86%) of 29 pump twins managed exclusively with percutaneous radiofrequency thermablation survived, with a mean gestational age at delivery of 35 weeks.²⁰² No direct comparative studies have been performed. The advantage of the radiofrequency ablation technique is use of a single 14- or 17-gauge needle, compared with a typical 2- to 3-mm fetoscope for cord ligation approaches. **The recurrence risk for TRAP is estimated at 1 in 10,000.**¹⁹²

Conjoined Twins

Conjoined twins are a subset of monozygotic twin gestations in which incomplete embryonic division occurs 13 to 15 days after conception, resulting in varying degrees of fusion of the two fetuses. The estimated frequency of conjoined twinning is 1 in 50,000 births.³⁴ The prenatal diagnosis should be straightforward and is confirmed by failure to visualize two fetuses separately in what appears to be a single amniotic sac. Other sonographic features that assist in making the diagnosis include bifid appearance of the first-trimester fetal pole, more than three umbilical cord vessels, heads persistently at the same level and body plane, and failure of the fetuses to change position relative to each other over time.²⁰³ Prenatal diagnosis of conjoined twins has been made in the first trimester with the aid of three-dimensional sonography.²⁰⁴ However, caution should be exercised in making a definite diagnosis of conjoined twins at less than 10 weeks' gestation, because false-positive diagnoses have been documented.²⁰⁵

By careful sonographic survey of the shared anatomy, it should be possible to classify conjoined twins into one of the following five types:

1. Thoracopagus, in which the two fetuses face each other, accounts for 75% of conjoined twins (Fig. 25-6). The fetuses usually have common sternum, diaphragm, upper abdominal wall, liver, pericardium, and gastrointestinal tract. Because 75% of thoracopagus twins have joined hearts, prognosis for surgical division is extremely poor.
2. Omphalopagus (or xiphopagus) is a rare subgroup of thoracopagus in which there is an abdominal wall connection, often also with common liver. Because joined hearts are rare in omphalopagus, twins in this subgroup have a much better surgical prognosis than twins with other forms of thoracopagus.
3. Pygopagus accounts for 20% of cases; the twins share a common sacrum and face away from each other. There is a single rectum and bladder, and prognosis for surgical separation is usually good.
4. Ischiopagus, in which the twins share a single common bony pelvis, accounts for 5% of conjoined twins. Surgical prognosis is good, although the remaining lower spines are often abnormal.
5. Craniopagus accounts for 1% of cases and is marked by partial or complete fusion of skull, meninges, and vascular structures. Surgical prognosis depends on the degree of fusion of vascular structures, in particular the presence of an adequate superior sagittal sinus to allow venous drainage.²⁰³

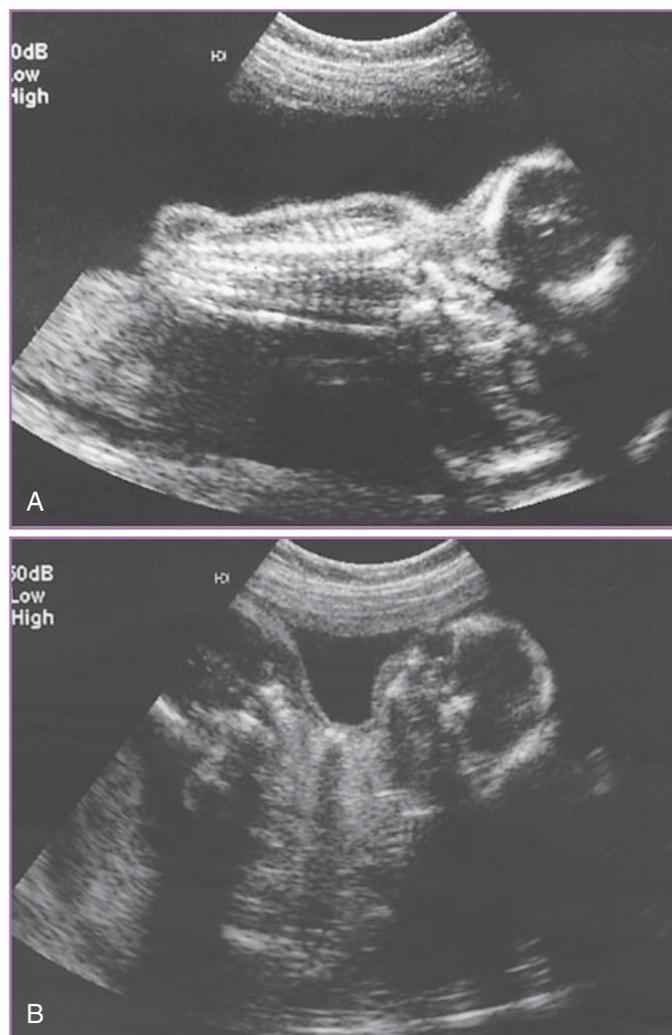

FIGURE 25-6 Conjoined twins. Thoracopagus conjoined twins at 20 weeks' gestation, demonstrating a single trunk containing two parallel spines (A) and leading to two separate heads (B).

Termination of pregnancy is commonly requested by parents of conjoined twins, especially in cases of thoracopagus with joined hearts. If expectant management is selected by the parents, fetal echocardiography and possibly magnetic resonance imaging should be used to delineate the exact extent of union and assist in neonatal surgical planning.²⁰⁶ In addition, a careful search must be made to exclude other anomalies that commonly coexist with conjoined twins. In one series of 14 sets of prenatally diagnosed conjoined twin pregnancies from a single center, the combination of prenatal ultrasonography, echocardiography, and magnetic resonance imaging accurately defined the anatomy in all cases.²⁰⁷ In this series, 3 pregnancies were terminated, 1 resulted in intrauterine death; of the remaining 10 pregnancies delivered after viability, 5 individual fetuses survived. When expectant management is selected, cesarean section (usually through a classical incision) is the delivery method of choice to minimize maternal and fetal trauma.^{34,111} Vaginal delivery is reasonable only in cases of extreme prematurity in which fetal survival is not an issue and maternal trauma should be less likely than with a cesarean section.

The surgical separation of conjoined twins, although beyond the scope of this chapter, has been summarized in the surgical litera-

ture.^{208,209} One of the largest series of conjoined twins managed at a single center was reported from South Africa, where 46 pairs of conjoined twins were seen over 40 years. In total, 17 sets underwent surgical separation, with 22 children (65%) surviving.²¹⁰ A survival rate of 85% was reported from another series of 10 sets of conjoined twins treated by surgical separation.²⁰⁶ Tremendously complex moral and ethical issues occur in the neonatal period regarding appropriate surgical options in conjoined twins when only one twin has the potential of survival.²¹¹ We are unaware of any reported cases of recurrence after the diagnosis of conjoined twins.

Intrauterine Demise of One Fetus

Intrauterine demise of one fetus in a multiple gestation during the first trimester is common and was originally thought to have no effect on the prognosis for the surviving fetus or fetuses. Such a “vanishing twin” has been reported to occur in 21% of twin pregnancies, with no obvious detrimental effect on the remaining fetus.²¹² However, it now appears that intrauterine demise of one fetus in a monochorionic twin pregnancy as early as 12 weeks’ gestation can result in profound neurologic injury to the surviving fetus.²¹³ In a series of 55 spontaneous first-trimester twin deaths in dichorionic pregnancies, there was an increased rate of preeclampsia and lower birth weight among surviving co-twins, compared with singleton pregnancies.²¹⁴ A further series of 642 surviving fetuses from vanishing twin pregnancies also confirmed an increased risk of small for gestational age, with risk being proportional to the gestational age at time of co-twin demise.²¹⁵ Intrauterine demise of one fetus in the second or third trimester is rarer (2% to 5% of twin pregnancies; 14% to 17% of triplet pregnancies) and probably has far greater potential for significant morbidity to the surviving fetus or fetuses.³⁴ After the death of one twin in a monochorionic gestation, approximately 12% of remaining fetuses also die, compared with approximately 4% of remaining fetuses in a dichorionic gestation.²¹⁶ The outcome of multiple gestations complicated by a single intrauterine demise is worse for monochorionic than for dichorionic gestations, with mean gestational ages at delivery of 30.6 and 32.9 weeks, respectively.²¹⁷

The risk of significant neurologic morbidity is increased after intrauterine death of one fetus in a monochorionic, but not in a dichorionic, gestation. Serious neurologic abnormality, such as multicystic encephalomalacia leading to profound neurologic handicap, occurs in 18% of surviving fetuses after the death of a co-twin in a monochorionic gestation.¹⁵⁴ Neurologic morbidity has been reported after the death of a co-twin as early as 12 weeks of gestation.²¹³ In a review of birth certificate data from the United Kingdom, 434 gender-concordant twin pregnancies were found in which intrauterine demise of one fetus had occurred.²¹⁸ The prevalence of cerebral palsy among surviving fetuses was 10.6%, and the prevalence of other neurologic injury was 11.4%. The main limitation of such birth certificate data is the inability to be sure of the prevalence of monochorionicity among the gender-concordant pairs. In a literature review of 119 monochorionic twin pregnancies complicated by single intrauterine fetal death, 9% of surviving fetuses subsequently died in utero, a further 10% subsequently died in the neonatal period, and 24% had serious neonatal morbidity, including porencephaly, multicystic encephalomalacia, renal cortical necrosis, and small-bowel atresia.²¹⁹

Neurologic injury in the surviving fetus probably occurs because of significant hypotension at the time of death of the co-twin. Fetal disseminated intravascular coagulopathy resulting from fetal-to-fetal transfer of thromboplastic material from the dead fetus was once advanced as a cause of neurologic injury but is unlikely.²²⁰ In a series

of fetal blood sampling studies performed immediately before and after intrauterine death of one twin, primarily in the setting of evaluation of TTTS, no evidence of fetal anemia was noted before fetal death, but all surviving fetuses were found to be anemic after death of the co-twin.²²⁰ This study suggested that acute blood loss from the surviving fetus into the dead fetus occurs proximate to fetal demise and that subsequent obstetric intervention may be too late to influence outcome for the surviving twin.

Because the risk of neurologic morbidity is present from the moment one twin dies, expectant management may not be appropriate for monochorionic gestations in which one fetus appears to be in a premorbid condition.²²¹ This 18% risk of profound neurologic injury after demise of a co-twin must be weighed against the risk of complications of prematurity with a premorbid fetus in a monochorionic multiple gestation. If fetal demise has already occurred, close surveillance of the surviving fetuses is recommended, although this may not prevent neurologic injury, which may already have occurred. Antenatal neurologic injury (e.g., multicystic encephalomalacia) may not be predictable by ultrasound or cardiotocographic monitoring. Delivery at 37 weeks, or after lung indices suggest maturity, is reasonable in such situations.

The maternal risks after intrauterine death of one fetus have probably been overestimated. The risk of maternal disseminated intravascular coagulopathy was once estimated at 25%, but in recent reviews of spontaneous fetal deaths and selective terminations in multiple gestations, no clinical cases of disseminated intravascular coagulopathy were noted. Our practice has been to obtain a baseline set of coagulation indices after diagnosis of the death of one fetus; subsequent laboratory surveillance with coagulopathy studies is probably unnecessary.²²¹

Selective Termination of an Anomalous Fetus

When a multiple gestation is complicated by the discovery of a significant anomaly in one fetus, counseling of the parents and management decisions are difficult. Factors to incorporate into the decision-making analysis include the following:

- Severity of the anomaly
- Chorionicity of the pregnancy
- Effect of the anomalous fetus on the normal co-twin or co-triplets
- Ethical beliefs of the parents

Three main choices are available²²¹: expectant management, termination of the entire pregnancy, and selective termination of the anomalous fetus.

The phrase “selective termination” refers specifically to deliberate termination of an anomalous fetus in a multiple gestation, typically in the second trimester. Selective termination is performed to optimize outcome for the normal fetus and to prevent delivery of an abnormal fetus. This differs from “multifetal reduction,” which refers to a non-specific reduction in the number of fetuses present in a higher-order multiple gestation, almost always in the first trimester, to lower the risk of prematurity for the remaining fetuses.²²²

Expectant management of a multiple gestation complicated by a single anomalous fetus leads to a 20% increase in the risk of preterm delivery attributable to the presence of an anomalous fetus, a correspondingly lower birth weight, and a higher cesarean delivery rate than is reported in normal twin gestations.²²³ In addition, expectant man-

agement of twins discordant for anencephaly is associated with an increased rate of intrauterine death of the normal co-twin in monochorionic gestations, as well as an increased rate of premature delivery, probably secondary to polyhydramnios, in both monochorionic and dichorionic gestations.²²⁴ Amnioreduction to reduce the incidence of prematurity may be considered if significant polyhydramnios develops in twins discordant for anencephaly.

The method of selective termination depends on the chorionicity.²²¹ In dichorionic gestations, ultrasound-guided intracardiac injection of potassium chloride is the most common technique; in monochorionic gestations, complete ablation of the umbilical cord of the anomalous fetus is required to avoid death or neurologic injury in the normal fetus. When selective termination in a monochorionic gestation is considered in contemporary obstetric practice, ultrasound-guided cord occlusion, fetoscopic cord occlusion, or laser ablation is most commonly used.^{225,226} Techniques such as hysterotomy and injection of cord sclerosants are no longer used.^{200,227}

These selective termination procedures for monochorionic gestations are significantly more complicated than the potassium chloride injection procedure used for dichorionic gestations. Few data are available to counsel patients about the safety and efficacy of these monochorionic techniques. Fetoscopic cord ligation may be associated with a 10% procedure failure rate and up to a 30% risk of pPROM.²²⁵ In one series of 80 consecutive monochorionic cord coagulation procedures, the overall perinatal survival rate was 83%, and there was a 10% rate of unexpected intrauterine fetal death, most of which was related to pPROM before viability.²²⁸ Reports of mistaken fetoscopic ligation of the cord of the normal fetus have also been described.²²⁹ Bipolar cautery and aortic thermocoagulation using single fetoscopic ports or single spinal needle access with sonographic guidance may be safer, but there are insufficient data to recommend an optimal choice for selective termination in monochorionic gestations.

Before performing the procedure, the physician must confirm that the targeted fetus has the anomaly in question. If the abnormal fetus has a structural anomaly, correct fetal identification is straightforward. If a chromosomal abnormality exists without structural markers and there is doubt about the position of the target fetus, repeated chromosomal analysis using rapid techniques (PCR or FISH) is required immediately before termination. The physician must be certain of the chorionicity of the pregnancy. Potassium chloride injection is contraindicated if dichorionicity cannot be confirmed with certainty. If such sonographic confirmation cannot be obtained, DNA zygosity studies on amniocytes may be required to exclude monochorionicity.⁴⁶

Results of selective termination from a large multicenter study of 402 cases of twins, triplets, quadruplets, and quintuplets demonstrated a 100% technical success rate, with an 8% rate of pregnancy loss before 24 weeks (5% if the procedure was performed before 12 weeks, 9% if performed between 13 and 18 weeks, and 7% if performed between 19 and 24 weeks).²³⁰ All procedures used intracardiac potassium chloride injection. In addition, another 6% of patients delivered between 25 and 28 weeks, 8% between 29 and 32 weeks, and 17% between 33 and 36 weeks. There were no cases of laboratory or clinical coagulopathies or other complications in the mothers.²³⁰

A series of 200 cases of twins, triplets, and quadruplets at one center demonstrated increased risks of preterm delivery if the presenting twin was terminated and an increased risk of pregnancy loss among triplet pregnancies.²³¹ The overall rate of unintended pregnancy loss before 24 weeks' gestation at this center was 4%, but the rate increased to 11% for selective termination in triplet gestations. The pregnancy loss rate may increase to as high as 43% with the termination of more than one anomalous fetus in a pregnancy. There does not appear to be a

significant difference in pregnancy loss rates at various gestational ages.^{79,231}

Selective termination of a single anomalous fetus in a multiple gestation therefore seems to be a reasonable management option. These data should be used to counsel patients according to the unique circumstances of each case.

Multifetal Pregnancy Reduction

The goal of first-trimester MFPR is to reduce the number of fetuses in a higher-order multiple gestation so as to decrease the chance of premature delivery and thereby to improve the outcome for the remaining fetuses. Higher-order multiple gestations are associated with a significant risk of delivery before viability. Fetuses that reach viability have a significant risk of birth before 28 weeks, when serious long-term neonatal morbidity is likely.

The natural history of triplet gestation suggests a 7% to 8% risk of delivery between 24 and 28 weeks' gestation.^{8,79,232} The natural history of quadruplet gestation suggests a 14% risk of delivery before 28 weeks' gestation.^{79,232} The risk of spontaneous loss of a triplet pregnancy before 24 weeks' gestation is approximately 11%.²³² The risk of losing the entire pregnancy before 20 or 24 weeks in quadruplet or higher gestations is unknown, because, in general, only pregnancies that successfully reach 20 weeks' gestation are reported in the literature. In addition, the risks to maternal health of expectantly managed higher-order multiple gestations are significant. The risks just described should be carefully discussed with each couple during counseling before a management plan is selected in all cases of higher-order multiple gestations.

The technique of transabdominal MFPR, as typically performed between 10 and 13 weeks' gestation, is straightforward.²³³ The patient is given a single oral antibiotic dose (dicloxacillin, 500 mg) immediately before the procedure. Ultrasonography is used to map the location of all gestations precisely within the uterus, and measurements are taken of crown-rump length and nuchal translucency thickness. If an abnormality is found or these measurements are abnormal in a particular fetus, that fetus is selected for reduction. Otherwise, the fetus or fetuses that are technically easiest to access are chosen, with the exception of the fetus overlying the internal os, which is rarely selected. If a monochorionic pair of fetuses exists within a higher-order multiple gestation, that pair is usually selected for reduction.⁷⁹ Under continuous ultrasound guidance with sterile technique, a 22-gauge needle is placed into the thorax of the targeted fetus, 2 to 3 mEq of potassium chloride is injected, and asystole is observed for at least 3 minutes. The procedure is then repeated for additional fetuses as required, with a different needle. Another ultrasound study is performed 1 hour after the procedure and again 1 week later to confirm demise of the targeted fetuses and viability of the remaining fetuses. Transvaginal MFPR is less commonly performed because it is associated with significantly higher loss rates when compared with the transabdominal approach (12% versus 5%).²³⁴

A current area of debate with MFPR is the role of prenatal diagnosis before or after the procedure. Options include amniocentesis for surviving fetuses 4 weeks after MFPR and CVS for some or all fetuses before MFPR. Amniocentesis after MFPR does not appear to further increase the risk of pregnancy loss.²³⁵ The main drawback of amniocentesis is that, if an abnormality is discovered, patients may have to consider yet another reduction procedure. CVS has also been shown to be safe when it is performed before MFPR, with success rates greater than 99% and with no obvious increase in the risk of pregnancy loss.²³⁶ Decisions of which placentas to sample are made based on starting

fetal number, finishing fetal number, likely target fetuses, and ease of access to particular placentas. Fetuses that are chromosomally abnormal or untested are preferentially selected for reduction.⁷⁹ For example, in a quadruplet pregnancy to be reduced to twins, it is reasonable to perform CVS only for the two fetuses being retained; if these fetuses are confirmed to be chromosomally normal, the remaining two fetuses can then be reduced.

The overall pregnancy loss rate before 24 weeks for transabdominal MFPR procedures has fallen from 8% to 5%, reflecting a procedure-related learning curve.²³⁴ The relative contribution to the overall loss rate of procedure-related loss, as opposed to the spontaneous loss typical of multiple gestations, is uncertain. International collaborative MFPR data from more than 3500 pregnancies documented a loss rate before 24 weeks that was directly related to both the starting and the finishing number of fetuses.²³⁴ This loss rate decreased, respectively, from 22% to 15%, 12%, 6%, and 6% with six, five, four, three, and two fetuses present at the start of the procedure. In addition, the risk of very premature delivery at 25 to 28 weeks decreased from 6% to 6%, 4%, 3%, and 1%, respectively. The optimal finishing number of fetuses appeared to be twins, with a loss rate before 24 weeks of 9%, compared with 20% for triplets. Reflecting the importance of the learning curve, these authors reported that the pregnancy loss rates for MFPR procedures performed most recently (1995 to 1998) were 4% for triplets reduced to twins and 7% for quadruplets reduced to twins.²³⁴ A single-center series of MFPR described 1000 cases, with a pregnancy loss rate of 5% before 24 weeks' gestation.²³⁷ This group subsequently updated their experience from 2000 consecutive MFPR cases and noted an increase in the number of patients choosing to reduce to a singleton.²³⁸ These authors also noted a significant increase in the number of patients undergoing CVS before the MFPR procedure (1.5% in the first 1000 cases, and 44% in the second 1000 cases). The documented safety of CVS, as well as the increasing desire of patients to be more selective about which fetuses to reduce and to be confident of not leaving viable fetuses with chromosomal abnormalities, appear to underlie these changing trends.²³⁸

For fetuses that reach viability after MFPR, 85% to 90% can be expected to be born at 32 weeks' gestation or later, with only 3% to 5% born between 25 and 28 weeks.^{233,239} It is now clear that MFPR is associated with better outcomes for patients with quadruplet and higher gestations. When counseling such patients, the option of MFPR should be presented, and patients should be informed that their best chance of delivering healthy, surviving infants is by undergoing MFPR. Much debate still exists, however, on the role of MFPR for triplet gestation. Over the last 15 years, there have been 17 studies published in which the outcome of expectantly managed triplet gestations was compared with the outcome after reduction of triplets to twins, with some also comparing outcome to nonreduced twin pregnancies.¹¹ The results from a meta-analysis of these data are summarized in Table 25-4. Reduction of triplets to twins yields a significant prolongation of gestation, but at the expense of an increased rate of earlier miscarriage.

From a total of 893 triplet pregnancies reviewed, 411 were expectantly managed and 482 underwent MFPR to twins. The rate of miscarriage before 24 weeks was 4% in the expectantly managed group but 8% in the MFPR group. This worse outcome with MFPR was offset by a reduction in the rate of preterm delivery between 24 and 32 weeks, from 27% in the expectantly managed group to 10% in the MFPR group.¹¹ Additionally, some data suggest that maternal complications can also be decreased when triplets are reduced to twins, with one study indicating a 22% incidence of gestational diabetes among non-reduced triplet pregnancies, compared with 6% among triplets reduced to twins.²⁴⁰

The data in Table 25-4 may be a little misleading, however, particularly with reference to perinatal mortality. MFPR involves the obligate death of one fetus in a triplet gestation, so the overall fetal mortality rate for triplets reduced to twins must be at least 333 per 1000. This may not be clear to patients if only perinatal mortality rates focusing on survivors of the MFPR procedure are presented. Additionally, no long-term outcome data for the survivors of reduced triplet pregnancies are available. We believe the available information does make a convincing argument to include MFPR in the counseling of all patients with triplet gestations. For an individual patient to select MFPR with triplets, she must decide whether the obligate death of one fetus, together with an increased risk of procedure-related pregnancy loss, justifies a 50% reduction in the risk of delivery before 32 weeks' gestation. This decision should be individualized in all cases.

After the MFPR procedure, patients should be observed closely for the usual complications of multiple gestation. Surveillance for appropriate fetal growth is recommended, because there may be an increased risk of intrauterine growth restriction after MFPR.²⁴¹ In addition, the psychological implications for mothers who have undergone MFPR can be significant. Seventy percent of these women demonstrate grief reactions, and 84% describe the procedure as very stressful.²⁴²

In view of the complex issues involved, MFPR should not be considered a simple solution to the problems of higher-order multiple gestations in this era of assisted reproductive technologies.²³³ Instead, attention should be focused on prevention of the problem, which may be alleviated at least in part through careful supervision of assisted reproductive practices. The American College of Obstetricians and Gynecologists recommends that it is preferable to terminate an ovulation induction cycle if a higher-order multiple gestation appears to be likely, and to limit the number of embryos transferred in an in vitro fertilization, rather than allow a situation to develop in which patients have to consider the option of MFPR.²⁴³ The ethical challenges associated with MFPR decision making are complex and are different from those concerning elective abortion. In the latter situation, the patient's intent is to avoid the birth of a child, whereas in the former, the opposite scenario exists: the patient is considering MFPR precisely because she wants to maximize her chance of having a healthy child.²⁴³

TABLE 25-4 META-ANALYSIS OF STUDIES COMPARING OUTCOME OF EXPECTANTLY MANAGED TRIPLET GESTATIONS WITH THAT OF TRIPLETS REDUCED TO TWINS

Management	Number of Pregnancies	Pregnancy Loss (<24 Wk)	Preterm Delivery (24-31 wk)
Expectant management	411	18/411 (4%)	105/393 (27%)
Reduction to twins	482	39/482 (8%)	46/443 (10%)

Chapter 26

Hemolytic Disease of the Fetus and Newborn

Kenneth J. Moise, Jr., MD

Red Cell Alloimmunization in Pregnancy

Terminology

Maternal antibodies to red blood cell antigens can pass across the placenta, attach to fetal red cells, and lead to their destruction. Historically, the perinatal effects of these antibodies could not be assessed until after delivery, and the descriptive term *hemolytic disease of the newborn* (HDN) was used. The advent of such diagnostic tools as ultrasound and fetal blood sampling (FBS) has allowed for the diagnosis of fetal anemia and hydrops fetalis before delivery. For this reason, the term *hemolytic disease of the fetus and newborn* (HDFN) is more appropriate to describe this disorder. Another historical term, *erythroblastosis fetalis*, was first used when neonatal studies revealed a large percentage of circulating erythroblasts in patients with severe HDFN. This represents a profound state of fetal anemia that probably occurs in only a small percentage of cases of HDFN. Therefore, the term *erythroblastosis fetalis* should be replaced by *HDFN*. Finally, the maternal etiology of HDFN, namely the formation of antibodies to red cell antigens, should be called *red cell alloimmunization* instead of the older term of *red cell isoimmunization*.

Historical Perspectives

The first case of HDFN was probably described in 1609 in the French literature by a midwife.¹ The case was a twin gestation in which the first fetus was stillborn and the second twin developed jaundice and died soon after birth. There is some suggestion that HDFN caused by the rhesus D (RhD) antibody may have played a role in the ultimate formation of the Anglican Church.² Henry VIII's first wife, Katherine of Aragon, conceived six children; five died in the perinatal period from presumed HDFN. Only one daughter, Mary Tudor, survived the union. The ultimate inability of Katherine to bear a viable male heir to the English throne resulted in a divorce that the Roman Pope would not grant. This led to Henry's declaration of the formation of the Church of England. The modern era of Rhesus disease probably began in 1939 when Levine and Stetson³ described an antibody in a woman who gave birth to a stillborn fetus. The patient experienced a severe hemolytic transfusion reaction after later receiving her husband's

blood. In 1940, Landsteiner and Weiner⁴ injected red cells from rhesus monkeys into guinea pigs. The antibody that was isolated from the guinea pigs was used to test human blood samples from Caucasian individuals, and agglutination was noted in 85% of them. One year later, Levine and associates⁵ were able to demonstrate a causal relationship between RhD antibodies in RhD-negative women and HDFN in their offspring.

The advent of therapy for HDFN began in 1945 with the description by Wallerstein⁶ of the technique of neonatal exchange transfusion. Later, Bevis⁷ and then Liley⁸ proposed the use of amniotic fluid bilirubin assessment as an indirect measure of the degree of fetal hemolysis. Sir William Liley's⁹ major contribution to the story of rhesus disease was the introduction of the intraperitoneal fetal transfusion (IPT). He learned from a visiting geneticist who had returned from Africa that the infusion of red cells into the peritoneal cavity of neonates with sickle cell disease produced normal-appearing red blood cells on peripheral blood smear. Liley realized that he had previously inadvertently entered the peritoneal cavity of fetuses at the time of amniocentesis, as indicated by the marked contrast in the yellow hue of the ascitic fluid compared with amniotic fluid. He postulated that purposeful entry into the fetal peritoneal cavity could be accomplished. After three unsuccessful attempts that resulted in fetal deaths, the fourth fetus was delivered at 34 weeks and 4 days of gestation after undergoing two IPTs at 32 weeks 1 day and 33 weeks 4 days.⁹ Several investigators made futile attempts to transfuse the fetus by direct access via hysterotomy using the fetal femoral artery, saphenous vein, and internal jugular vein.¹⁰⁻¹²

Early attempts at IPT used fluoroscopy for needle guidance. With the introduction of real-time ultrasound in the early 1980s, IPTs became a safer procedure as fluoroscopy was abandoned. Rodeck and coworkers¹³ are credited with the first intravascular fetal transfusion (IVT); they used a fetoscope to guide the transfusion needle into a placental plate vessel. Bang and coworkers¹⁴ performed the first ultrasound-guided IVT using the intrahepatic portion of the umbilical vein.

The 1990s saw the introduction of genetic techniques using amniocentesis to perform fetal red cell typing. With the dawn of the new millennium, the noninvasive detection of fetal anemia through Doppler ultrasound became a reality. The noninvasive determination of fetal antigen status using free DNA in the maternal circulation has also now entered clinical practice.

Incidence

The advent of the routine administration of antenatal and postpartum rhesus immune globulin (RhIG) resulted in a marked reduction in cases of red cell alloimmunization secondary to the RhD antigen. A report from surveillance hospitals of the Centers for Disease Control and Prevention noted in 1991 that 1 in every 1000 liveborn infants exhibited some effect from rhesus hemolytic disease.¹⁵ Data from a 2003 review of the national registry of U.S. birth certificates indicated an incidence of 6.8 cases per 1000 live births.¹⁶ Although this would appear to indicate an increasing incidence, reporting bias in the latter study probably explains this difference. Clearly, a shift to other red cell antibodies associated with HDFN has occurred as a result of the decreasing incidence of RhD alloimmunization.

Geifman-Holtzman and coworkers¹⁷ evaluated 37,506 serum samples from female patients at two New York blood centers between the years of 1993 and 1995. Sixty percent of the women were of child-bearing age. A positive screen for an antibody previously reported to be associated with HDFN was identified in 424 (1.1%) of the samples. Rhesus antibodies were the most common, accounting for more than half of significant antibodies, with the RhD antibody accounting for almost one fourth of all antibodies. Kell antibodies were next most frequent (29%), followed by Duffy (7%), MNS (6%), Kidd, and anti-U. These authors compared their findings with previous investigations of antibody prevalence. As expected, secondary to the widespread adoption of RhIG prophylaxis, the incidence of RhD alloimmunization decreased from 43.3 per 1000 samples in 1967 to 2.6 per 1000 in 1996 (Fig. 26-1).¹⁸ Kell alloimmunization was higher in the 1996 series (3.2 per 1000), compared with studies of the U.S. population in 1967 (1.6 per 1000); this increase was thought to be related to enhanced detection of antibodies through improvement of blood banking techniques. Alternatively, increasing maternal age could result in a higher likelihood of exposure to blood transfusions that have the potential to result in Kell sensitization. Finally, these investigators noted important differences in the incidence of such antibodies as Kell when comparing the U.S. population with similar populations in Australia¹⁹ or Sweden²⁰ (Kell incidence, 3.2, 0.5, and 0.4 per 1000, respectively). These differences are most likely explained by geographic variations in gene frequency, although specific national transfusion practices could also have an influence.

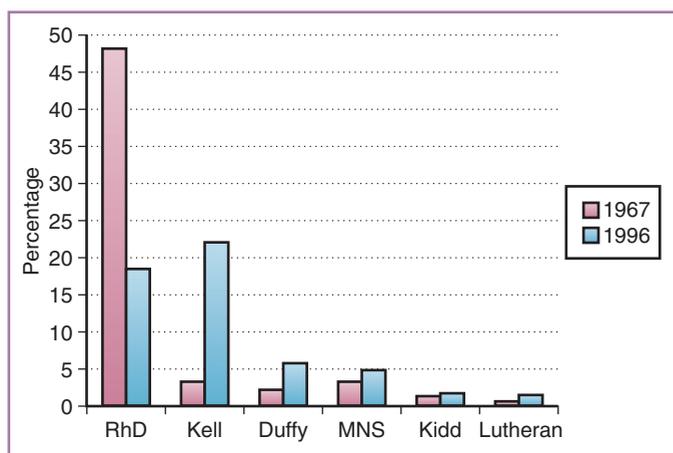

FIGURE 26-1 Incidence of maternal anti-red cell antibodies associated with hemolytic disease of the fetus and newborn in women of reproductive age. Graph shows changes in incidence from 1967 to 1996 in the United States.

Pathophysiology

It is well established that the fetal-maternal interface is not an absolute barrier, because there is evidence that considerable trafficking of many types of cells occurs between the fetus and the mother throughout gestation. In most cases, the antigenic load of a putative antigen on the fetal erythrocytes and erythrocytic precursors is insufficient to stimulate the maternal immune system. However, in the case of a large antenatal fetomaternal hemorrhage (FMH) or an FMH at delivery, B lymphocyte clones that recognize the foreign red cell antigen are established. The initial maternal production of immunoglobulin M (IgM) is short-lived and is followed by a rapid change to an IgG response. A human antiglobulin titer can usually be detected by 5 to 16 weeks after the sensitizing event.

The anti-D immune response is the best characterized of the anti-red cell antibodies associated with HDFN. In one third of cases, only subclass IgG1 is produced; in the remainder of cases, a combination of IgG1 and IgG3 subclasses are found.²¹ IgG3 anti-D is thought to promote monocyte-red cell interaction more efficiently than IgG1. A longer hinge region in its structure enables the IgG3 molecule to more easily bridge the gap between sensitized red cells and reticuloendothelial cells.²² Anti-D IgG is a nonagglutinating antibody that does not bind complement.

After the initial antigenic exposure, memory B lymphocytes await the appearance of red cells containing the putative antigen in a subsequent pregnancy. If stimulated by fetal erythrocytes, these B lymphocytes differentiate into plasma cells that can rapidly proliferate and produce IgG antibodies and an increase in the maternal titer. Maternal IgG crosses the placenta and attaches to fetal erythrocytes that have expressed the paternal antigen. These cells are then sequestered by macrophages in the fetal spleen, where they undergo extravascular hemolysis, producing fetal anemia. Fetal sex may play a significant role in the fetal response to maternal antibodies. Ulm and associates²³ reported that the chance for hydrops fetalis was increased by 13-fold in RhD-positive male fetuses compared with their female counterparts; the adjusted odds ratio for perinatal mortality was 3.38 in male fetuses.

Several important physiologic responses occur in fetuses as a result of this anemia. An enhanced bone marrow production of reticulocytes is noted when the fetal hemoglobin deficit exceeds 2 g/dL, compared with norms for gestational age, and erythroblasts from the fetal liver occur at a hemoglobin deficit of 7 g/dL or greater.²⁴ Cardiac output increases, and 2,3-diphosphoglycerate levels are enhanced. Tissue hypoxia appears as anemia progresses. An increased umbilical artery lactate level occurs when the fetal hemoglobin falls below 8 g/dL, and increased venous lactate is noted with a hemoglobin below 4 g/dL.²⁵

Hydrops fetalis, a collection of fluid in serous compartments, heralds end-stage disease, with hemoglobin deficits of 7 g/dL or greater.²⁴ It first manifests as fetal ascites; later, there are findings of pleural effusion and scalp edema. The exact pathophysiology of this condition is unknown. Lower serum albumin levels have been reported, presumably owing to depressed synthesis by the fetal liver, which shifts to an erythropoietic function.²⁶ Colloid osmotic pressure also appears to decrease.²⁷ However, congenital analbuminemia is not associated with hydrops fetalis, and experimental removal of fetal plasma proteins does not produce hydrops.^{28,29} Recently, Pasman and colleagues³⁰ studied albumin levels of 224 fetuses in Rh-alloimmunized pregnancies. A serum albumin concentration of less than 2 standard deviations below the mean was noted in only 14% of fetuses with mild hydrops and in 63% of fetuses with severe hydrops. An alternative hypothesis

suggests that tissue hypoxia resulting from anemia enhances capillary permeability. Iron overload resulting from ongoing hemolysis may contribute to free radical formation and endothelial cell dysfunction.³¹ Central venous pressures do appear to be elevated in the hydropic fetus with HDFN.²⁷ This may cause a functional blockage of the lymphatic system at the level of the thoracic duct as it empties into the left brachiocephalic vein. This theory is supported by reports of poor absorption of donor red blood cells infused into the intraperitoneal cavity in cases of hydrops.³²

Several specific antibody situations probably affect the pathophysiology of HDFN. Spong and coworkers³³ reported an increased degree of fetal anemia when multiple maternal antibodies associated with HDFN were present, compared with anti-D alone. Red cell sensitization to multiple antibodies was associated with a 1.8-fold increased need for intrauterine transfusions (IUTs), compared with patients who had only anti-D. The body of in vitro and in vivo evidence suggests that fetal anemia in cases of Kell (anti-K1) sensitization is secondary to two mechanisms: hemolysis and erythropoietic suppression. Vaughan and coworkers³⁴ studied 11 anemic fetuses from pregnancies with Kell alloimmunization who were matched for gestational age and hematocrit (Hct) with 11 anemic fetuses from pregnancies complicated by RhD alloimmunization. The anti-Kell group was noted to have a lower level of both reticulocytosis and erythroblastosis. Weiner and Widness³⁵ compared 11 fetuses from Kell-sensitized pregnancies with 54 from RhD-sensitized pregnancies. Like the previous investigators, they noted an inverse correlation between fetal hemoglobin concentration and reticulocyte count in the RhD fetuses; such a correlation could not be demonstrated in the Kell fetuses. Finally, Vaughan and colleagues³⁶ undertook an in vitro analysis of erythroid progenitors to assess the impact of anti-K1 antibodies compared with anti-D antibodies. Kell- and Kell+ erythroid cell lines were established from umbilical cord blood. Serum from 22 women sensitized to Kell suppressed the growth of Kell+ erythroid burst-forming and colony-forming units; no suppression occurred in Kell- cultures. Monoclonal anti-K1 antibody caused a dose-dependent suppression of growth in Kell+ cell lines but not in Kell- cell lines. Monoclonal anti-RhD antibody exhibited no suppression in either cell line. The role of the Kell antigen in red cell physiology is unknown; however, the Kell protein has structural similarities to endopeptidases and therefore may be involved in protein regulation and cell growth in the erythroid cells. At this time, little is known as to whether other anti-red cell antibodies are associated with suppression of fetal erythropoiesis.

Rhesus Alloimmunization and Hemolytic Disease of the Fetus and Newborn

Genetics

Fischer and Race³⁷ first proposed the concept of three genes that encode for the three major Rh antigen groups—D, C/c, and E/e. Some 45 years later, the Rh locus was localized to the short arm of chromosome 1.³⁸ Only two genes were identified—an RhD gene and an RhCE gene. Each gene is 10 exons in length, and there is 96% homology between the genes. This led some to conclude that these genes represent a duplication of a common ancestral gene. Production of two distinct proteins from the *RHCE* gene probably occurs as a result of alternative splicing of messenger RNA.³⁹ One nucleotide difference, a change from cytosine to thymine in exon 2 of the *RHCE* gene, results in a single amino

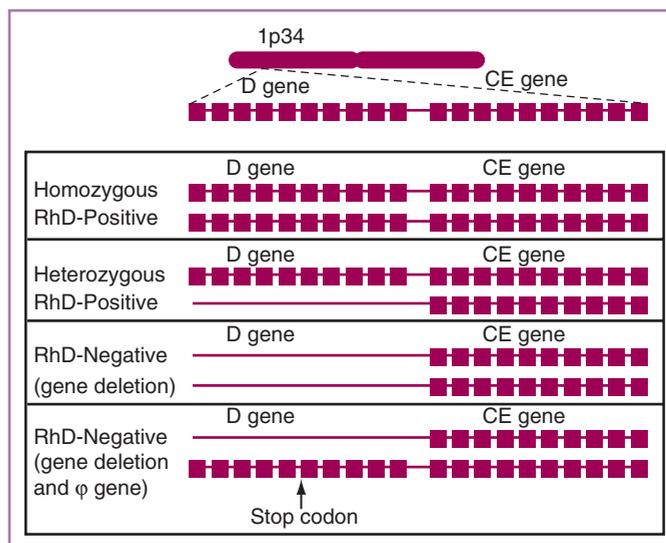

FIGURE 26-2 Schematic diagram of Rh gene locus on chromosome 1. Four genotypes are demonstrated: homozygous RhD-positive, heterozygous RhD-positive, typical RhD-negative, and RhD-negative with pseudogene (ψ).

acid change of a serine to proline. This causes the expression of the C antigen as opposed to the c antigen.⁴⁰ A single cytosine-to-guanine change in exon 5 of the *RHCE* gene produces a single amino acid change of a proline to alanine, resulting in formation of the e antigen instead of the E antigen.⁴¹

The gene frequency found in various ethnic groups can be traced to the Spanish colonization in the 15th and 16th centuries. Native populations of certain land masses (Eskimos, Native Americans, Japanese, and Chinese individuals) have less than a 1% incidence of RhD negativity. The Basque tribe in Spain is noted to have a 30% incidence of Rh negativity. This may well be the origin of the RhD gene deletion that is the most common genetic basis of the RhD- state in whites (Fig. 26-2). Whites of European descent exhibit a 15% incidence of RhD negativity, whereas an 8% incidence occurs in African Americans and Hispanics of Mexico and Central America. This latter incidence probably reflects ethnic diversity secondary to Spanish colonization of the New World.

An RhD pseudogene has been described in 69% of South African blacks and 24% of African Americans (see Fig. 26-2).⁴² In this situation, all 10 exons of the RhD gene are present; however, translation of the gene into a messenger RNA product does not occur because of the presence of a stop codon in the intron between exons 3 and 4. Therefore, no RhD protein is synthesized, and the patient is serologically RhD-. The presence of this gene in an RhD- pregnant patient has important implications for the prenatal diagnosis of the fetal blood type using amniocentesis, chorion villus biopsy, or free fetal DNA (see later discussion).

Prevention of RhD Hemolytic Disease of the Fetus and Newborn

Four RhIG preparations are currently available in the United States for the prevention of RhD alloimmunization. Two of the products (RhoGAM, Ortho-Clinical Diagnostics, Raritan, NJ, and HyperRHO S/D, Talecris Biotherapeutics-USA, Research Triangle Park, NC) are limited to intramuscular use because they are manufactured by Cohn

cold ethanol fractionation, a process that results in contamination with IgA and other plasma proteins. The remaining two products (WinRh-SDF, Cangene Corporation, Winnipeg, Canada, and Rhophlac, CSL Behring, Marburg, Germany) are prepared through sepharose column and ion-exchange chromatography, respectively. Currently, all available products are subject to solvent detergent treatment to inactivate enveloped viruses; many manufacturers also employ an additional micropore filtration step to further reduce the chance of viral contamination. Thimerosal, a mercury-derived preservative used to prevent bacterial and fungal contamination, has been removed from all RhIG products used in the United States.

Although Rh(D) antibody was once produced from the plasma of sensitized women, the decreasing prevalence of rhesus disease has necessitated the use of male donors who undergo repeated injections of RhD+ red blood cells. Because of concerns regarding Creutzfeldt-Jakob disease in the United Kingdom, only plasma from the United States is used as the source of antibody for RhIG preparation in that region at the current time. Occasional outbreaks of hepatitis C related to the administration of RhIG were reported in Ireland⁴³ and Germany⁴⁴ in the late 1970s, although none has occurred in the United States. Because RhIG is a blood derivative, patients who choose not to accept blood products secondary to religious beliefs should be informed of its source and asked for informed consent. Although most RhIG is issued from hospital blood banks, various manufacturers' products can be purchased by private physicians for use in their offices. A past recall by one manufacturer warrants that careful records of lot numbers be documented in the patient's medical chart and in a general clinic logbook.

The exact mechanism by which RhIG prevents alloimmunization to the RhD antigen is unknown. Studies using intramuscular human monoclonal anti-D antibodies revealed that only about 8% of RhD antigenic sites are bound by anti-D antibody after injection.⁴⁵ This negates the theory that masking of antigenic sites is the explanation for the effectiveness of RhIG. Passive anti-K has been shown to prevent the formation of anti-D in K- RhD- patients exposed to K+ RhD+ red cells.⁴⁶ Exogenous anti-D bound to RhD sites on the red cell is thought to bind to the IgG Fc receptors FcγRI, FcγRIIA, and FcγRIIIA on effector cells (macrophages and natural killer cells), thereby resulting in clearance of RhD+ red cells from circulation.⁴⁷ Inhibition of the activation of B lymphocytes through binding with FcγRIIB1 receptors also has been proposed as part of the mechanism for prevention of alloimmunization.⁴⁷

The limited resource of donors and issues with the safety of injection of exogenous red cells led several investigators to develop monoclonal anti-D preparations to replace the current polyclonal products that are on the market.⁴⁸ Polyclonal anti-D is composed of approximately 85% IgG1 and 15% IgG3. Trials have been reported with mixtures of monoclonal antibodies such as BRAD-5/BRAD-3.⁴⁹ Although most clinical trials have revealed enhanced clearance of RhD+ red cells from the circulation of RhD- subjects, most of the monoclones tested have not achieved rates of clearance that equal those of polyclonal anti-D. One of the larger trials using a BRAD-5/BRAD-3 combination monoclonal antibody revealed a failure rate of 2% for the prevention of alloimmunization.⁴⁹ Only the monoclonal antibody T125 has shown promise for red blood cell clearance equal to polyclonal anti-D in a mouse model of severe combined immunodeficiency disease (SCID).⁴⁷

All pregnant patients should undergo an antibody screen at the first prenatal visit. If there is no evidence of anti-D alloimmunization in the RhD- woman, recommendations in North America include the intramuscular administration of 300 μg of RhIG at 28 weeks of gesta-

tion.⁵⁰ This practice has been reported to reduce the incidence of antenatal alloimmunization from 2% to 0.1%.⁵¹ In the United Kingdom, an antenatal protocol of administering 100 μg (500 IU) of RhIG at 28 and 34 weeks is used.⁵² Limited resources have not allowed for extension of this protocol to all subsequent pregnancies. The American Association of Blood Banks recommends that a repeat antibody screen be obtained before administration of antenatal RhIG, although the incidence of alloimmunization before 28 weeks is very low.⁵³ The cost-effectiveness of this practice has been questioned by the American College of Obstetricians and Gynecologists.⁵⁰ If a repeat antibody screen is to be undertaken, a maternal blood sample can be drawn at the same office visit as the RhIG injection. Although the administration of the exogenous anti-D will eventually result in a weakly positive titer, this will not occur in the short interval of several hours because of the slow absorption from the intramuscular site. Some experts recommend that a second dose of RhIG be given if the patient has not delivered by 40 weeks' gestation.

Although they have not been well studied, additional indications for the antepartum administration of RhIG include spontaneous abortion, elective abortion, ectopic pregnancy, genetic amniocentesis, chorion villous sampling, and FBS. A dose of 50 μg of RhIG is effective until 12 weeks' gestation because of the small volume of red cells in the fetoplacental circulation.⁵⁰ From a practical sense, most hospitals and offices do not stock this dose of RhIG; therefore, a standard dose of 300 μg is often given. Data supporting use of RhIG in other scenarios in which the fetoplacental barrier is breached are lacking. However, most experts agree that such events as hydatidiform mole, threatened abortion, fetal death in the second or third trimester, blunt trauma to the abdomen, and external cephalic version warrant strong consideration for the use of RhIG. The administration of RhIG after a postpartum tubal ligation is controversial. The possibility of a new partner in conjunction with the availability of *in vitro* fertilization would seem to make the use of RhIG in these situations prudent. RhIG is not effective once alloimmunization to the RhD antigen has occurred. Currently, prophylactic immune globulin preparations to prevent other forms of red cell alloimmunization, such as anti-K1 (Kell), do not exist.

Because the half-life of RhIG is approximately 16 days, 15% to 20% of patients receiving it at 28 weeks will have a very low anti-D titer (usually 2 or 4) detected at the time of admission for labor at term.⁵⁴ In North America, the recommendation is to administer 300 μg of RhIG within 72 hours after delivery if umbilical cord blood typing reveals an RhD+ infant.⁵⁰ This is sufficient to protect from sensitization secondary to an FMH of 30 mL of fetal whole blood. In the United Kingdom, 100 μg of RhIG is given at delivery.⁵³

Approximately 1 in 1000 deliveries is associated with an excessive FMH; risk factors identify only 50% of these.^{55,56} Routine screening of all women at the time of delivery for excessive FMH should therefore be undertaken. A qualitative yet sensitive test for FMH, the rosette test, is first performed. Results return as positive or negative. A negative result warrants administration of a standard dose of RhIG. If the rosette is positive, a Kleihauer-Betke stain or fetal cell stain using flow cytometry is undertaken. The percentage of fetal blood cells is multiplied by a factor of 50 to estimate the volume of the FMH. Because this calculation includes an inaccurate estimation of the maternal blood volume, the blood bank typically indicates that an additional dose of RhIG should be administered beyond the calculated amount. No more than five standard doses (1500 μg, 2.5 mL) of RhIG should be administered by the intramuscular route in one 24-hour period. Should a large dose of RhIG be necessary, an alternative method would be to give the entire calculated dose using the intravenous preparations

of RhIG that are now available. The total dose should be calculated and administered in increments of 600 μg (3000 U) every 8 hours. Should RhIG be inadvertently omitted after delivery, it has been shown that some protection is provided by administration within 13 days; recommendations have been made to administer it as late as 28 days after delivery.⁵⁵ If delivery occurs less than 3 weeks from the administration of RhIG used for antenatal indications such as amniocentesis for fetal lung maturity or external cephalic version, a repeat dose is unnecessary unless a large FMH is detected at the time of delivery.⁵⁰ Despite the widespread acceptance of similar guidelines, studies from Scotland revealed that two thirds of rhesus-alloimmunized cases were secondary to antepartum sensitization, whereas an additional 13% were caused by failure to administer RhIG for the usual obstetric indications.⁵⁷

Diagnostic Methods

Maternal Antibody Determination

The maternal titer is the first step in the evaluation of the RhD-sensitized patient. Previous methodologies using albumin or saline should no longer be practiced because they detect varying levels of IgM antibody. Because the pentamer structure of this class of antibody does not allow for transplacental passage, the contribution of IgM to the titer quantitation has no clinical relevance. The human antiglobulin titer (indirect Coombs) is used to determine the degree of alloimmunization, because it measures the maternal IgG response.

By convention, titer values are reported as the reciprocal of the last tube dilution that led to a positive agglutination reaction; that is, a titer of 16 is the equivalent of a dilution of 1:16. Variation in results between laboratories is not uncommon, because many commercial laboratories use enzymatic treatment of red cells to prevent failure of detection of low-titer samples. However, in a single laboratory, the titer should not vary by more than one dilution if the two samples are run in tandem. This means that an initial titer of 8 that returns at 16 may not represent a true increase in the amount of antibody in the maternal circulation. A critical titer is defined as the titer associated with a significant risk for fetal hydrops. If a critical titer is present, further fetal surveillance is required. This titer varies with the institution and the methodologies used; however, most centers use a critical value for anti-D between 8 and 32.

In the United Kingdom, quantitation of anti-D is undertaken through the use of an automated device known as an autoanalyzer. Red cell samples are mixed with agents that enhance agglutination by the anti-D antibodies. Agglutinated cells are separated from nonagglutinated cells and then lysed. The amount of released hemoglobin is then compared with an international standard; results are reported as international units (IU) per milliliter. Levels of less than 4 IU/mL are rarely associated with HDFN. In one series of 42 fetuses undergoing serial FBS, a maternal anti-D level of less than 15 IU/mL was associated with only mild fetal anemia.⁵⁸ An increase in the maternal anti-D level of more than 15 IU/mL over a 2- to 3-week interval was associated with the development of moderate to severe fetal anemia in approximately 50% of cases.

In Vitro Tests

Because measurements of maternal anti-D have been poor predictors of HDFN, there has been considerable interest in in vitro assays that might better predict fetal disease by mimicking the red cell destruction that occurs in the fetus.⁵⁹ Typically, maternal serum containing anti-red cell antibodies is mixed with adult red cells heterozygous

for the specific antigen. These sensitized red cells are then combined with various types of reticuloendothelial cells, such as macrophages, monocytes, or lymphocytes. The degree of red cells hemolysis or activation of the reticuloendothelial cells is then quantitated. The three tests most commonly used are the antibody-dependent cell-mediated cytotoxicity (ADCC) assay, the monocyte monolayer assay, and the monocyte chemiluminescence test. In the ADCC assay, the release of chromium 51 from sensitized red cells previously incubated with this isotope is used as a measure of the in vitro destruction caused by the monocytes. The percentage of total monocytes involved in adherence or phagocytosis of red cells is assessed by microscopic examination in the monocyte monolayer assay. The chemiluminescence assay uses the photoactivity of luminol, a compound that generates light as it reacts with oxygen free radicals released from the activated monocytes.

Many of the original studies using these assays sought to predict the neonatal outcome of HDFN. In a multicenter trial using FBS to assess fetal disease, the percentage of phagocytosis in the monocyte monolayer assay was similar in antigen-negative fetuses; nonanemic, antigen-positive fetuses; and anemic, antigen-positive fetuses,⁶⁰ indicating that the monocyte monolayer assay was not useful to forecast the need for IUT. Zupanska and coworkers⁶¹ studied the ability of the chemiluminescence and ADCC assays to predict a fetal hemoglobin deficit of more than 3 g/dL, their threshold for IUT, in 37 pregnancies with anti-D sensitization. The chemiluminescence test was 89% predictive, whereas the ADCC was 78% predictive; the former was associated with fewer false-positive findings. Negative tests for the assays always predicted that FBS was not necessary.

These assays do not enjoy widespread use in the United States, although countries such as the Netherlands routinely use the ADCC performed at one central location (Central Laboratory of the Netherlands Red Cross) to decide when to proceed with invasive testing in the fetus.

Fetal Blood Typing through Genetics

Paternal zygosity plays an important role in the management of the red cell-alloimmunized pregnancy. In cases of a heterozygous paternal genotype, 50% of the fetuses will not express the involved red cell antigen and therefore will escape the hemolytic effects of the maternal anti-red cell antibody. In these cases, further maternal and fetal testing can be eliminated. Because the RhC/c and RhE/e antigens are inherited in a closely linked fashion to RhD, antisera for these antigens can be used with gene frequency tables based on ethnicity to determine the paternal zygosity at the RhD locus. Mathematic modeling should be employed to modify the incidence of heterozygosity based on the paternal history of previous RhD+ offspring.⁶² As an example, a white partner whose serologic testing results indicate a *Dce* phenotype and who has no history of an RhD+ progeny, has a 94% chance of being heterozygous. A history of repeated RhD+ offspring, however, would markedly decrease the chance of a heterozygous state (Table 26-1). Ethnicity must be taken into account when calculating the likelihood of heterozygosity, because disparate results can be noted with similar serologic findings.

Direct paternal zygosity testing is now available through quantitative polymerase chain reaction (PCR) techniques.⁶³ The PCR signal intensities of *RHD* exons 5 and 7 are compared with internal control genes (exon 7 of the *RHCE* genes) to determine the heterozygous or homozygous paternal state for the *RHD* gene (Fig. 26-3). The assay has also proved effective in detecting the RhD pseudogene.

First described in 1993, amniocytes have become the primary source used to test the fetal blood type in cases of a heterozygous

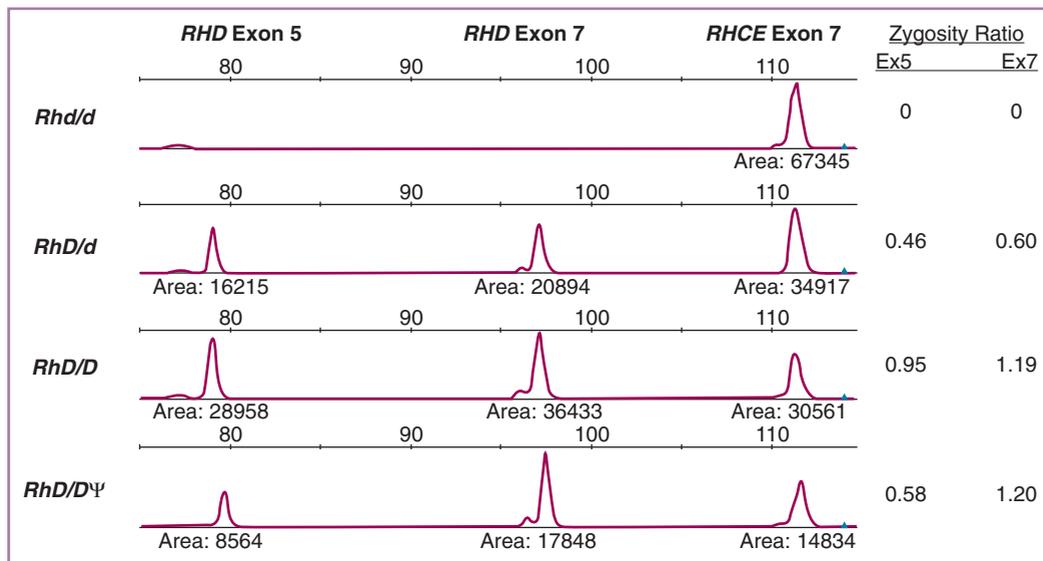

FIGURE 26-3 Paternal zygosity testing. Quantitative fluorescent polymerase chain reaction (PCR) was used to amplify exons 5 and 7 of the *RHD* gene as well as an internal control gene, exon 7 of the two *RHCE* genes. PCR products were analyzed on an automated sequencer. The ratio of *RHD* exon 5 or 7 peak areas was compared to the peak area derived from the two copies of exon 7 of the *RHCE* genes. *Upper panel*: *RHD* negative genotype (*Rhd/d*); no peak is seen for *RHD* exon 5 or *RHD* exon 7. *Upper middle panel*: *RHD* positive, heterozygous state (*RhD/d*); peaks for *RHD* exons 5 and 7 are approximately half of the peak area seen for the *RHCE* genes (ratios of 0.46 and 0.60). *Lower middle panel*: *RHD* positive, homozygous state (*RhD/D*); peaks for the *RHD* exons 5 and 7 are approximately equal to the peak area for the *RHCE* genes (ratios of 0.95 and 1.19). *Lower panel*: *RHD* positive, one copy of *RHD* gene and one copy of the *RhD* pseudogene (*RHDψ*) noted. The *RHD* exon 5 primers detect only *RHD* and not *RHDψ*, whereas the *RHD* exon 7 primers detect both *RHD* and *RHDψ*, explaining the copy number discrepancy in the *RHD/Dψ* sample (peak ratios of 0.58 and 1.20 versus the *RHCE* genes). (Courtesy of Daniel Bellissimo, PhD, Molecular Diagnostics Laboratory, The Blood Center of Wisconsin, with permission.)

paternal genotype.⁶⁴ Amniocentesis to detect fetal blood type actually assesses the fetal genotype instead of the fetal phenotype, which is the expression of the RhD antigen on the fetal red cells as determined by serology. Serologic fetal red cell typing can be performed on blood obtained by ultrasound-directed FBS, but this technique is associated with a rate of perinatal loss at least fourfold greater than with amniocentesis. Extensive experience with the use of amniocentesis for determining fetal blood type has revealed rare discrepancies. In the event of a DNA result that reveals an RhD– fetus when the fetus is RhD+ by serology, usual surveillance techniques would not be used and fetal loss can occur. In one series of 500 amniocenteses, this occurred in 1.5%

of cases.⁶⁵ Aside from erroneous paternity, the most likely etiology for this inconsistency is a rearrangement at the paternal RhD gene locus. Such rearrangements have been documented in approximately 2% of individuals.⁶⁶ Checking of the paternal blood, the source of the fetal RhD gene, with the same PCR primers used on the amniotic fluid verifies that a gene rearrangement is not a potential source of error. For this reason, most laboratories that offer fetal red cell typing on amniotic fluid require an accompanying paternal blood sample. Multiplex PCR, which targets at least two different exons of the RhD gene, is used by many centers to decrease the chance of nondetection of a gene rearrangement (Fig. 26-4).

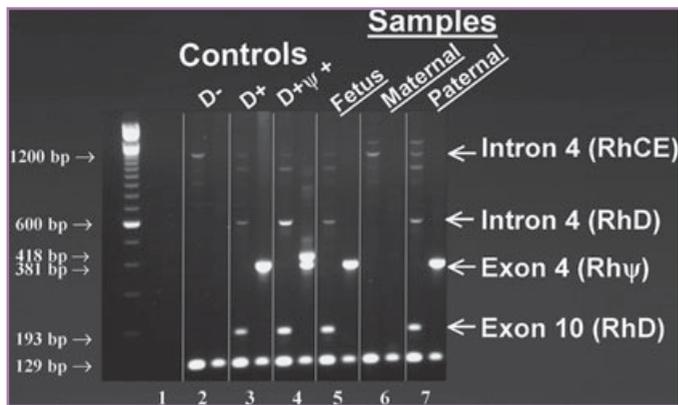

FIGURE 26-4 Electrophoresis gel of maternal, paternal, and amniotic fluid analysis for fetal RhD testing using multiplex polymerase chain reaction. Intron 4 of the *RHCE* gene (internal control), intron 4 and exon 10 of the *RHD* gene, and exon 4 of the RhD pseudogene (*RHDψ*) are used in the analysis. Lane numbers are indicated at bottom of figure. Lane 1, molecular weight ladder. Lane 2, RhD-negative control; a 1200-base pair (bp) band is noted, indicating *RHCE* amplification as internal control. Lane 3, RhD-positive control; the 1200-bp band for the *RHCE* gene is present, and additional bands of 600 bp (intron 4) and 193 bp (exon 10) are also noted, indicating the presence of the *RHD* gene. Lane 4, RhD/Dψ heterozygous control; 1200-bp (*RHCE*) as well as 600-bp and 193-bp (*RHD*) bands are noted. Additional bands are noted at 418 and 381 bp, indicating the presence of the Rh pseudogene. Lane 5, fetal sample, RhD-positive: 1200-bp (*RHCE*) as well as 600-bp and 193-bp (*RHD*) bands are present, but the 381-bp band is noted only from exon 4, indicating absence of the Rh pseudogene. Lane 6, maternal sample, RhD-negative: only the 1200-bp band is noted (*RHCE*). No *RHD* or *RHDψ* bands are present. Lane 7, paternal sample, RhD-positive: bands are present at 1200 bp (*RHCE*), as well as 600 bp and 193 bp (*RHD*), but only 381 bp of exon 4 is present, indicating absence of the Rh pseudogene. (Courtesy of Daniel Bellissimo, PhD, Molecular Diagnostics Laboratory, The Blood Center of Wisconsin, with permission.)

In situations where paternity is not assured or there is no partner available to send a blood sample for confirmation of PCR primers, the result of an RhD- fetal blood type performed by amniocentesis should be considered suspect. Hopkins⁶⁷ assessed serial titers in patients with RhD alloimmunization who subsequently delivered RhD- offspring and noted that serial maternal titers rose by fourfold in less than 2% of cases. In situations of questionable paternity, a repeat maternal antiglobulin titer should be obtained 4 to 6 weeks after the results of the amniocentesis as a confirmatory strategy (Fig. 26-5). If a fourfold rise in antibody titer is noted, then an RhD- PCR result on amniotic fluid should be questioned. Repeat amniocentesis to evaluate the spectral analysis of amniotic fluid at 450 nm (ΔOD_{450}) or FBS to determine the fetal RhD status using serologic techniques should be considered.

If the maternal ethnicity is black, then the presence of a maternal pseudogene must be excluded. In this situation, the pregnant patient is RhD- on serologic testing, but the entire RhD gene is present. Because the fetus inherits one of its RhD genes from the mother, amniotic PCR testing would yield a false-positive result—that is, the fetus would be RhD+ by genotype testing but RhD- by serology. This could lead to unnecessary intervention with its inherent risks. For this reason, a maternal blood sample should also accompany the amniotic fluid sent for fetal RhD testing, in an effort to rule out the presence of a maternal RhD pseudogene. If the maternal sample is positive for this

variant, then fetal testing for the pseudogene should also be performed (see Fig. 26-5).

Chorionic villus biopsy has been used for fetal red cell typing, but this technique should be discouraged in patients who wish to continue their pregnancy in the event that the fetus is found to be RhD+. Disruption of the chorionic villi during the procedure can result in FMH and a rise in maternal titer, thereby worsening the fetal disease.⁶⁸

Noninvasive fetal testing for the RhD gene now enjoys widespread clinical use in Europe and only recently has become available in North America.⁶⁹ Cell-free fetal DNA is now known to be present in the maternal circulation as early as 38 days of gestation; by term, it comprises 6% of the total DNA pool.^{70,71} The source of this DNA is thought to be apoptosis of placental trophoblasts; this would account for its relatively short half-life, measured in minutes after delivery. It is an attractive source for prenatal diagnosis, because there should not be any residual fetal DNA from previous gestations.⁷² The use of free DNA to determine fetal RhD status was first reported by Lo and associates in 1998.⁷³ Since that time, numerous reports have appeared in the literature. Geifman-Holtzman and colleagues⁷⁴ compiled reports of more than 2000 patients for whom fetal RhD status was determined from free DNA in maternal plasma, with an accuracy of 97%. A single center in the Netherlands has reported a 99.4% accuracy in more than 1200 cases.⁷⁵ Noninvasive fetal RhCc, RhE, and Kell typing are now available at some European centers using free fetal DNA as well.⁷⁶

Amniocentesis to Monitor the Severity of Hemolytic Disease of the Fetus and Newborn

Since it was first introduced to clinical practice by Bevis,⁷ the ΔOD_{450} has been used to measure the level of bilirubin, an indirect indicator of the degree of fetal hemolysis. Liley⁸ proposed a management scheme involving three zones based on gestational ages between 27 and 42 weeks. The Liley curve is useful for monitoring alloimmunized pregnancies, but extrapolation of Liley curves to gestational ages before 27 weeks has proved erroneous. Nicolaides and coworkers⁷⁷ correlated fetal hematologic values in 59 RhD-sensitized pregnancies between 18 and 25 weeks' gestation with ΔOD_{450} values on a Liley curve extrapolated to 18 weeks' gestation. They found that, if intervention were reserved for fetuses with ΔOD_{450} values in zone 3, 70% of cases of fetal anemia would not be detected. Even if all cases of fetal hydrops were excluded, 56% of cases of fetal anemia would still have been misdiagnosed. For a brief period after this report, many centers used FBS exclusively in cases of severe red cell alloimmunization if fetal assessment was indicated before 27 weeks' gestation. A modified ΔOD_{450} curve for such situations was proposed by Queenan and coworkers⁷⁸ from a series of 789 amniotic fluid samples obtained between 14 and 40 weeks' gestation (Fig. 26-6). Oepkes and associates⁷⁹ monitored 165 fetuses at risk for fetal anemia secondary to maternal red cell alloimmunization; 74 were subsequently found to exhibit severe anemia at the time of FBS. Serial ΔOD_{450} analysis using the Queenan curve was found to be superior to the Liley curve for the prediction of severe anemia (sensitivity, 81% versus 76%; specificity, 81% versus 77%). When limited to gestations of less than 27 weeks, the Queenan curve also proved to be more predictive than the modified Liley curve (sensitivity, 90% versus 84%).

If amniocentesis is used to monitor fetal disease, serial procedures are undertaken at intervals of 10 days to 2 weeks and continued until delivery to follow trends in the ΔOD_{450} values. Transplacental passage of the needle should be diligently avoided, because it can lead to FMH and a rise in maternal antibody titer. A rising or plateauing ΔOD_{450} value that approaches the IUT zone of the Queenan curve

(With permission from Queenan JT, Tomai TP, Ural SH, et al: Deviation in amniotic fluid optical density at a wavelength of 450 nm in Rh-immunized pregnancies from 14 to 40 weeks' gestation: A proposal for clinical management. *Am J Obstet Gynecol* 168:1370, 1993. Mosby, Inc., copyright 2001.)

or reaches the 80th percentile of zone 2 of the Liley curve requires further investigation by FBS. After 37 weeks' gestation, fetal lung maturity testing may be assessed, because induction of labor can be considered with a determination of maturity, instead of further amniocenteses.

Fetal Blood Sampling

Ultrasound-directed FBS (also called percutaneous umbilical blood sampling, cordocentesis, or funipuncture) allows direct access to the fetal circulation to obtain important laboratory values such as Hct, direct Coombs, fetal blood type, reticulocyte count, and total bilirubin. Serial FBS has been proposed as a primary method of fetal surveillance after a maternal critical titer is reached. Weiner and coworkers⁸⁰ studied 128 red cell–alloimmunized pregnancies and described four patterns that could be used to predict fetal anemia based on fetal values for hematocrit (Hct), direct Coombs assay, and reticulocyte count. FBS is associated with a 1% to 2% rate of fetal loss and up to a 50% risk for FMH with subsequent worsening of the alloimmunization.⁸¹ For these reasons, it is usually reserved for patients with elevated peak middle cerebral artery (MCA) Doppler velocities or elevated ΔOD_{450} values. However, if the fetal Hct is normal at the time of sampling, use of the direct Coombs and reticulocyte count may be of value to time subsequent procedures. Weiner⁸² also noted that a fetal umbilical venous total serum bilirubin concentration greater than 3 mg/dL was associated with the development of severe fetal anemia or postnatal hyperbilirubinemia in 94% of cases. If a transplacental approach has been used for FBS, a maternal antibody titer should be repeated in 1 week. If a large increase is noted as a result of an anamnestic response, the interval to the next FBS should be reduced, because the onset of fetal anemia can be rapid in these circumstances. When FBS is indicated by other first-line diagnostic modalities, blood should be immediately available for IVT if fetal anemia is detected (Hct <30% or <2 standard deviations for gestational age).

Ultrasound

Ultrasound plays a key role in the management of the alloimmunized pregnancy. It should be used early in the pregnancy to establish the

correct gestational age, because this parameter becomes important in determining such normative laboratory values as ΔOD_{450} levels and fetal hematologic values. Although hydrops fetalis can be easily detected with ultrasound, its presence represents the end-stage state of fetal anemia. Therefore, many investigators have sought alternative ultrasound parameters that could predict the early onset of anemia. In one large series, fetal abdominal circumference, head-to-abdomen circumference ratio, intraperitoneal volume, intrahepatic and extrahepatic umbilical vein diameter, and placental thickness were assessed to predict severe fetal anemia, defined as a fetal hemoglobin concentration of less than 5 g/dL.⁸³ Placental thickness and intraperitoneal volume detected only one fourth of cases, and the other parameters detected no more than 10% of severe cases.

Because the fetal liver is a site of extramedullary hematopoiesis in cases of severe fetal anemia, ultrasound has been used to measure the length of the right lobe as a marker of hepatomegaly.^{84,85} In one series, a liver length greater than the 95th percentile correctly predicted fetal anemia in 64 (93%) of 69 cases. The spleen is also a site of extramedullary hematopoiesis and destruction and sequestration of sensitized red cells in cases of severe HDFN. Determination of a splenic perimeter ($[\text{length} + \text{width}] \times 1.57$) greater than 2 standard deviations above the mean was predictive of severe fetal anemia in 94% and 100% of cases in two studies.^{86,87} Despite these data, hepatic length and splenic perimeter have not enjoyed widespread use for noninvasive surveillance in cases of red cell alloimmunization.

Many investigations have attempted to use Doppler ultrasound to correlate blood velocities in various fetal vessels to the level of fetal hemoglobin. Sites of study have included the descending aorta,⁸⁸ umbilical vein,⁸⁹ splenic artery,⁹⁰ and common carotid artery.⁹¹ The rationale for this approach is that decreasing fetal hemoglobin is associated with a lower blood viscosity, which produces less shearing in blood vessels, resulting in higher blood velocities. Alternatively, the increased cardiac output associated with fetal anemia may contribute to the higher blood velocities. Vyas and coworkers⁹² first described Doppler velocity in the MCA to detect fetal anemia. Using the intensity-weighted, time-averaged mean velocity of the MCA, these authors found one of the best correlations with fetal hemoglobin reported to date ($R = -0.77$). However, only 50% of the cases of fetal anemia were detected. Measurement of the peak systolic velocity in the fetal MCA has subsequently been shown to be the most accurate Doppler method for determination of fetal anemia. In the initial report by Mari and coworkers,⁹³ normative data for gestational age was established. Using receiver operating characteristic curve (ROC) analysis, a threshold value of 1.5 multiples of the median (MoM) was used to predict moderate to severe anemia (<0.65 MoM for fetal hemoglobin) (Fig. 26-7). These authors calculated that more than 70% of invasive tests could be avoided if this modality were used to monitor alloimmunized pregnancies.

A meta-analysis of noninvasive monitoring of alloimmunized pregnancies reported that the diagnostic test with the highest methodologic quality was the peak MCA velocity (positive likelihood ratio, 8.45; 95% confidence interval [CI], 4.7 to 15.6; negative likelihood ratio, 0.02 [CI, 0.001 to 0.25]).⁹⁴ In the first multicenter intent-to-treat prospective study, the peak MCA velocity proved accurate to detect moderate to severe anemia in 98% of fetuses from whom longitudinal measurements were obtained.⁹⁵ In the two cases of anemia that were not detected (neonatal hemoglobin concentrations, 5 and 8.2 g/dL), intervals of 17 and 21 days, respectively, had elapsed between the last Doppler study and delivery. In a prospective series, Oepkes and coworkers⁷⁹ found that the peak MCA Doppler value was superior to ΔOD_{450} measurements using both the Queenan and Liley curves in the detec-

tion of severe fetal anemia. The accuracy of MCA Doppler assessment was 85%, compared with 76% for the Liley curve and 81% for the Queenan curve.

The fetal MCA closest to the maternal skin should be evaluated using a minimal angle of insonation; angle correction can be used if necessary (Fig. 26-8). If the MCA vessel on the opposite side of the fetal head appears to provide a better angle for insonation, studies have shown that the results are comparable.⁹⁶ The Doppler gate is placed over the vessel just where it bifurcates from the carotid siphon. Placement of the gate on the more peripheral aspects of the MCA vessel will result in a false depression of the true peak systolic velocity. Color Doppler aids in determining the correct location. During the measurement, the Doppler baseline should be adjusted close to zero; the pulse

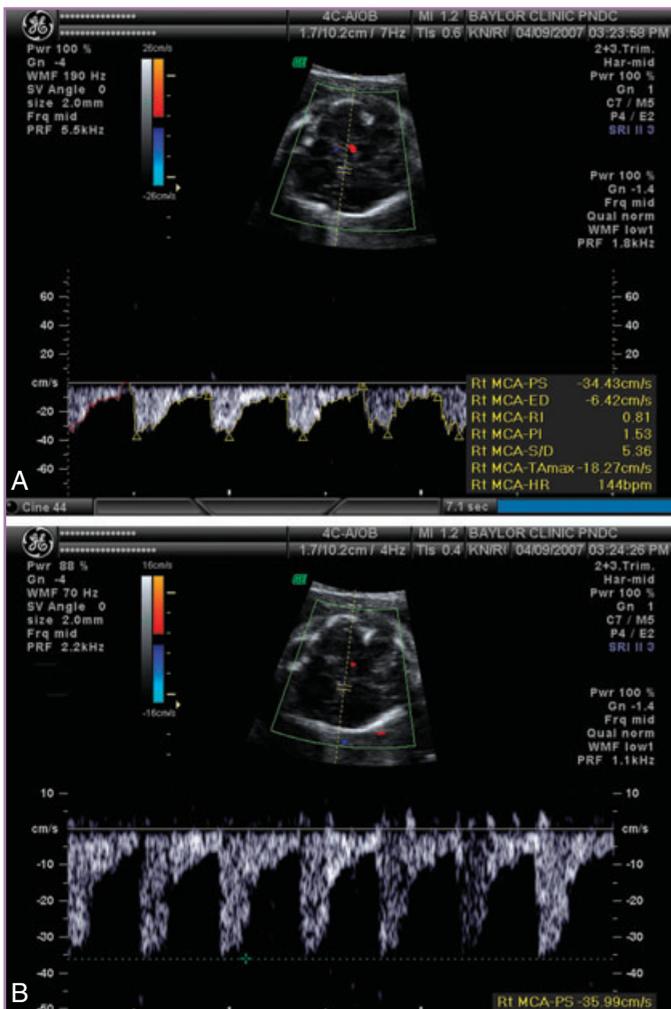

FIGURE 26-9 Optimization of Doppler parameters. **A**, Baseline and pulse repetition frequency (PRF) not optimized; automated software is used to measure a peak velocity of 34 cm/sec. **B**, Doppler baseline changed to 10 cm/sec, PRF optimized; manual caliper is used to measure a peak velocity of 36 cm/sec.

repetition frequency (PRF) should then be optimized to the approximate peak velocity (Fig. 26-9). These adjustments optimize the appearance of the waveform and make the true peak velocity more discernible. Peak systolic measurements should be made with the use of electronic calipers; automated software to trace the waveform typically underestimates the true peak velocity. Measurements can be initiated as early as 16 to 18 weeks' gestation and should be performed weekly (Fig. 26-10). Values should be reported in MoM to account for changes in gestational age. Internet-based calculators are available (see <http://www.perinatology.com/calculators2.htm>). After 35 weeks' gestation, the false-positive rate for the prediction of anemia increases, presumably secondary to fetal heart rate accelerations as a result of changes in the fetal behavioral state.^{95,97} In cases of a normal MCA peak velocity after 35 weeks, serial weekly measurements may be continued until induction of labor is scheduled.

Because a learning curve is associated with performing MCA Doppler measurements, Mari⁹⁸ suggested that a center having minimal experience with this technique should perform it in conjunction with serial amniocenteses for ΔOD_{450} . MCA Doppler assessment has revo-

lutionized the care of the RhD-sensitized pregnancy by minimizing invasive diagnostic testing.⁹⁹

Summary of Clinical Management

The approach using the available diagnostic tools is based on the patient's past history of fetal or neonatal manifestations of HDFN. As a general rule, the patient's first RhD-sensitized pregnancy involves minimal fetal or neonatal disease, and subsequent gestations are associated with a worsening degree of anemia.

First Affected Pregnancy

Once sensitization to the RhD antigen is detected (Fig. 26-11), maternal titers are repeated every month until approximately 24 weeks; titers are repeated every 2 weeks thereafter. Paternal blood is drawn to determine RhD status and zygosity. In the case of an RhD- paternal blood type, further maternal and fetal monitoring is unwarranted as long as paternity is assured (see Fig. 26-5).

Once a critical titer is reached (usually 32), the MCA peak systolic velocity is measured every week starting at about 24 weeks' gestation. MCA Doppler assessments may be started as early as 18 weeks' gestation if the maternal titer is significantly elevated (≥ 128). If a perinatal center skilled in the MCA Doppler technique is not geographically nearby, serial amniocenteses for ΔOD_{450} may be initiated and repeated at intervals of 10 days to 2 weeks. The Queenan curve should be used to analyze the results. In cases of a heterozygous paternal phenotype, an amniotic fluid sample along with maternal and paternal blood samples should be sent to a DNA reference laboratory at the time of the first amniocentesis to determine the fetal RhD status (this can be done at 24 weeks if one is following the Doppler protocol). If an RhD- result returns, further maternal and fetal testing can be eliminated.

If there is evidence of an RhD+ fetus (homozygous paternal phenotype or RhD+ fetus by PCR testing on amniotic fluid), serial MCA Doppler measurements are continued weekly. If the peak MCA exceeds 1.5 MoM (or if the ΔOD_{450} value on serial amniocenteses enters the upper aspect of the Rh+ affected zone of the Queenan curve), one should perform cordocentesis, with blood readied for IUT if the fetal Hct is found to be less than 30%.

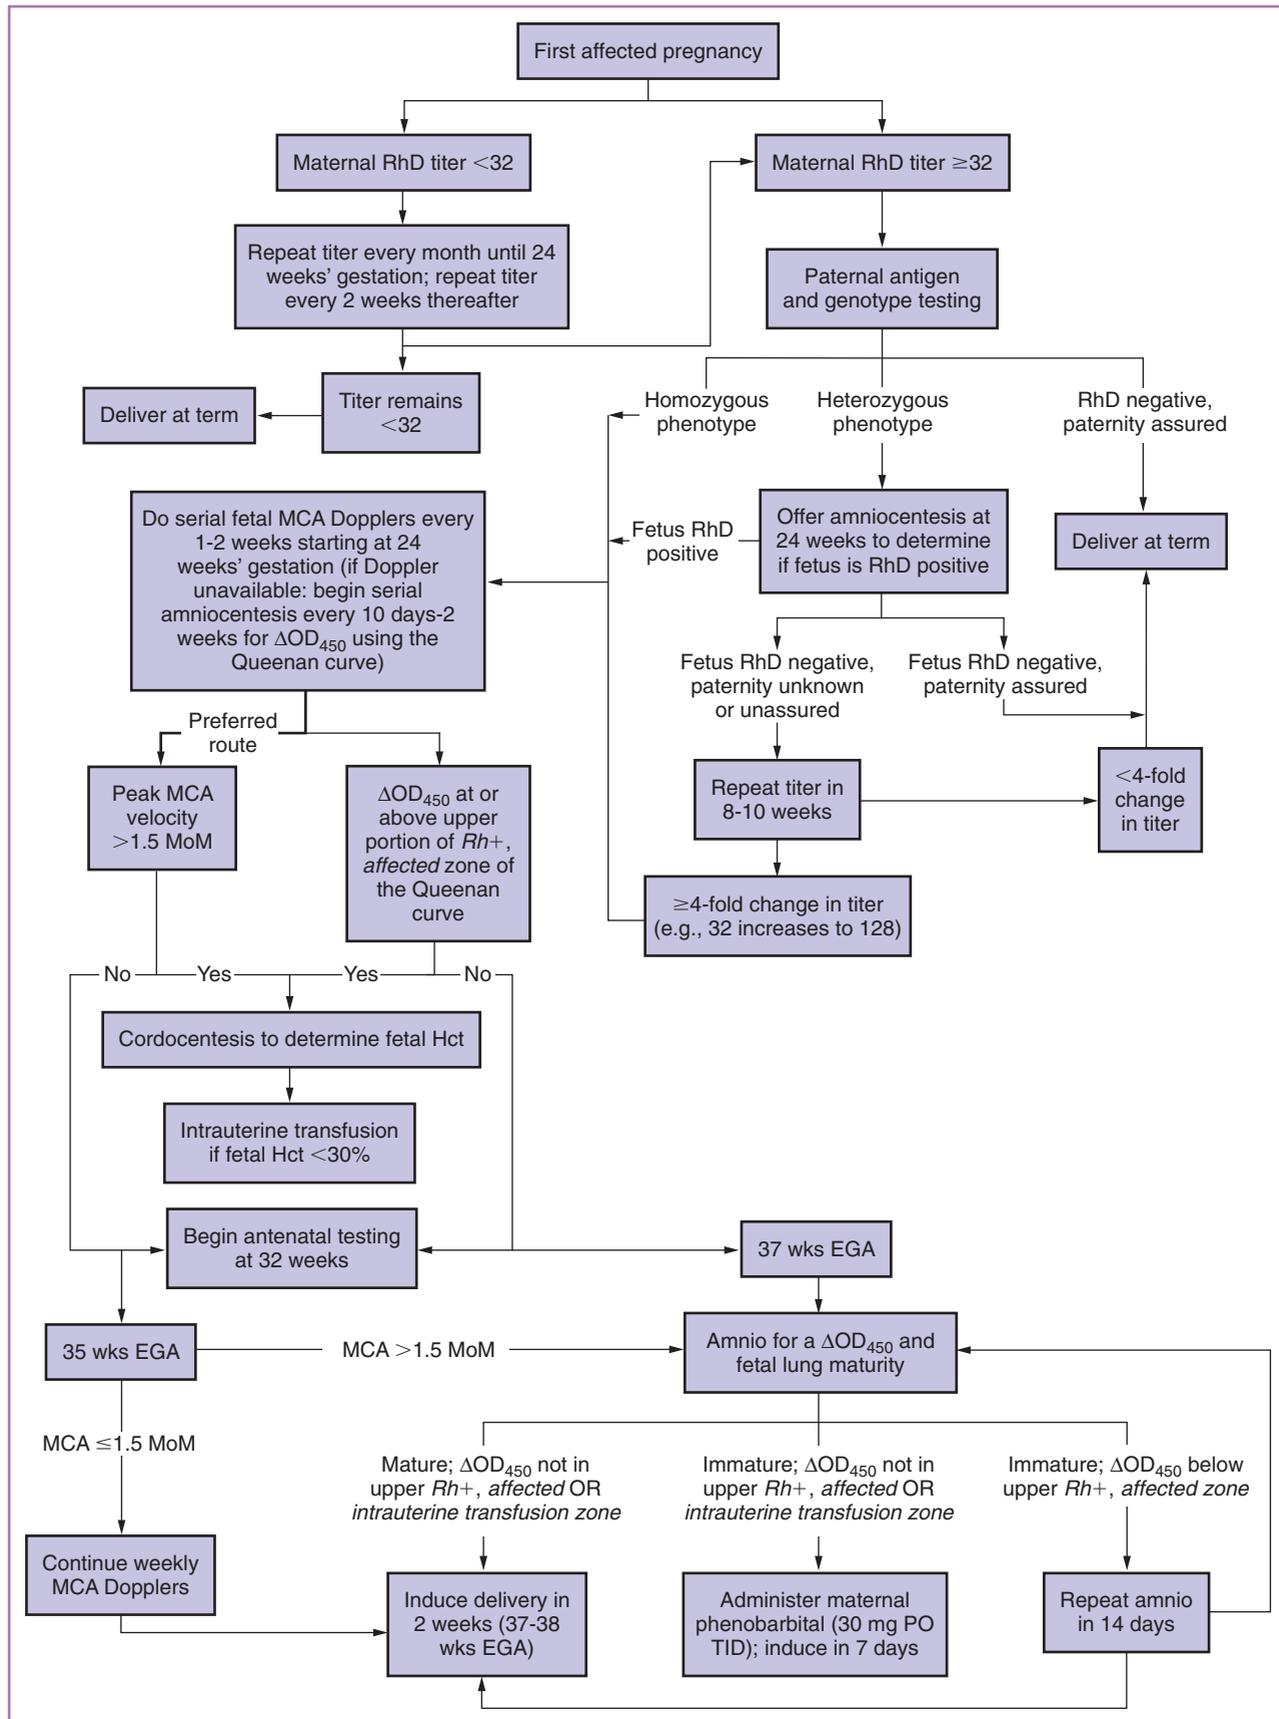

FIGURE 26-11 Algorithm for overall clinical management of the first red cell-sensitized gestation. For more information visit www.uptodate.com.)

Antenatal testing should be performed twice weekly, beginning at 32 weeks' gestation. At 35 weeks' gestation, serial weekly MCA Doppler assessments can be continued as long as they remain at less than 1.5 MoM. Induction at 37 to 38 weeks' gestation should be undertaken. If the MCA Doppler measurement is greater than 1.5 MoM at 35 weeks, amniocentesis for ΔOD_{450} should be considered because of the high false-positive rate of the Doppler measurement for detecting fetal anemia. If the ΔOD_{450} is below the upper portion of the RhD+ affected zone of the Queenan curve and fetal lung maturity is noted, labor should be induced in 2 weeks to allow time for hepatic maturity. If the ΔOD_{450} is at or above the upper portion of the RhD+ affected zone of the Queenan curve and fetal lung immaturity is present, treatment with 7 days of maternal phenobarbital (see Other Treatment Modalities) to enhance fetal hepatic maturity should be considered, with induction in 1 week. Finally, if the ΔOD_{450} is below the upper portion of the RhD+ affected zone of the Queenan curve and the fetal lungs are found to be immature, amniocentesis should be repeated in 2 weeks.

Previously Affected Fetus or Infant

If there is a history of perinatal loss related to HDFN, previous need for IUT, or previous need for neonatal exchange transfusions, the patient should be referred to a tertiary care center with experience in management of the severely alloimmunized pregnancy (Fig. 26-12). In these cases, maternal titers are not predictive of the degree of fetal anemia. In the case of a heterozygous paternal phenotype, an amniocentesis at 15 weeks' gestation to determine the fetal RhD status is indicated. The preferred method of surveillance is serial MCA Doppler measurements initiated at 18 weeks' gestation. If Doppler studies are not available at an otherwise experienced center, serial amniocenteses for measurement of ΔOD_{450} may be used, with the Queenan curve for reference values. If a rising value for peak MCA Doppler velocity greater than 1.5 MoM or a rising ΔOD_{450} value into the upper portion of the Rh+ affected zone of the Queenan curve is found, cordocentesis is recommended with blood readied for IUT if the fetal Hct is found to be less than 30%.

Intrauterine Transfusion ACCESS SITE

The cord insertion proximate to the fetal umbilicus should be avoided because vagal innervation is thought to be present, increasing the likelihood of fetal bradycardia. Weiner and coworkers⁸¹ also noted that puncture of the midsegment of the umbilical cord was associated with a 2.5-fold higher incidence of fetal bradycardia, compared with puncture at the placental insertion. Therefore, the cord insertion into the placenta is the preferred site for access. The vessel of interrogation should be the umbilical vein instead of one of the umbilical arteries. In one series of 750 diagnostic or therapeutic FBS procedures, the incidence of fetal bradycardia was 21% with puncture of the umbilical artery but only 3% with umbilical venous puncture.⁸¹ Several authors conjectured that this higher incidence of puncture may be the result of spasm of the muscularis of the umbilical artery. Other centers have advocated use of the intrahepatic portion of the umbilical vein in an effort to prevent fetal bradycardia. Nicolini and coworkers¹⁰⁰ reported a 2.3% incidence of fetal bradycardia using this approach in 214 procedures. These authors proposed that absence of the umbilical artery at the anatomic level of the intrahepatic vein explained their low incidence of fetal bradycardia. An additional advantage proposed by the authors was that blood loss from the cord puncture site would be minimized by absorption from the peritoneal cavity. Despite these theoretical advantages, IUTs using the intrahepatic vein have been

reported to be associated with an increase in fetal stress hormones (noradrenaline, cortisol, and β -endorphin).^{101,102} Similar changes in hormone levels were not detected when the cord/placental insertion was used as the site of transfusion. Puncture of the intrahepatic vein is technically more challenging than use of the placental insertion, predominantly because of fetal movement. The fetus must present with its spine toward the maternal back to allow access. Most centers in the United States therefore use the umbilical cord insertion into the placenta as the primary site of access for IUT. However, in cases of poor visualization, use of the intrahepatic vein is an option.

Direct cardiac puncture has been reported as a method of access for IUT. It has been associated with a high rate of fetal death, and therefore its use cannot be advocated. In one series of 158 cases of diagnostic cardiocentesis for the prenatal diagnosis of hemoglobinopathies, the corrected fetal loss rate was 5.6%, significantly higher than the 1% loss rate usually identified for FBS.¹⁰³

METHOD OF TRANSFUSION

Until the direct IVT was introduced in the mid-1980s, the IPT was the method of IUT for almost 20 years. With the advent of ultrasound-directed FBS, direct transfusion of cells into the umbilical circulation became the preferred method for IUT. Experience in hydropic fetuses indicated that the absorption of transfused red cells from the peritoneal cavity is compromised. Harman and colleagues¹⁰⁴ compared the direct IVT and IPT techniques, matching patients for severity of disease, placental location, and gestational age at the start of transfusions. Several important outcome differences were noted. When the fetuses were divided into nonhydropic and hydropic groups at the time of the first transfusion, a 13% greater survival was observed in nonhydropic fetuses for IVT compared with IPT; in the hydropic fetuses, the rate of survival was almost doubled with IVT. IVT resulted in fewer neonatal exchange transfusions compared with IPT and a shorter stay in the intensive care nursery. Direct IVT therefore has become the preferred method of transfusion of the anemic fetus (Fig. 26-13). Initial interest in performing the IVT by an exchange technique, much like neonatal exchange transfusions, waned after further experience with the direct IVT. It was soon realized that the fetus could tolerate large transfusion volumes because of the capacity of the placental vasculature to vasodilate. The IPT remains a practical method for delivery of red cells to the nonhydropic fetus if there is difficulty with access to the umbilical cord or intrahepatic umbilical vein. Bowman¹⁰⁵ proposed a formula for calculating the intraperitoneal transfusion volume that has withstood the test of time. The volume of red cells to be infused (in milliliters) is calculated by subtracting 20 from the gestational age in weeks and multiplying the result by 10. Blood in the peritoneal reservoir can be expected to be absorbed over a 7- to 10-day period.

Serial Hct values from fetuses transfused with IVTs alone revealed a marked decline between procedures of approximately 1% per day.¹⁰⁶ To avoid this problem, we investigated whether a combined IPT/IVT technique would result in a more stable fetal Hct between IUTs.¹⁰⁷ The technique involved administering enough packed red cells (Hct, 75% to 85%) by IVT to achieve a final fetal Hct of 35% to 40%; this was followed by a standard IPT. The hypothesis was that the intraperitoneal infusion of blood would serve as a reservoir, allowing the slow absorption of red cells between procedures and producing a more stable Hct. A combined direct IVT and IPT achieved a more stable fetal Hct compared with direct IVT alone, resulting in a decline in Hct of 0.01% per day between transfusions, versus 1.14% per day with direct IVT alone. Although these data suggest several theoretical advantages of a combined transfusion technique, most centers exclusively use the direct

IVT, citing the need for two punctures and prolonged procedure times as the disadvantages of a combined approach.

Data on IUTs in twin gestations are limited to case reports. In one series of nine pregnancies complicated by RhD alloimmunization, five required IUT.¹⁰⁸ In four of the five cases, the twins were dizygotic based on first-trimester ultrasound. In one case, only one fetus was RhD+, illustrating the need to sample each fetus for antigen testing. In one case of monozygotic gestation, the IUT of one fetus was quickly followed by movement of donor red blood cells through intraplacental anastomoses, as illustrated by a positive Kleihauer-Betke stain at the time of FBS of the second twin. In subsequent IUTs, the transfusion of only one member of the twin pair resulted in adequate levels of hemoglobin in both twins. Therefore, caution against overtransfusion should be observed in the monozygotic gestation. The intrahepatic portion of the umbilical vein may be the preferred target for vascular access when transfusing a twin gestation if the corresponding placental cord insertions are difficult to identify.

AMOUNT TO TRANSFUSE

The end point for the completion of an IUT varies considerably. Most centers use a target Hct to decide when a transfusion is completed. Advocates of direct IVT often transfuse to a final Hct value of 50% to 65%. This allows a reasonable interval between procedures based on a projected decline in Hct of 1% per day. However, caution should be exercised in transfusing the fetus to nonphysiologic values for Hct. Welch and coworkers¹⁰⁹ demonstrated that a marked rise in whole blood viscosity is associated with fetal Hct values greater than 50%. Centers that use a combined IVT/IPT technique usually choose a final target Hct of 35% to 40% for the intravascular portion of the procedure.

Several authors have proposed formulas to calculate the volume of red blood cells to be transfused. The method of Mandelbrot and coworkers¹¹⁰ requires calculation of the fetoplacental volume (mL)

TABLE 26-2 COEFFICIENT FOR CALCULATING VOLUME OF PACKED RED BLOOD CELLS NEEDED FOR INTRAUTERINE TRANSFUSION

from the ultrasound estimate of the fetal weight by multiplying the weight in grams by a factor of 0.14. The volume of red cells in milliliters to be transfused is then calculated by the following formula:

$$V_{\text{transfused}} = \frac{V_{\text{fetoplacental}} (\text{Hct}_{\text{final}} - \text{Hct}_{\text{initial}})}{\text{Hct}_{\text{transfused blood}}}$$

Giannina and coworkers¹¹¹ proposed a simpler method of calculating the volume of packed red cells needed for IUT. Assuming an Hct of approximately 75% for the donor unit, a series of transfusion coefficients were determined for raising the initial fetal Hct to a desired final value (Table 26-2). The operator simply multiplies the coefficient by the ultrasound estimation of fetal weight in grams to calculate the volume of the transfusion in milliliters needed to achieve the final desired fetal Hct. This practical approach is used exclusively at our center.

After the first IUT, subsequent procedures are scheduled at 14-day intervals until suppression of fetal erythropoiesis is noted on Kleihauer-Betke stain or fetal cell stain using flow cytometry. This usually occurs by the third IUT. Thereafter, the interval for repeat procedures (usually 3 to 4 weeks) can be determined based on the decline in Hct for the individual fetus.

The peak MCA velocity can be used to determine the transfusion interval.¹¹² In 64 fetuses that had undergone one IUT, a threshold for the MCA of 1.69 MoM yielded a sensitivity of 100% and a specificity of 94% for the prediction of severe fetal anemia (fetal hemoglobin <0.55 MoM) at the time of the second IUT. An MCA value of 1.32 MoM resulted in a sensitivity of 100% with a specificity of 63% in the ability to detect moderate anemia (fetal hemoglobin, 0.65 to 0.55 MoM). The rheology of the mixture of fetal and adult hemoglobins as a result of the transfused red cells would appear to make the peak MCA velocity less sensitive for the detection of moderate to severe fetal anemia. If MCA Doppler ultrasonography is used to time the second transfusion, a threshold of 1.32 MoM for the peak MCA should be used. Although serial monitoring with weekly MCA Doppler measurements may prove useful in timing the second IUT, the effectiveness of this technique in determining when to undertake subsequent transfusions should be questioned. In one series of 39 fetuses undergoing MCA peak Doppler measurements before a third IUT, a threshold value of 1.5 MoM failed to detect 5 cases of severe anemia and 4 of the 7 cases of moderate anemia.¹¹³

The Severely Anemic Early-Second- Trimester Fetus

The severely anemic fetus at 18 to 24 weeks' gestation presents a special challenge to the perinatologist. Often, technical limitations do not allow ready access to the fetal circulation through cordocentesis. Kilby and colleagues¹¹⁴ reported on six pregnancies with a history of severe fetal anemia and hydrops before 20 weeks' gestation; perinatal mortality was 60% with attempted IUTs. In the subsequent pregnancies, IPTs were initiated at 16 weeks' gestation until IVTs could be undertaken at 22 weeks; this approach resulted in perinatal survival in five of six cases. The severely anemic second-trimester fetus is less able to adapt to the acute correction of its anemia by IVT, resulting in a higher perinatal mortality rate. An increase of greater than 10 mm Hg in umbilical venous pressure at the conclusion of an IVT correctly predicted fetal death within 24 hours with a sensitivity of 80%.¹¹⁵ This finding may be the result of cardiac failure in these fetuses secondary to an acute change in viscosity associated with correction of the fetal Hct into the normal range. Radunovic and coworkers¹¹⁶ reported 37% mortality within 72 hours after IVT in fetuses presenting with severe anemia and hydrops. These authors recommended that, in the severely anemic fetus, the final post-transfusion Hct after IVT should not exceed a value of 25% or a fourfold increase from the pretransfusion value.

If severe anemia occurs in the fetus at less than 24 weeks' gestation, a stepwise progression in correction of the fetal Hct should be undertaken, using the fourfold rule for increase in Hct at the time of the first procedure. A repeat IVT is performed within 48 hours to correct the fetal Hct into the normal range; the third procedure is scheduled in 7 to 10 days. Thereafter, repeat transfusions are undertaken based on the results of fetal Hct and Kleihauer-Betke stain. If a combined procedure is used, an IPT should not be undertaken until there is resolution of fetal hydrops, owing to impaired absorption associated with this condition. A stepwise correction of the Hct in cases of severe fetal anemia after 24 weeks' gestation is rarely necessary, because these fetuses can compensate for an acute change in Hct into the normal range.

Adjunctive Measures

The safety of fetal transfusion is enhanced by the use of fetal paralysis during the procedure. Before this modification, fetal movement often resulted in injury to fetal viscera during IPT or umbilical cord damage during IVT. Fetal paralysis was first introduced by de Crespigny and colleagues¹¹⁷ in Australia. Initial use in the United States involved the intramuscular injection of D-tubocurarine into the fetal thigh under ultrasound guidance.¹¹⁸ Later, pancuronium bromide was used intravascularly.¹¹⁹ More recently, short-acting agents such as atracurium besylate and vecuronium bromide have been used.^{120,121} The latter agents do not appear to cause the fetal tachycardia and loss of short-term heart rate variability associated with pancuronium.¹²² A vecuronium dose of 0.1 mg/kg of the ultrasound-estimated fetal weight produces almost immediate cessation of fetal movement after intravascular injection at the start of the IUT. Fetal paralysis can be expected to last 1 to 2 hours. No untoward effects have been observed in neonates treated in this manner. In cases of anterior placentation, some centers do not routinely use fetal paralysis. Anecdotally, we have noted cord trauma resulting from fetal movement even in this scenario; therefore, we use vecuronium in all cases of IUT.

Prophylactic antibiotics have not been studied in association with IUT but are used by many centers. A broad-spectrum cephalosporin with coverage that includes gram-positive skin flora would appear to be appropriate.

Source of Red Blood Cells

Red cells used for IUT must undergo the same rigorous testing that occurs for any allogeneic donation. In the United States, this includes a written questionnaire that inquires about illicit substance abuse, high-risk sexual behavior, and travel outside of the continental United States. Serum testing for antibodies to syphilis, hepatitis B core antigen, human immunodeficiency viruses (HIV) types 1 and 2, hepatitis C virus, and human lymphotropic viruses types I and II, as well as testing for the p24 antigen of the HIV, the hepatitis B surface antigen, and alanine aspartate transferase, is undertaken. Additional testing by nucleic acid amplification for the HIV, hepatitis C virus, and West Nile virus is also done. In the United Kingdom, all donors are screened for the hepatitis B surface antigen and antibodies against HIV types 1 and 2, hepatitis C virus, and syphilis. In both countries, red cells to be used for IUT are often cytomegalovirus (CMV) seronegative or leukocyte reduced to decrease the risk of transmitting CMV. A fresh unit is preferred to stored blood, to enhance the level of 2,3-diphosphoglycerate. Standards in the United Kingdom require that red cells used for IUT have a shelf life of less than 5 days. A 1997 review reported that six cases of graft-versus-host reaction have been reported in infants who underwent IUT.¹²³ Bohm and colleagues¹²⁴ proposed that this was due to the induction of immune tolerance to engrafting lymphocytes that gained entry into the fetal circulation through large volumes of blood infused during IUTs. The standards of the British Blood Transfusion Task Force¹²⁵ and the American Association of Blood Banks¹²⁶ require that red cell units for IUT undergo γ -irradiation using 25 Gy to prevent graft-versus-host reaction. Leukodepletion is required in the United Kingdom. It is not routinely practiced in the United States but is often used to reduce CMV risk and will probably be universally accepted soon.

Maternal blood donation is an excellent source of red cells for IUT. In a series of 21 patients, up to six units of blood per patient were harvested for IUT.¹²⁷ No serious maternal or fetal effects were noted. Theoretical advantages to the use of maternal blood include a decreased risk for sensitization to new red cell antigens, a longer circulating half-life in the fetus because of the fresh source of cells, and a decreased risk for transmission of viral agents. Vietor and coworkers¹²⁸ investigated the source of new red cell antibodies in 91 patients undergoing 280 IUTs. Twenty-six percent of the women developed new antibodies. In 14 cases, the source of the sensitizing antigen could be determined; in one fifth of these cases, donor red cells carried the involved antigen. Therefore, it appears that the use of maternal blood as the source of red cells for IUT would theoretically prevent the development of new anti-red cell antibodies in 5% of cases.

In a study of the fetal effects of maternal red cells ($n = 76$) versus unrelated donor red cells ($n = 213$) for IUT,¹²⁹ the fetal Hct did not decline as rapidly when maternal red cells were used; however, this difference did not manifest until after 33 weeks' gestation. Infants who received maternal blood required fewer neonatal transfusions than those who received unrelated donor cells. The authors conjectured that this finding could be related to an increased maternal reticulocytosis that probably occurs secondary to repeated blood donation. Such reticulocytosis would result in a younger population of red cells with a longer half-life in the fetus. They concluded that maternal red cells were preferred over unrelated donor red cells because they offered the potential advantage of decreasing the total number of IUTs necessary for the treatment of a particular fetus. To date, no study has compared maternal versus unrelated donor red cells in regard to the risk of fetal viral infection.

In a maternal blood donation program, if IUTs are likely, the patient can donate a unit of red cells after the first trimester. The unit can be

separated into two smaller aliquots and refrigerated for up to 42 days. If not used by this time interval, the unit can then be frozen for use for up to 10 years. Patients should be supplemented with iron therapy (324 mg ferrous sulfate twice daily) and folate (1 mg daily) in addition to prenatal vitamins. The left lateral recumbent position should be used during the donation, and the donated volume should be replaced with isotonic intravenous fluids. Fetal monitoring during the procedure is unnecessary.¹³⁰ A standard volume of 450 ± 45 mL is taken, because subsequent processing will markedly reduce the final volume available for IUT. The blood is washed several times to remove the offending antibody present in any contaminating plasma. The use of maternal blood in the CMV-seropositive patient is controversial. Dormant CMV virus is noted to reside in the polymorphonuclear leukocytes. Both leukoreduction and washing have been demonstrated to be effective mechanisms to reduce transmission of CMV.¹³¹ For this reason, use of maternal CMV-seropositive blood, after careful counseling of the patient, can be considered. Finally, the use of ABO-incompatible maternal red cells for IUT has raised concern. With fetal typing now available at the first FBS, situations may arise in which the patient is found to be type A or B and the fetus is typed as O. We have used maternal blood in two such cases with no deleterious effects noted in the fetus. Follow-up at 3 years of age in one of these infants revealed anti-A and anti-B titers that were appropriate for age.

Timing of Delivery

Until the introduction of the direct IVT, fetuses were routinely delivered by 32 weeks' gestation. Hyaline membrane disease and the need for neonatal exchange transfusions for the treatment of hyperbilirubinemia were common. As experience with IVT became widespread, several centers began to question this policy of premature delivery. Klumper and colleagues¹³² compared perinatal mortality for IUTs undertaken before and after 32 weeks' gestation. Perinatal loss occurred in 3.4% of 409 early IUTs and in 1% of 200 procedures performed after 32 weeks' gestation. Most experienced centers now perform the final IUT at up to 35 weeks' gestation, with delivery anticipated at 37 to 38 weeks. This practice allows maturation of the hepatic enzyme systems, which virtually eliminates the need for neonatal exchange transfusions. After a viable gestational age is attained, performing the transfusion in immediate proximity to the labor and delivery suite and allowing the patient nothing by mouth in the preoperative period appear to be prudent measures, so that cesarean section can be undertaken if fetal distress should occur.

Outcome

Survival after IUT varies with the center, with experience, and with the presence of hydrops fetalis. Overall survival in one review was 84%; up to one fourth fewer hydropic fetuses survived with IUT (70%), compared with fetuses who underwent their first IUT when they were not hydropic (92%).¹³³ The experience of a single treatment center with 213 fetuses receiving 599 IUTs was very similar. Survival with any degree of hydrops was 78%, compared with 92% for nonhydropic fetuses.¹³⁴ The authors further classified hydrops as mild (only mild ascites) or severe (significant ascites with scalp edema and pericardial effusion or pleural effusion). Mild hydrops reversed in 88% of cases, whereas severe hydrops reversed in 39%, a finding clearly linked to overall perinatal survival: 98% of fetuses survived after reversal of hydrops. With persistent hydrops, 39% of fetuses survived; if the hydrops was severe and persisted, only one fourth survived.

Immediate follow-up studies of infants treated with IVTs in utero revealed a need for top-up transfusions in the early months of life. Typically, these infants are born with a virtual absence of reticulocytes

and a red cell population consisting mainly of transfused red cells containing adult hemoglobin. Exchange transfusions for hyperbilirubinemia are rarely necessary. However, at 1 month of age, these infants often require a simple transfusion because of symptoms associated with anemia. In our series of 36 infants who had undergone IUTs, 50% required top-up transfusions at a mean age of 38 days, with a range of 20 to 68 days.¹³⁵ Studies of these infants indicated erythroid hypoplasia of the bone marrow accompanied by low levels of circulating erythropoietin and reticulocytes.¹³⁶ This finding led Ovali and coworkers¹³⁷ to study the use of exogenous erythropoietin in neonates after IUTs. Twenty infants were randomized to receive 200 U/kg of recombinant human erythropoietin or saline placebo administered subcutaneously three times a week between the second and eighth week of life. Infants in the treatment group required a mean of 1.8 red cell transfusions, compared with a mean of 4.2 transfusions in the placebo group. Recovery of the neonate's bone marrow occurred earlier in the treatment group in control subjects.

Because of this phenomenon, neonatal Hct and reticulocyte determinations should be checked weekly until hematopoiesis recovers in infants who have undergone IUTs. Proposed criteria for transfusion of the infant vary and are usually described for premature infants. A more conservative approach was advocated by Maier and coworkers.¹³⁸ A threshold for transfusion is an Hct of less than 27% if the infant is asymptomatic, or less than 32% with symptoms. Shannon and colleagues¹³⁹ proposed a threshold value for Hct of less than 20% without symptoms or less than 30% in conjunction with symptoms. If erythropoietin is to be used, initiation in the first week of life in the infant with a persistent low circulating reticulocyte count may prove beneficial. Supplemental iron therapy is unnecessary because of the high levels of circulating iron in these infants secondary to ongoing hemolysis in utero. Supplemental folate therapy (0.5 mg/day) should be considered.

Investigations regarding the long-term neurologic evaluation of infants who have been treated with IUTs are limited. Hardyment and colleagues¹⁴⁰ reported a series of fetuses transfused with IPT between 1966 and 1975, when the survival rate was only 48%. Twenty-one of the 27 fetuses underwent evaluation, and evidence of cerebral palsy was found in 10%. Advancements in treatment techniques suggest that more moribund and severely anemic fetuses now survive. Doyle and coworkers¹⁴¹ evaluated 38 surviving infants at 2 years of age. They noted one case of cerebral palsy, one case of mild disability with a mental developmental index of 72, and one case of severe developmental delay associated with seizures. Comparison with a group of 51 randomly selected infants of normal birth weight who underwent a similar assessment at 2 years of age yielded no significant differences in the incidence of sensorineural outcomes. Janssens and coworkers¹⁴² studied 69 infants for 6 months to 6 years of age. Seven percent of the children exhibited some evidence of neurologic handicap; 4% were diagnosed with cerebral palsy. Sixteen percent of the children were noted to have developmental delay: six cases showed mild delay, and five others exhibited severe delay. The overall 10% rate of disability in their group was comparable with that in a cohort of normal Dutch children with 6% disability and a cohort of high-risk children with 12% disability. We observed 40 surviving infants for up to 62 months of age; only one case of spastic hemiplegia was detected. Gesell and McCarthy developmental scores were similar to norms for the general population.¹⁴³ Grab and colleagues¹⁴⁴ monitored 30 infants and noted mild sensorineural disabilities in 2. One infant exhibited delayed speech development at 24 months; the second had mild psychomotor developmental delay at 1 year that had resolved by 6 years of age.

Hearing loss in the neonate has been reported in association with high bilirubin levels. Because red cell destruction can lead to high levels of in utero bilirubin and elevated levels in neonatal life, HDFN could be associated with sensorineural hearing loss. Janssens and colleagues¹⁴² found that 14% of 58 children screened at 9 months had evidence of hearing loss. However, five of these cases were thought to be conductive in nature because of their association with middle ear or respiratory infection and the transient nature of the findings. Hudon and coworkers¹⁴³ tested 21 infants just before discharge. Two infants had mild peripheral sensitivity loss, with recovery noted in one at 5 months of age; the other child was lost to follow-up. A third child exhibited severe bilateral deafness. Based on these studies, it would appear that the prevalence of hearing loss is increased 5- to 10-fold over the general population in infants requiring in utero therapy for HDFN. Therefore, careful follow-up of these infants is warranted.

The issue of enhanced survival of the hydropic fetus and its relationship to long-term outcome was addressed in two investigations. Using a two-sample analysis, Janssens and coworkers¹⁴² found no correlation between either the presence of hydrops or the number of IUTs and poor neonatal neurologic outcome. Using a multivariate analysis, our group¹⁴³ could find no relationship between global developmental scores and the number of IUTs, the lowest fetal Hct, or the presence of hydrops. These data are reassuring in counseling couples with a severely anemic fetus. A normal neurologic outcome can be expected in more than 90% of surviving infants, even if hydrops fetalis is noted at the time of the first IUT.

Other Treatment Modalities

Plasmapheresis

Plasmapheresis has been relegated to an historical treatment modality for HDFN since the advent of modern IUT techniques. Most literature reports include single cases or relatively small case series. Reported protocols vary considerably, but all involve repeated procedures because of a rebound increase in antibody titer. In animal studies, Bystryn and coworkers¹⁴⁵ experimentally lowered antibody levels by exchange transfusion. Antibody levels were noted to rebound to more than 200% of the initial levels, with the greatest increase (50% to 80%) seen in the first 48 hours. Most reports suggested starting plasmapheresis after 12 weeks of gestation. This approach seems reasonable in view of the documented transplacental passage of up to 60% of maternal IgG1 and 30% of IgG3 antibodies by this period of gestation.¹⁴⁶ The plasma that is removed requires replacement; saline, plasma protein fraction, Rh- plasma, and albumin have all been used. With modern concerns regarding viral transmission through blood products, 5% albumin would seem to be the preferred fluid. Automated cell separators are now routinely used for the procedure, with citrate being used in the machine's extracorporeal circuit to prevent coagulation. Angela and coworkers¹⁴⁷ reported a 15% incidence of complications among 261 procedures in pregnant women. These included delayed vertigo, headache, allergic reaction to plasma, peripheral edema, and syncope; 10 cases involved mild citrate toxicity. The latter is usually heralded by circumoral paresthesia and can be treated with oral calcium. In some cases, intravenous calcium gluconate is required at the conclusion of the procedure.

Intravenous Immune Globulin

Intravenous immune globulin (IVIG) has been used effectively as the sole antenatal treatment for HDFN. In the largest series reported to date, Margulies and coworkers¹⁴⁸ described the use of IVIG without

IUTs in 24 patients with severe rhesus disease. The study population represented a high-risk group, with more than half the patients having experienced a fetal or neonatal death in a previous pregnancy and 12% having had two or more perinatal losses. All patients in the series were noted to have an RhD+ fetus, three having undergone FBS because of a heterozygous paternal genotype. Patients received a total dose of 2 g/kg IVIG administered over 4 consecutive days (400 mg/kg/day); the dose was repeated at 2- to 3-week intervals throughout the pregnancy. The patients were divided into three groups based on gestational age at the initiation of IVIG therapy: less than 20 weeks' gestation, 20 to 28 weeks' gestation, and more than 28 weeks' gestation. There was a total of three fetal losses in groups 1 and 2; all three fetuses were noted to be hydropic at the start of therapy. There were no neonatal deaths, yielding a perinatal survival rate for the series of 88%. Half the neonates in group 1, one third of those in group 2, and 88% of those in group 3 required exchange transfusions, leading the authors to conclude that IVIG is not effective if initiated after 28 weeks' gestation. Interestingly, the maternal anti-D titers declined in all three groups, although this difference was not statistically significant in group 2.

In a follow-up case-control study of 69 patients, this same group of investigators compared the outcomes of pregnancies treated with IVIG before 20 weeks' gestation followed by IUT versus the use of only IUTs after 20 weeks.¹⁴⁹ Again, the study group represented cases of severe rhesus alloimmunization, in that 73% of the IVIG group and 56% of the IUT group had experienced previous perinatal losses. Significant differences were noted between the groups. Hydrops at the first IUT occurred in one fourth of the IVIG/IUT group, compared with three fourths of the IUT-alone group. The first IUT was performed a median of 1.5 weeks later in those patients who had received IVIG. Fetal death was 2.5-fold more likely in the IUT-only group (51% versus 20%). Neonatal death occurred in 8% of the IVIG-IUT group and in 21% of the IUT-only group, although this difference did not achieve statistical significance.

The mechanism of action of IVIG in cases of severe HDFN is not well understood. At least three different theories for its effect have been postulated: decreased production of maternal anti-red cell antibodies, decreased placental transport of antibodies, and fetal reticuloendothelial blockade. Dooren and coworkers¹⁵⁰ randomized 20 patients to receive either IVT alone or IVT in conjunction with direct fetal infusion of IVIG. No significant differences in transfusion requirement or clinical outcome could be demonstrated between the two groups. However, the average fetal IVIG dose of 85 mg/kg was fairly low compared with the 500-mg/kg dose usually used to treat neonatal HDFN.¹⁵¹ In a case report, Alonso and coworkers¹⁵² used between 406 and 481 mg/kg of IVIG and administered this directly to the fetus on four occasions at the time of FBS. Fetal Hct increased and ΔOD_{450} values decreased with advancing gestation. To further elucidate the protective mechanism of IVIG, one investigation compared six pregnancies treated with maternal IVIG with seven control sensitized pregnancies that were monitored only with serial FBS.¹⁵³ No obvious inhibitory effect on transplacental passage of anti-D or on maternal anti-D production was noted. Finally, Besalduch and colleagues¹⁵⁴ reported a case in which IVIG was used in a patient with early hydrops fetalis secondary to anti-E alloimmunization. These authors used a pepsin-treated preparation resulting in a purified IgG product with loss of Fc receptors. Fetal hydrops and hepatosplenomegaly were noted to resolve with repeated IVIG administration. The authors postulated that the effectiveness of the IVIG in their case was related to suppression of maternal antibody levels, because their product could not have crossed the placenta owing to the lack of Fc receptors.

Yu and Lennon¹⁵⁵ proposed a mechanism to explain the potential ability of IVIG to cause the accelerated catabolism of circulating anti-red cell antibodies. An intracellular Fc receptor abundant in endothelial cells normally binds the IgG that has entered the cell through pinocytosis and presents it to the surface of the cell for release back into the microcirculation. In cases of excess circulating IgG secondary to IVIG, the protective intracellular Fc receptors become saturated, allowing accelerated catabolism of free IgG molecules that enter the endothelial cells. These data would lead one to conclude that multiple mechanisms may contribute to the effectiveness of IVIG. Although the primary effect may be suppression of the level of maternal antibody, a fetal reticuloendothelial blockade may also be involved.

Combined Plasmapheresis and Intravenous Immune Globulin

Berlin and coworkers¹⁵⁶ used a combined plasmaphereses/IVIG approach when problems with continued venous access precluded continued plasmaphereses in a patient with severe anti-D alloimmunization. A total of 10 L of plasma was exchanged over 4 days at 25 weeks' gestation. This was followed by an IVIG dose of 0.4 g/kg/day over 5 consecutive days. Ruma and associates¹⁵⁷ reported on a series of nine patients treated with a combined plasmapheresis/IVIG protocol. Among the seven women with a previous history of a perinatal loss, a live birth was achieved in all treated cases. Their protocol included a single-volume plasmapheresis every other day for three procedures in the 12th week of gestation, with 5% albumin used for volume replacement. The IgG pool was replaced after the third procedure by administering a 1 g/kg loading dose of IVIG diluted in normal saline. The 10% IVIG infusion was started at a rate of 60 mL/hr and increased by 30 mL/hr every 30 minutes to a maximum rate of 240 mL/hr. A second dose of 1 g/kg IVIG was given the following day. The patients were then treated with a weekly dose of 1 g/kg IVIG until 20 weeks' gestation. All patients eventually required IUT therapy.

Typical side effects encountered during IVIG administration include urticaria and severe headache.¹⁵⁸ Premedication with 1000 mg of oral acetaminophen several hours before the scheduled infusion and administration of 25 mg of intravenous diphenhydramine HCl just before treatment aids in preventing these symptoms. In some situations, a change to a different manufacturer results in fewer headaches in some patients. On occasion, patients complain of a mild desquamation of the palmar surface of the hands; the cause of this phenomenon is unknown.

In the case of a heterozygous paternal genotype, an amniocentesis is undertaken at 15 weeks' gestation using DNA techniques to determine the fetal red cell antigen status. If the fetus is found to be antigen negative, the IVIG is discontinued. Standard noninvasive or invasive fetal testing is used to determine the timing of the first IUT in the case of a homozygous paternal phenotype or an RhD+ fetus by amniocentesis. In our experience, this approach is successful in deferring the need for the first IUT until approximately 24 to 26 weeks' gestation.

Oral Tolerance

Studies to date attempting oral desensitization to red cell antigens have revealed conflicting results. In 1979, Bierme and associates¹⁵⁹ investigated the use of oral RhD antigen in seven severely alloimmunized women. All previous pregnancies had resulted in intrauterine death, even though IUTs were used in four cases. RhD titers were noted to remain stable in all cases. In some cases, a new anti-Rh class of antibody appeared, of the IgM or IgA variety. In six of the seven treated cases, an RhD+ infant was born at 35 weeks' gestation in good condi-

tion. In an attempt to duplicate these results, American investigators treated four patients with RhD alloimmunization who had a history of severe HDN with oral erythrocytes using the method of Bierme and associates.¹⁶⁰ All four cases resulted in either fetal or neonatal death; hydrops fetalis was noted in all cases. In a rebuttal letter to the editor, Bierme's group reported on a larger series of 16 pregnancies that resulted in 12 live births using oral erythrocyte therapy in conjunction with oral promethazine.¹⁶¹ The authors proposed that a therapeutic trial should be undertaken.

Three years later, Barnes and coworkers¹⁶² conducted a scientific investigation to study the effects of oral erythrocyte membrane therapy in the nonpregnant patient. Six previously sensitized women were administered a 2-g/day dose of a lyophilized preparation of erythrocyte membranes for 4 weeks. Half of the patients received an erythrocyte preparation made from RhD- red cells, and half received RhD+ red cell preparations. In three subjects, there was no change in antibody levels; in the remaining three, there was a clear elevation in antibody titers. Two of these three had received RhD+ oral antigen. These findings led the authors to conclude that their oral preparation was not tolerogenic but in fact immunogenic. No further reports can be found in peer-reviewed literature regarding this therapy, because it appears to have been abandoned as a potential treatment with the advent of more effective methods of IUT.

Chemotherapeutic Agents

In vitro, promethazine interferes with the ability of human fetal macrophages to phagocytize red cells coated with anti-RhD antibodies.¹⁶³ This finding led several investigators to use this agent in an effort to ameliorate the effects of maternal anti-red cell antibodies in HDFN. Gusdon and associates¹⁶⁴ treated 72 patients with RhD alloimmunization with promethazine, 3.7 to 5.0 mg/kg/day divided in four doses beginning as early as 14 weeks' gestation. The lower dose was used in patients with their first affected pregnancy, whereas the highest dose was used in patients with a history of previous IUTs or fetal death. When compared with previous pregnancy, there was a marked improvement in outcome. Three perinatal deaths occurred in the pregnancies treated with promethazine, compared with eight deaths in previous pregnancies. The infants in 28% of the treated pregnancies required neonatal exchange transfusion, whereas 44% needed neonatal exchange transfusion in the previous pregnancies in these patients. A similar investigation in 21 pregnancies was undertaken,¹⁶⁵ giving a general impression that promethazine was not beneficial in view of the continued need for IUTs. However, a therapeutic effect was possibly seen in some gestations in women with previous neonatal death.

Steroids have been proposed as a treatment for HDFN, but no case series have been published.¹⁶⁶ Agents such as betamethasone and dexamethasone cross the placenta and have been associated with decreases in ΔOD_{450} .¹⁶⁷ However, these changes have not been associated with a decrease in the severity of HDFN but instead are probably related to alterations in fetal bilirubin metabolism.¹⁶⁶

Antenatal treatment with maternal phenobarbital has been proposed as a method to decrease the need for neonatal exchange transfusions for hyperbilirubinemia. This agent has been shown to enhance the neonatal hepatic capacity to conjugate and eliminate bilirubin through stimulation of glucuronyl transferase. Trevett and colleagues¹⁶⁸ retrospectively evaluated 71 pregnancies that had been treated with serial IUTs; 31 of these were treated with 30 mg of oral phenobarbital three times daily for the last 7 to 10 days before anticipated delivery. The need for any neonatal exchange transfusion was 9% in those cases treated with phenobarbital, compared with 52% in those not receiving the drug. After controlling for confounding variables, maternal phe-

nobarbital treatment was associated with a 75% reduction in the need for neonatal exchange transfusions.

Sensitization to Paternal Leukocyte Antigens

In vitro data and clinical case reports suggest that maternal alloantibodies to paternal leukocytes may result in an Fc blockade, thereby protecting the fetal red cells from hemolysis in cases of RhD alloimmunization. Neppert and coworkers¹⁶⁹ reported that human sera with human leukocyte antigen (HLA)-A, -B, -C, and -DR antibodies inhibited the binding activity and phagocytosis of monocytes. The authors proposed that this inhibitory effect of maternal anti-HLA antibodies on the fetal reticuloendothelial system may explain the lack of clinical disease in cases of HDFN with a strongly positive direct Coombs finding at birth.¹⁷⁰ Dooren and coworkers¹⁷¹ studied 12 cases of RhD alloimmunization in which the ADCC assay predicted severe fetal disease but the neonatal clinical course was instead benign. When donor monocytes were replaced in the assay by paternal cells (monocytes that should share HLA antigens with the neonate), seven of the repeat assays revealed lack of lysis of the sensitized red cells. Six of these seven cases involved maternal monocyte-reactive antibodies of the paternal HLA-DR specificity. Three reports of clinical cases have appeared in the literature in which maternal HLA antibodies were thought to be the explanation for the mild clinical course in HDN.^{172,173} In two cases, the specificity of the maternal antibody was HLA-DR, whereas in the remaining case the antibody was directed against the HLA-A10 and -DR13 antigens. Data suggest that these alloantibodies prevent the binding of anti-D-sensitized fetal red cells to FcγR-bearing splenic phagocytes, thus reducing the severity of HDN.^{174,175}

We showed in a rabbit model for HDFN that alloimmunization to paternal leukocytes produces fetal hemoglobin levels that approach normal in does previously sensitized to red cells.¹⁷⁶ Limitations of this method of treatment for severe red cell alloimmunization are substantial. In human trials, any contamination of the paternal leukocytes with red cells could produce a substantial anamnestic effect in the maternal antibody titer. Maternal sensitization to paternal HLA antigens could produce alloimmune thrombocytopenic purpura in the fetus or neonate.

Nasal Tolerance to the RhD Antigen

Hall and associates¹⁷⁷ developed transgenic mice for the human HLA-DR15 gene and then immunized them to purified human RhD protein. Four candidate peptides were developed that represented significant epitopes for helper T cells; these were then administered intranasally to the immunized mice. A blunted antibody response was noted when the mice were rechallenged with the purified RhD protein. It is confirmed in subsequent human clinical trials, such therapy may prove useful in the treatment of the severely alloimmunized pregnant patient.

Hemolytic Disease of the Fetus and Newborn Caused by Non-RhD Antibodies

More than 50 different red cell antigens have been reported to be associated with HDFN (Table 26-3). However, the antibodies frequently associated with severe HDFN appear to include those against RhD, Rhc, and Kell (K1). In a series from Manitoba, Canada, encompassing the years 1962 to 1988, 1022 cases of non-RhD

From Issitt PD, Anstee DJ: Hemolytic disease of the newborn. In Issitt PD, Anstee DJ (eds): *Applied Blood Group Serology*. Durham, NC, Montgomery Scientific Publications, 1998, p 1045; Daniels G: Blood group antibodies in haemolytic disease of the fetus and newborn. In Hadley A, Soothill P (eds): *Alloimmune Disorders in Pregnancy: Anaemia, Thrombocytopenia, and Neutropenia in the Fetus and Newborn*. Cambridge, UK, Cambridge University Press, 2002, p 21.

alloimmunization were accumulated.¹⁷⁸ Only anti-c was associated with severe HDFN that ended in a hydropic stillbirth or necessitated IUT. Anti-c resulted in twofold and sevenfold greater incidence of hemolytic disease compared with anti-K1 and anti-E antibodies, respectively. Anti-c and anti-K1 antibodies were equally likely to be associated with the need for neonatal exchange transfusion or phototherapy; anti-E was half as likely to require neonatal treatment. A selected population of 22 patients was referred from outside Manitoba during the same time period.¹⁷⁸ Antibodies against the following antigens were associated with the need for IUTs: K1 ($n = 9$), k (1), c (7), cE (1), Fy^a (1), Jk^a (1), CC^w (1), and E (1). In a series of 258 pregnancies managed with IUTs at a single national referral center in the Netherlands from 1988 to 2001, 85% of cases involved RhD alloimmunization.¹³⁴ Ten percent of cases involved anti-K1, and 3.5% involved anti-c; anti-RhE, anti-Rhe, and anti-Fy^a were each associated with a single case.

Antibodies to the red cell antigens Lewis, I, and P are often encountered through antibody screening during prenatal care. Because these antibodies are typically of the IgM class, they are not associated with HDFN.¹⁷⁹

Rhesus

Anti-Rhc

Anti-c antibody has been associated with severe HDFN of a similar magnitude to that caused by anti-D. In one series, more than half of pregnant patients had a history of a previous blood transfusion.¹⁸⁰ These authors reported a series of 177 pregnancies with 1 neonatal death secondary to hydrops and 11 other infants requiring exchange transfusions. Wenk and associates¹⁸¹ reported 70 cases of maternal alloimmunization to Rhc with a known c-antigen-positive infant. Eight cases resulted in hydropic stillborns or perinatal deaths, 26% of cases had mild HDFN and did not require transfusions after birth, and an additional 29% had moderate HDFN requiring transfusion therapy. Kozlowski and coworkers¹⁸² reported that, among 100 c-antigen-positive neonates born to alloimmunized parturients, only one pregnancy required IUTs, whereas 14% of the infants required neonatal exchange transfusions. Finally, Hackney and colleagues¹⁸³ found that 25% of c-antigen-positive fetuses exhibited severe HDFN; 7% of the total group were hydropic, and 17% required IUTs.

Anti-RhC, -RhE, and -Rhe

Antibodies against the rhesus antigens C, E, and e are usually found as a low titer in conjunction with anti-RhD antibody (for example, anti-D, 128, with anti-C, 2). Their presence may be additive to the hemolytic effect of the anti-D on the fetus.³³ IUTs are only rarely reported when these antibodies occur as the sole finding.^{134,184} Joy and coworkers¹⁸⁵ reported 32 pregnancies alloimmunized exclusively to RhE. Fifteen percent of offspring were noted to have evidence of fetal or neonatal anemia; one fetus presented with hydrops fetalis.

Anti-RhG

In some patients, the anti-D and anti-C titers are observed to be equal; alternatively, the value of the anti-C titer may actually exceed that of the anti-D (for example, anti-D, 128, with anti-C, 256). In these cases, one should suspect the presence of anti-RhG. Consultation with a blood bank pathologist should be undertaken to clarify whether anti-RhG is present. Previous case reports have indicated that anti-G is associated with mild HDFN; however, a high titer can be associated with significant fetal disease necessitating IUT.¹⁸⁶ Importantly, if in-

sive fetal procedures are indicated, RhIG should be administered to prevent the formation of anti-D.

Kell

The Kell red cell antigen system includes 23 different members. Individual antigens in the system are designated by name, letter abbreviation, or number. Antibodies to at least nine of the antigens have been associated with HDFN. The most common of these are Kell (K, or K1) and Cellano (k, or K2). Additional antibodies that have been reported to be causative for HDFN include anti-Penny (Kp^a, or K3), -Rautenberg (Kp^b, or K4), -Peltz (Ku, or K5), -Sutter (Js^a, or K6), -Matthews (Js^b, or K7), -Karhula (U1^a, or K10), and -K22.¹⁸⁷

Anti-K (K1)

The K1 antigen is found on the red cells of 9% of whites and 2% of blacks, with virtually all antigen-positive individuals being heterozygous (Table 26-4). Kell antibody was detected in 127 of 127,076 pregnancies in one series, yet, because of the low gene frequency, only 13 cases resulted in Kell+ fetuses.¹⁸⁸ Hydrops fetalis was noted in four cases; three of these infants suffered in utero or neonatal death. Bowman and colleagues¹⁸⁹ reported a 46-year experience of 459 Kell-alloimmunized pregnancies in 311 women. Fourteen percent of these pregnancies ended in spontaneous or induced abortion, 82% resulted in Kell- infants or infants with no recorded clinical disease, and the remaining 4% were affected. Among these last 20 infants, there was 1 neonatal death, and 3 fetuses with hydrops died in utero. In a referral series of 16 pregnancies that occurred between 1970 and 1985, the authors reported a perinatal mortality rate of 67% before the advent of IVT, compared with a rate of 10% after this technique began to be used.

Berkowitz and colleagues¹⁹⁰ described a case of Kell alloimmunization with a maternal titer of 2048. Amniocenteses at 20 and 21 weeks revealed a declining trend in the ΔOD_{450} values; however, a hydropic fetal death was noted at 24 weeks' gestation. Amniocentesis at that time revealed a ΔOD_{450} value lower than the previous ones. These findings led the authors to conclude that ultrasound detection of fetal hydrops could be a better predictor of fetal deterioration than amniotic fluid bilirubin. Four years later, Caine and Mueller-Heubach¹⁸⁸ reported on three cases of poor perinatal outcome, with fetal hydrops in two cases and one neonatal death. ΔOD_{450} values 1 week before delivery were noted to be in upper zone 2 of the Liley curve. In a matched comparison, Vaughan and coworkers³⁴ noted lower amniotic fluid bilirubin levels in Kell-alloimmunized pregnancies compared with pregnancies complicated by RhD alloimmunization. They suggested that, for this reason, serial amniocenteses were not a reliable method of management of the Kell-alloimmunized pregnancy. In a similar matched comparison, Weiner and Widness³⁵ noted that Kell-affected fetuses exhibited a lower total serum bilirubin concentration than their RhD counterparts. These authors suggested that serial FBS, rather than ΔOD_{450} analysis, would appear to be the preferred method for monitoring the pregnancy complicated by Kell alloimmunization.

Bowman's group¹⁸⁹ suggested that ΔOD_{450} values are still useful in the management of the Kell-alloimmunized pregnancy. Twelve Kell+ fetuses were monitored with amniocenteses. Two cases involved hydropic losses at 21 and 24 weeks after a previous low or mid-zone 2 reading. Combining these results with the ΔOD_{450} values in the Kell- fetuses, the authors suggested an 83% to 89% accuracy for serial amniocenteses, compared with an accuracy of 95% cited for rhesus disease. They recommended use of a ΔOD_{450} value greater than 0.15 before 20 weeks' gestation and a subsequent value in excess of the 65th

TABLE 26-4 GENE FREQUENCIES AND ZYGOSITY FOR NON-RhD RED CELL ANTIGENS ASSOCIATED WITH HEMOLYTIC DISEASE OF THE NEWBORN

percentile of zone 2 of the Liley curve as the threshold to initiate FBS and suggested that a critical maternal titer of 8 be used, instead of 16 or 32, as the threshold for initiating serial amniocenteses.

Use of the peak MCA systolic velocity has proved successful for the detection of fetal anemia in cases of K1 alloimmunization. Van Dongen and colleagues¹⁹¹ reported on 27 pregnancies complicated by Kell alloimmunization; 17 fetuses were noted to have severe anemia at the time of cordocentesis. A peak MCA of greater than 1.5 MoM yielded an 89% sensitivity and specificity (false-positive rate, 1%) for detecting the subgroup with anemia. When those fetuses with ultrasound evidence of hydrops were excluded, the sensitivity and specificity for the detection of severe anemia was unchanged. Similarly, Rimon and coworkers¹⁹² observed eight fetuses that were documented to be K1+ by amniocentesis and at risk for severe HDFN. They were successful in detecting all cases of severe anemia with weekly MCA Doppler assessments.

Management of the K1-sensitized pregnancy should entail paternal red cell typing and genotype testing. If the paternal typing returns a K1- genotype (*kk*) and paternity is assured, no further maternal testing is undertaken. If paternal testing reveals a positive result, maternal titers of less than 4 should be reassessed monthly until a critical value of 8 is attained. At that time, if the paternal genotype is heterozygous, amniocentesis for DNA typing of the fetus should be offered after 15 weeks' gestation, because 50% of fetuses will be unaffected. Paternal blood should be studied simultaneously with amniotic fluid, using the same PCR primers, to assess for the accuracy of the technique. However, cases of gene rearrangements in the Kell gene have not been reported to date. If the fetus is found to be K1-, no further fetal or maternal testing is warranted. In the case of a homozygous paternal genotype or a K1+ fetus, serial MCA Doppler measurements are repeated every 1 to 2 weeks starting at 18 weeks' gestation. An elevated value of more than 1.50 MoM is followed by FBS with blood readied for IUT.

Anti-k (K2)

Bowman and colleagues¹⁹³ reviewed 20 years of antibody screening of approximately 350,000 pregnancies in a Manitoba population and detected only 1 case of anti-k alloimmunization. Levine and col-

leagues¹⁹⁴ reported the first case of HDN secondary to anti-k, which resulted in a mildly affected infant; this was followed by the report of a second mild case by Bryant.¹⁹⁵ Additional individual cases of HDN have required treatment with a single neonatal exchange transfusion, a single simple neonatal transfusion, and a simple neonatal transfusion followed by a top-up transfusion for delayed neonatal anemia.^{193,196,197} A sixth case referred to Bowman's group¹⁹³ required three IUTs beginning at 30 weeks' gestation. The maternal titer was noted to be 16. In the second case reported from their institution, the maternal anti-globulin titer was 8. These findings led these investigators to surmise that anti-k antibody, analogous to anti-K1 antibody, may produce fetal erythropoietic suppression at lower maternal titers than are typically used for a critical value in cases of anti-RhD.

MNS

The MNS system consists of 40 red cell antigens, with antibodies to the M, N, S, s, and U antigens representing the members of this group that have been more commonly associated with HDFN. The M and N antigens can be expressed simultaneously on the glycophorin A molecule, or they can be expressed alone. The S, s, and U antigens are expressed on the glycophorin B molecule in various combinations. In most cases, the paternal genotype is positive for antigen, with most genotypes being heterozygous (see Table 26-4).

Anti-M

Anti-M is a naturally occurring IgM antibody that typically presents as a cold agglutinin. An IgG type can occur rarely and can be associated with HDFN. A total of six patients with severe HDFN have been reported in the English literature. The first case involved a maternal anti-M albumin titer of 1000 in association with a hydropic fetal death in one twin and the need for exchange transfusions in the sibling.¹⁹⁸ A second patient with a titer of 2048 was noted to have a history of four fetal deaths.¹⁹⁹ Matsumoto and colleagues²⁰⁰ reported a patient who had experienced three fetal losses in conjunction with a maternal anti-M titer of 1024. Furukawa and coworkers²⁰¹ reported a patient with a history of three perinatal losses. A successful outcome was achieved in

a fourth pregnancy after intensive plasmapheresis to treat a titer of 4096; the infant required only phototherapy. Duguid and coworkers²⁰² described a patient with a titer of 16 who gave birth to a child requiring phototherapy and exchange transfusion. Kanra and colleagues²⁰³ investigated a patient who had experienced seven pregnancies with losses occurring between 10 and 33 weeks' gestation secondary to in utero or neonatal death; five of these pregnancies were associated with hydrops fetalis. A maternal anti-M titer of 512 was detected, although little information is available regarding the evaluation of the neonates.

De Young-Owens and colleagues²⁰⁴ reviewed a 26-year experience at their institution and noted an anti-M antibody in 115 pregnancies in 90 women. They reported a threefold to sevenfold increased incidence of detection over the course of the study period; anti-M comprised 10% of all pregnant patients with a positive antibody screen. Explanations offered for the increasing frequency included a change in antibody screening technique from albumin to ethylene glycol and the addition of indicator red cells homozygous for the M antigen to their red cell screening panel. The antiglobulin titer was less than 4 in 90% of cases. In five cases, there was more than a two-tube increase in titer. However, the fetuses were noted to be negative for the M antigen in four of these five cases; in the fifth case, the M antigen status of the fetus was unknown. In 42 cases of antigen-positive fetuses, there was no increase in maternal titer. Clinical outcome for the fetuses revealed minimal disease. Of the 70 infants who tested positive for the M antigen, only 17% had a positive direct Coombs test at birth. Only one of these infants required phototherapy. In that case, the maternal anti-M antibody titer was 1, and the finding of a neonatal 3+ direct Coombs result was believed to be related to an ABO incompatibility. Four additional infants required phototherapy; all had negative direct Coombs testing and were associated with a maternal titer of less than 2. The authors proposed that prematurity accounted for the need for phototherapy, because all four infants were born at less than 36 weeks' gestation.

These data led De Young-Owens and coworkers²⁰⁴ to conclude that, if there is no previous history of an affected pregnancy, an initial titer of 4 or less requires no further evaluation. If the titer is greater than 4 or there is a history of a previously affected fetus or infant, serial titers should be obtained. Bowman¹⁷⁸ recommended amniocentesis for ΔOD_{450} assessment if the indirect Coombs titer is 64 or higher. At our center, we elected to use serial maternal titers until a value of 32 is reached. Consultation with the transfusion service is then obtained to determine whether the antibody class is predominantly IgM or a combination of IgM and IgG.²⁰⁵ This can be accomplished by treating the serum with dithiothreitol or 2-mercaptoethanol. These agents disrupt the disulfide bonds between the components of the pentamer structure of the IgM molecule, thereby abolishing its agglutinating and complement-binding properties. Serum treated with dithiothreitol containing only an IgM antibody exhibits a loss of reactivity and a subsequent negative titer. Serum containing a mixture of IgM and IgG antibody exhibits a decrease in the original titer. Once the IgG component of the titer reaches 32, we proceed with serial MCA Doppler assessments. If the paternal genotype is heterozygous, fetal typing using PCR techniques on amniotic fluid is available for the M antigen (M. J. Hessner, personal communication, The Blood Center of Wisconsin), using a technique previously described by Corfield and colleagues.²⁰⁶

Anti-S

In one series of 175,000 pregnancies during a 5-year period in the Oxford region of England, anti-S antibody was detected in 22 pregnancies in 19 women.²⁰⁷ Previous transfusions were believed to be the likely source of sensitization in 13 patients. A positive direct Coombs assay

was noted in only four cases; one infant required exchange transfusions. Most cases of HDFN described in the literature involve mild neonatal disease.²⁰⁸ Only three cases of severe disease have been described. The first case was reported in 1952; the infant died of kernicterus at 60 hours of life.²⁰⁹ Griffith²¹⁰ described a case of stillbirth at 41 weeks' gestation complicated by the finding of a maternal anti-S antibody and autopsy findings consistent with erythroblastosis fetalis. Finally, Mayne and coworkers²⁰⁷ reported a case of maternal anti-S alloimmunization that resulted in the birth of a neonate requiring three exchange transfusions and 5 days of phototherapy.

Anti-s

Three cases of severe HDFN and one case of mild HDN associated with anti-s have been reported.²¹¹

Anti-N

One case of mild HDFN associated with anti-N, which required only phototherapy, has been reported.²¹² PCR typing of the fetus in amniotic fluid has proved problematic, particularly in the black race, where there is up to 15% discordance between paternal serology and genotype (M. J. Hessner, personal communication, The Blood Center of Wisconsin).

Anti-U

The U antigen is a high-frequency antigen: It is universally found in the white population and only rarely absent in patients of African heritage. Smith and colleagues²¹³ reviewed six of their own cases of HDFN secondary to anti-U alloimmunization and an additional nine cases from peer-reviewed literature. The neonates in four cases managed at their institution required only phototherapy for treatment despite maternal antibody titers of as high as 4000 in conjunction with a strongly positive direct Coombs assay on cord blood. One patient delivered an infant who required six simple transfusions after birth. A subsequent pregnancy in this same patient was complicated by the need for four IUTs. After delivery, two additional exchange transfusions and three simple transfusions were necessary during the neonatal course. Their review of the nine cases reported in the literature described one stillbirth at 35 weeks,²¹⁴ three neonates requiring exchange transfusions,²¹⁵⁻²¹⁷ one infant with late-onset of anemia at 3 weeks of age,²¹⁸ and four additional cases with minimal evidence of HDFN.²¹⁹⁻²²¹ Based on the clinical course noted in these 15 cases, the authors recommended a threshold for a critical titer of 128 if there was no HDFN in a previous pregnancy. Experience in several of their cases indicated that amniocentesis for ΔOD_{450} was an accurate method of assessing the severity of fetal anemia.

In cases of anti-U alloimmunization requiring treatment with IUT, maternal blood should be strongly considered as the primary source of red cells, because fresh U- blood is often not readily available due to the high frequency of this antigen in the white population, the primary source of the donor pool.¹²⁷ Alternatively, maternal siblings or parents may be tested to determine whether they can serve as donors.

Duffy

The Duffy antigen system consists of two antigens, Fy^a and Fy^b. Inheritance is by codominant alleles that result in four possible phenotypes. Only anti-Fy^b antibodies have been associated with mild HDFN. A review of 19 cases of HDFN secondary to anti-Fy^a antibody between 1956 and 1975 revealed a neonatal mortality rate of 18%, with almost one third of the infants requiring neonatal exchange trans-

fusion.²²² Maternal titers as low as 8 were associated with moderate HDFN necessitating exchange transfusion. PCR typing of the fetus through amniocentesis is available in cases of a heterozygous paternal genotype.²²³

Kidd

The Kidd antigen system consists of two antigens, Jk^a and Jk^b. Inheritance is by codominant alleles that produce four possible phenotypes, although the Jk^a-/Jk^b- genotype is extremely rare. Rare cases of mild hemolytic disease have been reported. PCR typing of the fetus through amniocentesis is available in cases of a heterozygous paternal genotype.²²⁴

Summary

Irregular anti-red cell antibodies associated with HDFN will continue to challenge the practitioner, because the development of these antibodies is often related to transfusion therapy necessitated by complications in pregnancy. Prophylactic immune globulins are unlikely to be developed because of the rarity of these situations. In Australia, only K1- red cells are used for transfusion in female children and women of reproductive age, in an effort to markedly decrease the incidence of Kell alloimmunization. Such policies should receive further consideration in other countries.

Guidelines for intervention in cases of irregular antibodies are limited by the bias of anecdotal reports in the literature in favor of severe cases of HDFN. Large published series of patients with anti-K1 or anti-M in which most fetuses and neonates were minimally affected or unaffected substantiate this bias. In general, principles used in the management of the RhD-alloimmunized patient should be followed in most cases of irregular anti-red cell antibodies as well. A notable exception is K1 or K2 alloimmunization. A lower maternal critical titer of 8 and serial MCA Doppler studies should be used to decide when to proceed to cordocentesis.

Chapter 27

Nonimmune Hydrops

Isabelle Wilkins, MD

Hydrops fetalis is the term used to describe generalized edema in the neonate. This edema is accompanied by collections of fluid in serous spaces. In the past, most cases of hydrops fetalis were caused by severe erythroblastosis due to Rh alloimmunization. Potter¹ was the first to describe nonimmune hydrops fetalis in a group of infants without erythroblastosis whose mothers were Rh-positive.

Since it was first described 60 years ago, nonimmune hydrops (NIH) has become more common than hydrops from alloimmunization. Santolaya and associates² reported a series of 76 hydropic fetuses, of which 87% had NIH. Only 4 (4.5%) of 87 cases assessed at a fetal medicine unit reported by Sohan and associates³ were caused by red cell alloimmunization, and Ismail and coworkers⁴ reported 63 prenatally detected cases, of which only 8 (12.7%) had an immune basis. Graves and Baskett⁵ examined all babies born at their institution with hydrops and reported that 76% of cases were nonimmune. More recently, Trainor and Tubman reported their experience over three time periods, showing a dramatic increase in the percentage of nonimmune cases of hydrops at delivery, from 0% in 1974 to 80% in 2002.⁶

The incidence of NIH at delivery in published accounts is approximately 1 in 1500 to 1 in 3800.^{5,7,8} A large, unselected prenatal ultrasound screening clinic in Finland had a similar rate of 1 in 1700.⁹ Trainor and Tubman⁶ did not include stillbirths and found a rate of 1.34 per 1000 live births. Reviews from ultrasonography referral centers, however, show an incidence between 1 in 150 and 1 in 766 sonographic examinations.^{2,10,11}

NIH is a heterogeneous disorder with a large number of possible causes and associations. Overall, the prognosis is poor; a 52% to 98% perinatal mortality rate is typical.^{3,4,9,12} Elucidation of etiology is of primary importance, because treatment and prognosis of this disorder are determined by the underlying fetal condition, but the task may be difficult. Most authors differentiate the rate of prenatal detection of etiology, which is lower than the rate after delivery or at autopsy. Both are important in counseling families and discussing recurrence risks, but only prenatal detection is useful in guiding management and therapy. In most series, cause is found in approximately 51% to 85% of cases before delivery but in up to 95% after delivery, depending in part on parental acceptance of autopsy and karyotyping.^{3,4,9,10,12} It is clear that both success in determining etiology and survival statistics differ between early and late gestation, largely because of the different gestational ages at which hydrops of various causes presents. In general, presentation before 24 weeks of gestation occurs in more severe cases, in which the cause is easier to ascertain but perinatal survival is worse.^{3,4,9,10-12}

Presenting Signs and Symptoms

Although NIH is a clinical diagnosis concerning the neonate, the condition can be determined antenatally by obstetric sonographic examination, with a success rate of almost 100%. The indication for ultrasonography varies among series. In 1986, Watson and Campbell¹³ found that 63% of cases of NIH were discovered on routine ultrasonography, whereas another 30% of patients were referred because of suspected hydramnios. Graves and Baskett⁵ found that NIH was less commonly discovered on routine ultrasonography than on ultrasonography ordered for a specific indication. The most common indications in their population were hydramnios, size greater than dates, fetal tachycardia, and maternal pregnancy-induced hypertension. Other frequently cited indications for ultrasound evaluation have included abnormal serum screening, decreased fetal movement, and antenatal hemorrhage.^{11,14-15}

Maternal complications of pregnancy are also increased in NIH. Hydramnios, pregnancy-induced hypertension, severe anemia, postpartum hemorrhage, preterm labor, birth trauma, gestational diabetes, a retained placenta, and difficult delivery of the placenta are all frequently mentioned in large series.^{5,7,12,15,16}

An uncommon maternal complication of fetal hydrops is called *mirror syndrome*. This condition is rarely a presenting complaint and may develop during conservative management of such pregnancies. Patients generally experience edema and pulmonary edema and may have hypertension and proteinuria. The similarity to severe preeclampsia has led some authors to refer to this condition as pseudotoxemia. The patients may be gravely ill but recover after delivery. The syndrome may also develop after delivery, as it did in two mothers in one series.¹² Although no series exist to direct management, most authors do not advise continuation of the pregnancy.^{11,17,18} A case report of fetal hydrops caused by parvovirus infection with concomitant maternal mirror syndrome was self-limited. As the fetal hydrops reversed, so did maternal symptoms, and a term delivery subsequently occurred.¹⁹ Stepan and Faber²⁰ reported a similar case in which maternal levels of soluble fms-like tyrosine kinase 1 (sFlt1) were extremely elevated initially and dropped after fetal transfusion resulted in resolution of both maternal and fetal symptoms. Espinoza and colleagues²¹ investigated levels of soluble vascular endothelial growth factor receptor-1 (sVEGFR-1) in four patients with mirror syndrome. This antiangiogenic

genic factor may be related to the pathogenesis of preeclampsia, and sVEGFR-1 was elevated in these cases.

Ultrasonography

Ultrasound examination is essential to the diagnosis of NIH, and criteria for definition of the disorder in the fetus are based exclusively on ultrasound parameters. The fluid that accumulates may include ascites, pleural effusions, pericardial effusions, and skin edema. Several definitions of fetal NIH have been proposed based on the quantity and distribution of excess fetal water. Variations in these definitions have made direct comparisons among published series inexact. Mahony and coworkers²² defined hydrops as generalized skin edema with or without an associated serous effusion. Although others have also used this definition,²³ NIH is more commonly defined as edema with one or more effusions, or effusions in at least two spaces; that is, two of the following must be present: ascites, pleural effusion, pericardial effusion, or skin edema.^{24,25}

The degree or severity of hydrops is generally subjective. Hutchison and associates⁷ described a score based on total number of serous space effusions. Because the only requirement for the definition of NIH was edema, it was possible to have a score of zero (0) with no serous involvement. This score was not predictive of outcome in their series, because the overall perinatal mortality rate was close to 100%. Saltzman and colleagues²⁶ described a different scoring system, in which each effusion was quantified. With this system, they were able to predict which cases were most likely caused by fetal anemia and which were from other causes. Although they included isoimmunized pregnancies in their series, other forms of anemia followed the same general pattern.

Fluid in one of these spaces may be an early finding in a fetus destined to develop hydrops. At the very least, a careful search for fluid in other serous sites is warranted. Such fetuses should undergo follow-up over time to ensure that hydrops is not developing. In general, these fetuses have a better prognosis than fetuses with hydrops.^{27,28}

Fetal Fluid Accumulation

Ascites appears sonographically as an echolucent rim of varying size in the fetal abdomen (Fig. 27-1). A small rim of ascites may be hard to distinguish from a similarly located area of echo dropout common with normal fetuses.²⁴ One possible distinguishing feature is that a true rim of fluid should be visible all the way around the abdomen in the transverse viewing plane. Longitudinally, the edge of the liver, bladder, or diaphragm may be outlined. When ascites is more marked, the entire liver is outlined and the bowel is compressed (Fig. 27-2). In these more extreme cases, the diagnosis is relatively easy.

Pleural effusions may be unilateral or bilateral. Although the effusions may appear as small rims of fluid outlining the pleural space and diaphragm, more commonly they are large and compress the lung (Fig. 27-3). It is uncommon for a unilateral effusion to shift the mediastinum. In such a case, an extrinsic fluid-filled mass, such as a diaphragmatic hernia or another space-occupying lesion, is likely to be present. Pulmonary hypoplasia is a frequent cause of death in neonates with NIH, and the size of pleural effusions may help to predict this complication.¹⁶

Pericardial effusions are smaller in total volume and are therefore more difficult to see than ascites or pleural effusions (Fig. 27-4). Some authors²⁴ have proposed that pericardial effusions indicate cardiac

FIGURE 27-1 Transverse image of the fetal abdomen at the level of the stomach. A large rim of ascites is seen within the abdominal wall.

FIGURE 27-2 Longitudinal image of the fetus. Ascitic fluid is seen outlining the liver (*large arrow*), and there is a pleural effusion above the diaphragm (*small arrow*).

FIGURE 27-3 Transverse image of the fetal chest. Bilateral pleural effusions are seen.

decompensation and that this is the earliest sign of hydrops in fetuses with cardiac lesions. In a group of patients with mixed etiology, Carlson and colleagues²⁹ found that the biventricular dimension, an indicator of overall cardiac size as measured on M-mode examination, was highly predictive of survival.

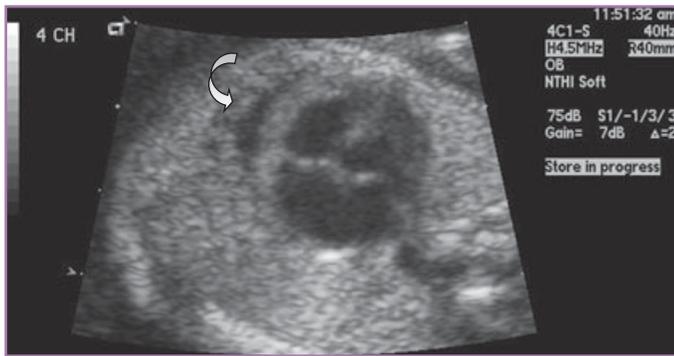

FIGURE 27-4 Transverse image of the fetal chest. Small pericardial effusion (arrow).

FIGURE 27-5 Transverse image of the fetal chest. Skin edema over fetal chest wall. Rib is marked by large arrow and skin edge with small arrow.

Skin edema is usually a generalized process, although it is easiest to see with ultrasonography over the chest wall or scalp, where soft tissue is typically thin and any thickness can be appreciated (Fig. 27-5). The usual definition of edema is greater than 5 mm of subcutaneous tissue. This may be misleading if the fetus has redundant skin folds or is macrosomic.

Placental thickening is frequently considered a sign of hydrops as well. Abnormal thickening is usually defined as a thickness of greater than 6 cm,^{25,30} although some authors have used a cutoff of 4 cm.^{31,32} With hydramnios, the placenta may appear compressed and instead be thin. If therapeutic amniocenteses are performed because of severe hydramnios, the placenta may “thicken” by the end of the procedure, and this occurrence implies that hydrostatic pressure was responsible for the thinned appearance.³³

According to various authors, hydramnios is present in 40% to 75% of cases of NIH. Although the definition of hydramnios differed among these series, when the condition was present, it was often severe and would therefore have been detected by any quantifying technique. In some cases of fetal hydrops, oligohydramnios is present, and many authors consider this an ominous or late finding. Although oligohydramnios is generally associated with poor pregnancy outcome, its prognosis in NIH depends on the underlying cause rather than simply on this sonographic feature.

Etiology

One of the greatest challenges in the management of a fetus with NIH is ascertaining the cause of the disorder. Causes are numerous, and new associations continually appear in the literature. The causes may be divided into several broad categories that are helpful in organizing an approach to this often-frustrating problem (Table 27-1).

Many of the conditions listed in Table 27-1 are categorized somewhat arbitrarily. For example, many anatomic cardiac lesions have a chromosomal basis. Similarly, viral syndromes that lead to NIH may be associated with fetal anemia, with fetal malformation complexes, or with myocarditis. It is also obvious that some of these syndromes are extremely rare and others are more common. In addition, many of these conditions represent congenital anomalies whereas others are acquired defects. Classifying these conditions differently may be helpful when considering particular problems such as management, recurrence risks, or possible fetal therapy.

Table 27-1 is not a list of etiologic factors but, rather, a list of conditions associated with NIH. The pathophysiology of NIH is well worked out in only a few cases. Furthermore, not all cases have the same pathophysiological mechanism.

A review by Machin³⁴ tried to elucidate some of these mechanisms. As he pointed out, hydrops is a common end stage for a variety of diseases reached by several pathways. He proposed five basic disease processes that lead to hydrops: cardiovascular failure, chromosomal abnormalities, thoracic compression, twinning, and fetal anemia. He believed that each of these has a common pathway for the development of hydrops. Furthermore, he suggested that most causes could be classified into one of these large groups.

Cardiovascular Causes

Fetal cardiac abnormalities are among the most common causes of hydrops in most series. Congenital heart disease is a common problem, with an incidence of 8 or 9 per 1000 liveborn infants. Malformations of the cardiovascular system are of varying degrees of complexity and seriousness, but it is not always clear why some of these fetuses experience hydrops and others are born in a well-compensated condition.³⁵ No forms of congenital heart disease reliably lead to hydrops, although one would expect that the more minor abnormalities are less likely to cause the ultimate decompensation of the fetus. Overall, a structural malformation of the heart with associated fetal hydrops carries an extremely poor prognosis, with a mortality rate approaching 100%.^{36,37}

Structural heart disease is diagnosed by means of ultrasonography, with either a targeted ultrasound examination or fetal echocardiography. In general, regardless of the presence of hydrops, cases of cardiac malformation that are diagnosed prenatally have a poor outcome. Crawford and coauthors³⁷ found only a 17% survival rate in such fetuses. Copel and coworkers³⁸ suggested that 30% of fetuses with prenatally diagnosed structural congenital heart disease have an abnormal karyotype. For this reason, they recommended that chromosome analysis be obtained whenever this diagnosis is made. Because of the poor prognosis associated with hydrops when an abnormal karyotype is involved, such fetuses usually are not considered candidates for in utero fetal therapy or for active intervention with early delivery and vigorous resuscitation.

Cardiac arrhythmias are also an important cause of hydrops, but the prognosis is entirely different from that for structural heart disease.

TABLE 27-1 CONDITIONS ASSOCIATED WITH NONIMMUNE HYDROPS**Cardiovascular**

Malformation

Left heart hypoplasia
 Atrioventricular canal defect
 Right heart hypoplasia

Tachyarrhythmias associated with hydrops usually carry a better prognosis than most other causes of NIH.^{25,39} Arrhythmias may be of several types, including tachyarrhythmias, bradyarrhythmias, and dysrhythmias. If an arrhythmia is associated with underlying structural heart disease, the prognosis is as poor as for heart disease without arrhyth-

mia, as described earlier.⁴⁰ Bradyarrhythmias with hydrops carry a very poor prognosis, although successful fetal therapy had been described.^{41,42}

Premature closure of the foramen ovale is typically idiopathic and can occur at any time during gestation. It can be diagnosed by careful

ultrasound examination of the fetal heart, with Doppler studies and color Doppler studies as useful adjuncts to imaging. Usually, this diagnosis is made only after the onset of hydrops, and prognosis is therefore poor.

Premature closure or narrowing of the ductus arteriosus also has been associated with fetal hydrops.⁴³ In one case, it was associated with other congenital heart disease, a coarctation of the aorta.⁴⁴ In other reported cases, the mother was receiving indomethacin for the arrest of preterm labor.⁴⁵ Moise and associates⁴⁶ described narrowing of the ductus in response to maternal indomethacin ingestion but found it to be measurable and reversible. Vanhaesebrouck and colleagues⁴⁷ described NIH with neonatal ileal perforation in fetuses exposed to indomethacin for the arrest of preterm labor.

A variety of other cardiac abnormalities can lead to hydrops. For example, neoplasias such as rhabdomyomas may be present with hydrops. In such cases, one should seek a family history of tuberous sclerosis, because this autosomal dominant disorder may manifest in this fashion.^{48,49}

Cardiac failure from myocarditis is responsible for at least some cases of hydrops in fetuses that have congenital infections.⁵⁰ Such cases have been documented with fetal parvovirus B19, with cytomegalovirus (CMV), and, much more rarely, with toxoplasmosis. These conditions are discussed later under infectious causes of hydrops.

Various noncardiac lesions can lead to high-output cardiac failure, a presumed mechanism of hydrops. Sacrococcygeal teratomas are large vascular tumors that act as arteriovenous shunts and may be associated with hydrops on this basis.^{51,52} The majority of these tumors are well tolerated by the fetus, however, and do not lead to hydrops.⁵³ Open fetal surgery with resection of the tumor has been attempted in cases associated with fetal hydrops, but only one success has been reported to date.⁵⁴

Placental tumors may also lead to hydrops. These are most commonly chorioangiomas, which are vascular and likely act as arteriovenous shunts.^{7,18,55-59}

Other causes of presumed high-output failure associated with fetal hydrops include fetal adrenal neuroblastomas, multiple cases of which have been reported. These rare tumors most likely lead to heart failure based on increased catecholamine release, much as they would in a child with the same lesion. Other angiomas that may lead to hydrops have been described in the cord⁶⁰ and in a fetus in the angio-osteohypertrophy syndrome.⁶¹

Chromosomal Abnormalities

Chromosomal abnormalities are fairly common in cases of fetal hydrops, and they may cause the disorder by any of several mechanisms.³⁴ Among chromosomally abnormal fetuses with hydrops, cystic hygromas are common.⁶² In fact, cystic hygromas are one of the most common causes of hydrops, particularly among fetuses diagnosed before 20 weeks of gestation.² The chromosomal abnormality most frequently seen in these fetuses is 45,X, or Turner syndrome. On the other hand, fetuses with this phenotype may also have trisomy 21 or a normal karyotype.^{63,64} Among fetuses with a 45,X karyotype, two common structural abnormalities can lead to the development of hydrops. Although one is cystic hygroma, fetuses with this condition also frequently have a tubular coarctation of the aorta. There is some controversy about which of these is the more important mechanism for causing NIH.³⁴

Other chromosomal abnormalities have also been described in fetuses with hydrops. The most common are trisomy 21, trisomy 18, trisomy 13, and triploidy. Sex chromosome abnormalities that result

in Turner syndrome, such as 45,X/46,XX, have also been reported, as have a large number of more unusual autosomal rearrangements. Structural cardiac lesions are common in aneuploid fetuses and may be associated with hydrops. If no structural cardiac lesion is found, the pathophysiology for the development of hydrops in this situation is unclear. The myeloproliferative disorder common in neonates with Down syndrome has been described in four fetuses with Down syndrome and NIH.⁶⁵

If the karyotype is abnormal, the prognosis is poor, and important information can be given to the parents about recurrence risk and diagnosis in future pregnancies. The overall rate of chromosome abnormality in fetuses with hydrops varies between 7% and 45%, with higher rates among those in whom hydrops is detected before 24 weeks' gestation.^{2-4,9,12,42,62,66} Obtaining a fetal karyotype is an essential part of the workup of any fetus with hydrops.

Thoracic Abnormalities

Increases in intrathoracic pressure may lead to the development of hydrops by obstructing venous return and altering cardiovascular hemodynamics. Most of these conditions involve space-occupying lesions of the thorax.

Cystic adenomatoid malformation of the lung is divided into several different subtypes, depending on the size and distribution of the cysts. In most cases, if pulmonary hypoplasia is not life-threatening, this lesion is amenable to surgery in the neonate. These fetuses may develop hydrops, however, and this markedly worsens the prognosis.

Most cases of cystic adenomatoid malformation of the lung associated with hydrops involve a single large cyst and a shift of the mediastinum. Continuous drainage of the solitary cyst by means of pleuroamniotic shunt placement or cyst aspiration has been proposed.⁶⁷ In cases in which cysts are microscopic or otherwise not amenable to shunt placement and hydrops is present, open fetal surgery has been performed. Although the outcomes have been poor, some of the fetuses have survived; left untreated, they would not have.⁶⁷⁻⁶⁹ A substantial proportion of prenatally diagnosed cystic adenomatoid malformations resolve spontaneously or regress but do not entirely resolve, including cases with NIH; this has led some to continue expectant management.⁷⁰

Other types of masses or lesions in the chest may be associated with hydrops as well. These include diaphragmatic hernias, hamartomas or other neoplasms of the lung or chest, pulmonary extralobar sequestration syndrome, and various bronchogenic cysts. Diaphragmatic hernia is the most common of these lesions, but it is unusual for affected fetuses to experience hydrops.

Unilateral hydrothorax may present as a space-occupying lesion in the chest and is frequently associated with hydrops. Bilateral hydrothorax may be indistinguishable from other causes of NIH, because one of the features of hydrops is pleural effusion. In such cases, the effusions are the primary event and the hydrops a secondary problem. Many authors have considered unilateral or bilateral fetal hydrothorax to be analogous to neonatal chylothorax.^{71,72} Because there are no chylomicrons in the fetus, this is not known with certainty, and in most cases after birth no particular surgery on the presumably abnormal lymphatic system is performed.⁷³ Overall, these fetuses have a relatively poor prognosis, because pulmonary hypoplasia is frequently present. In the neonate, isolated pleural effusion without hydrops has a much more favorable prognosis, with a 15% mortality rate.⁷⁴

Some authors recommend diagnostic fetal thoracentesis if unilateral or bilateral hydrothorax is suspected. In cases of isolated hydro-

thorax, lymphocytes predominate in the fluid obtained, although Eddleman and coauthors⁷⁵ reported on two cases in which this test was misleading. There are many reports of placement of a pleuroamniotic shunt for continual drainage of this space. The results of such therapy have increased survival to between 40% and 70%.^{71,72,74}

The rate of aneuploidy in association with fetal hydrothorax or isolated pleural effusion is high. Rodeck and associates⁷³ placed shunts before the availability of a fetal karyotype, and one of eight fetuses had Down syndrome. Petrikovsky and colleagues⁷⁶ reported three consecutive cases of pleural effusion, all of which involved aneuploid fetuses. However, more recent reports showed a lower rate in apparently isolated cases.^{71,72}

Twinning

When one of a set of twins is determined to have fetal hydrops, the differential diagnosis requires special considerations. If it is known that the twins are not monozygotic, the cause is probably unrelated to the twin pregnancy, and the diagnostic approach to the twin with hydrops should be similar to that for any other fetus with the condition. In the case of monozygotic twins, the hydrops is probably related to abnormal vessels in the placenta, resulting in twin-to-twin transfusion syndrome (see Chapter 24).

In the twin-to-twin transfusion syndrome, the fetus with hydrops may be either the donor or the recipient.¹⁵ In the classic situation, the donor twin has growth restriction and oligohydramnios, and the recipient twin has plethora, hydramnios, and perhaps hydrops.^{77,78} Presumably, this scenario results from cardiac overload and congestive heart failure; however, it is also possible for the donor twin to have hydrops, in which case the pathophysiology is likely to be related to anemia.⁷⁹

Twin-to-twin transfusion syndrome carries a poor prognosis, particularly if it is found early in gestation or if hydrops is present. Various aggressive therapies have been proposed, including serial amniocenteses, in utero laser ablation of communicating placental vessels, and transabdominal needle septostomy of the dividing membrane. The best treatment is still controversial, because several large series have shown conflicting results, particularly in long-term follow-up of surviving twins.⁸⁰⁻⁸⁴

Fetal Anemia

Anemia is a well-known cause of fetal hydrops, and the model used to elucidate the pathophysiology of this condition is alloimmunization. Because immune hydrops has been extensively studied, this anemia is the best-understood mechanism for the development of NIH as well.

One of the most common causes of hydrops in patients from Asia or the eastern Mediterranean region is α -thalassemia.^{42,85} This recessive disorder causes formation of abnormal tetramers of the β chain of hemoglobin, which cannot carry oxygen (see Chapter 42). The result is massive tissue hypoxia. Fetuses with this disorder commonly develop hydrops as early as 20 weeks' gestation. Because long-term survival of fetuses with homozygous α -thalassemia is extremely rare, there is no current recommendation for treatment. However, proper diagnosis is important for counseling and prenatal diagnosis in future pregnancies.

Fetomaternal hemorrhage is relatively common and, in rare instances, may be massive enough to cause fetal hydrops.^{86,87} In most cases, the cause of the fetomaternal hemorrhage or transfusion is unknown. This diagnosis can be made by use of a Kleihauer-Betke stain to examine peripheral maternal blood for the presence of fetal

cells. It is also possible to detect a fetomaternal bleed by an abnormally elevated maternal serum α -fetoprotein level. Although the hemorrhage may be self-limited, if the fetus has developed hydrops, many authors have advocated more aggressive management because of the risk for fetal death. There have now been several case reports of fetuses treated with serial intravascular transfusions with resolution of hydrops and an ultimately good outcome.⁸⁷⁻⁹⁰

Fetal hemorrhage with subsequent anemia and hydrops formation has also been reported. This has usually been associated with an intracranial hemorrhage, and, in the absence of a history of trauma, one should suspect a fetal coagulation deficiency such as alloimmune thrombocytopenia.^{91,92}

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is a common X-linked condition in African Americans and persons of Mediterranean heritage. This disorder is characterized by hemolytic crises, usually in response to various stimuli including sulfa drugs, aspirin, and fava beans. Female carriers are usually asymptomatic. There are two reports of affected male fetuses' developing anemia and hydrops after maternal ingestion of these substances.^{93,94}

A number of inherited erythrocyte enzyme deficiencies can cause fetal anemia and, in rare cases, fetal hydrops.^{95,96} Examples include glucose phosphate isomerase deficiency and pyruvate kinase deficiency. These conditions commonly lead to chronic hemolytic anemia, but rarely to severe anemia, in fetal life.

Congenital leukemia can cause anemia and hydrops, and leukemic infiltration of the myocardium has also been demonstrated.⁹⁷ Transmission of maternal antibodies to erythroid precursors in a mother who had acquired red blood cell aplasia has been reported. Transfusions to the fetus reversed the hydrops and resulted in a healthy live-born infant with a normal outcome.⁹⁸

Mari and associates⁹⁹ predicted anemia in fetuses with immune hydrops, based on the velocity of blood flow in the middle cerebral artery (MCA). This method was substantiated in subsequent trials and is now widely accepted.¹⁰⁰⁻¹⁰² The same findings appear to be true in fetuses affected by anemia from other causes, including NIH. The most studied model is in parvovirus-induced anemia (see later discussion).¹⁰³⁻¹⁰⁶

Infections

A great deal of literature concerns congenital infection as a cause of NIH. Although many different viruses, bacteria, and parasites cause congenital infection, the effects on the fetus are variable, and no infection predictably results in hydrops fetalis (see Chapter 38). In addition, although researchers have long believed anemia to be the common mechanism for the development of hydrops in these fetuses, myocarditis, hepatitis, or other pathways yet to be elucidated may also be involved.

Syphilis

Congenital syphilis is a well-known cause of fetal hydrops. One can confirm the diagnosis by obtaining a positive serologic test result in the mother. A dark-field examination of amniotic fluid may also be helpful.¹⁰⁷ A fetus with syphilis and hydrops faces a poor prognosis compared to one with a milder case of congenital syphilis. Management remains the same, however: treating the infection in the mother.

Cytomegalovirus

CMV is a common perinatally acquired infection. Although 20% to 30% of maternal primary infections are transmitted to the fetus, fewer

result in symptomatic CMV in the fetus or neonate.^{108,109} Symptomatic fetuses may show growth restriction, placentomegaly, polyhydramnios or oligohydramnios, hydrops, microcephaly, echogenic bowel, or intracerebral calcifications.^{108,110} Ideally, maternal infection is determined by documentation of seroconversion or, alternatively, by rising titers of CMV immunoglobulin (IgG) antibody. Primary infection causes prolonged viral shedding, and a positive maternal urine culture also may be helpful.

Prenatal diagnosis is complicated by the gestational age and the time since maternal infection. In general, multiple parameters are used, including ultrasound findings, amniotic fluid, and fetal blood assays for CMV DNA and CMV-specific IgM in fetal blood after 22 weeks of gestation.^{109,110} Blood obtained from the fetus can be tested for CMV-specific IgM if the fetus is past 22 weeks' gestation and is capable of producing IgM. Determination of fetal IgG levels is unhelpful, because these levels may merely reflect transplacental passage of maternal IgG.¹⁰⁹⁻¹¹² With amniotic fluid culture or polymerase chain reaction (PCR) testing for CMV DNA, gestational age at the time of sampling is important, because many false-negative results are obtained before 20 weeks' gestation. In addition, the time from infection to sampling is important. In the face of a presumptive clinical diagnosis, one should consider repeating amniocentesis, cordocentesis, or both if these have yielded negative results.^{112,113}

At present, there is no established in utero antiviral therapy for fetal CMV infection. However a nonrandomized trial of hyperimmune globulin given to women with known transplacental infection showed a decrease in neonatal infection and disease in the treatment group.¹¹⁴

Parvovirus

The most frequent manifestation of infection with parvovirus B19 is fifth disease, or erythema infectiosum. This common disorder may be acquired by a pregnant woman from an affected child. It causes a characteristic rash, flu-like symptoms, and arthralgias that may be mild. Fetal infections clearly occur, but the transmission rate is not established.

A recent study from Germany of more than 1000 women with documented seroconversion showed a fetal death rate of 6.3%. All cases of fetal death occurred at less than 20 weeks of gestation, and in that period the fetal death rate was 11%. The risk of NIH was 4%.¹¹⁵

Until the recent advent of PCR testing of amniotic fluid and serum, the diagnosis of human parvovirus infection in a fetus with hydrops was difficult.^{116,117} Data from older series were based on diagnoses made by isolating virus from fetal blood, detecting parvovirus-specific IgM in fetal serum, or demonstrating virus in fetal tissues.^{118,119} Viral particles can be detected by electron microscopy, by PCR, or by finding intranuclear inclusions on cytologic specimens.^{50,120-122} Fetal serology may be negative in some cases of fetal infection in which hydrops has developed.¹²³⁻¹²⁵ Easier diagnosis has led to an appreciation of how common this infection is. In a review of published series, Von Kaisenberg and Jonat¹²⁶ found that it accounted for 27% of all cases of NIH. Human parvovirus infection may also underlie a substantial portion of NIH cases previously labeled idiopathic.^{118,120} The transient nature of this infection and the absence of fetal demise have led many investigators to speculate that the virus may be a causative agent in cases of ascites or hydrops that spontaneously resolve in utero.^{125,127}

A characteristic although nonspecific finding in fetuses with this infection and hydrops is elevated maternal serum α -fetoprotein.¹²⁸ Data from Carrington and colleagues¹²³ and from Bernstein and Capeless¹²⁹ suggest that a highly elevated maternal serum α -fetoprotein level

is a useful marker because it may herald the onset of hydrops in an affected pregnancy. The usual mechanism for the development of hydrops in parvovirus infections is presumably anemia from an aplastic crisis. Parvovirus-infected fetuses undergoing percutaneous umbilical blood sampling or, more recently, MCA velocimetry have been found to be severely anemic.^{104,105,123,130} However, the virus has been shown to invade myocardium, and myocarditis may also account for hydropic changes, particularly in less anemic fetuses.^{50,131}

Because this virus is not known to be associated with congenital malformations or long-term sequelae, aggressive in utero supportive therapy has been attempted. Transfusions of packed cells to the fetus have resulted in some good outcomes.^{115,125,132,133} On reviewing published descriptions of 705 confirmed cases of fetal parvovirus in which 230 fetuses received transfusions, Von Kaisenberg and Jonat¹²⁶ concluded that aggressive therapy has a benefit over expectant management. However, more recent long-term follow-up has shown neurodevelopmental abnormalities in survivors unrelated to degree of anemia or hypoxia. The authors speculated that CNS involvement may be a previously unrecognized part of this infection.¹³⁴

Other Infections

Various other infectious agents have been related to hydrops in at least a few cases.¹³⁵⁻¹⁴¹ These include adenovirus, toxoplasmosis, herpes simplex, rubella, Coxsackie virus, influenza, enterovirus, and *Listeria*. In some cases, an infectious process is suspected, but no causative organism can be identified.^{142,143}

Metabolic Disease

A variety of genetic metabolic diseases, particularly lysosomal storage diseases, can cause hydrops in the fetus.¹⁴⁴ Gaucher disease, generalized (GM₁) gangliosidosis, Salla disease, sialidosis, mucopolysaccharidosis types 4 and 7, Tay-Sachs disease, and others can all present in this manner.¹⁴⁵⁻¹⁴⁸ Gaucher disease is the most common of these disorders and has been reported the most frequently, but presentation with hydrops is rare.¹⁴⁹ These conditions can recur in subsequent pregnancies because they are typically inherited in an autosomal recessive fashion. Establishing the correct diagnosis is therefore extremely important. This can be accomplished by analysis of oligosaccharides in fetal or neonatal urine or blood, enzyme analysis and carrier testing in the parents, or histologic examination of appropriate fetal tissues.^{144,150,151}

Several authors have recently recommended approaches to the diagnostic workup for these disorders based on their experience. Because there are many possible disorders in patients with no family history, they outlined suggested stepwise testing schemes.^{152,153}

Other Malformations

A variety of chondrodysplasias may manifest with fetal hydrops. Pretorius and coworkers¹⁵⁴ found all such cases to be associated with fatal dwarfing syndromes. In these cases, the chest is compressed, and the neonates die of respiratory insufficiency. The most common skeletal dysplasias described with fetal hydrops are short-rib polydactyly syndrome, thanatophoric dysplasia, and achondrogenesis. One can diagnose skeletal dysplasia fairly easily with ultrasonography by measuring the extremities relative to head and abdominal size, but classifying the type of chondrodysplasia in a fetus by ultrasonography alone can be difficult. After birth, x-ray studies and examination of other phenotypic features of the neonate can be used to determine the specific type of chondrodysplasia. Because many of the lethal types are

inherited in a recessive fashion, the recurrence rate is high. For several of these disorders, the gene responsible has been identified, and the genetic abnormality can be detected on fetal or neonatal tissue specimens.

A number of other genetic syndromes have also been associated with fetal hydrops. These include congenital myotonic dystrophy, arthrogyposis, multiple fetal pterygia, Neu-Laxova syndrome, and Pena-Shokeir syndrome type 1.^{62,155,156}

Urinary tract malformations have been described in conjunction with hydrops in numerous reports; however, close examination of these cases reveals that most involved isolated ascites with a urinary tract malformation. This condition, known as urinary ascites, is common, well described, and generally self-limited. It rarely progresses to hydrops.

Various intra-abdominal processes related to the gastrointestinal tract commonly manifest with ascites, but in rare cases they are associated with hydrops. These include meconium peritonitis, small bowel volvulus, and various intestinal atresias.

Other Causes

Diabetes is frequently cited as a cause of NIH, and several large series have included a few cases in which preexisting maternal diabetes was the only etiology.¹⁵⁷ It is not clear whether these fetuses were structurally normal. Other authors found no association between maternal diabetes and NIH.¹⁵

Several maternal medications have been reported to be associated with NIH in the fetus. Indomethacin may be associated with ductal narrowing, as described earlier. Other reported cases have involved mycophenolate with fetal and neonatal anemia, propylthiouracil (PTU), and enalapril.¹⁵⁸⁻¹⁶⁰

The list of causes given here is certainly not complete. Numerous case reports have described other syndromes or malformations associated with fetal hydrops. In some of these cases, the association might not be causative or might be unproven, but in others it is more convincing. The literature is constantly being updated, not only with series but with case reports, and this discussion is therefore not exhaustive.

Experimental Management of Idiopathic Cases

Various management strategies have been attempted in cases of NIH of unknown etiology. Shimokawa and associates¹⁶¹ injected albumin on two occasions into the peritoneal cavity of a fetus with hydrops, and hydrops subsequently resolved. This group later published a series of 21 cases treated with a combination of red blood cell transfusions and serial albumin injections. Improvements occurred only in fetuses without pleural effusions, but within that group, five (72%) of seven fetuses survived.¹⁶²

Lingman and colleagues¹⁶³ attempted direct intravascular albumin transfusion on five occasions in a fetus later found to have a lysosomal storage disease. Doppler studies and blood counts before and after the procedures indicated effective plasma expansion and peripheral vasodilatation.

Goldberg and associates¹⁶⁴ placed a peritoneal-amniotic shunt in a second-trimester fetus with NIH of unknown etiology and massive ascites. Although the ascites resolved, other features of hydrops developed, and the fetus ultimately died.

Diagnostic Approach to the Fetus with Hydrops

The workup for a patient with a diagnosis of fetal hydrops should be directed at possible causes. Because the diagnosis is confirmed with ultrasonography, this is frequently the first test performed. During a careful ultrasound examination, the known causes of NIH should be kept in mind. Many of the fetal conditions, congenital anomalies, and malformation sequences that are known to cause hydrops can be found or eliminated on the initial ultrasound examination. Twins, cardiac arrhythmias, and hydrothorax are all examples of obvious ultrasonography-derived diagnoses. The blood-flow velocity of the MCA should be assessed to screen for fetal anemia.

If the examination is unsatisfactory, it should be repeated later to delineate the fetal anatomy as well as possible. Although the underlying diagnosis is far more predictive of outcome than are any specific ultrasonographic parameters, the initial examination can be used to assess the severity of the hydrops and to initiate antenatal testing, if appropriate, depending on gestational age. Assessing the severity of the hydrops is particularly important if the fetus is observed for some length of time or if fetal therapy is attempted. Ultrasound parameters can be longitudinally monitored to predict fetal decompensation or fetal response to in utero therapy.

A history should be taken, with particular attention to ethnic background and any family history of genetic diseases or congenital anomaly, consanguinity, recent maternal infections or exposures, and maternal medications. Once again, careful scrutiny of the listed causes of hydrops gives direction to the types of questions that should be asked of the mother and family.

The initial testing of the mother should include elimination of immune causes of hydrops with blood typing and the indirect Coombs test. A screen for hemoglobinopathies, a Kleihauer-Betke test to look for fetal red blood cells in the maternal circulation, and titers for toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex (TORCH) are also useful at this time. Some of these tests may not be immediately available, but blood should be drawn and sent to the laboratory.

In addition to careful ultrasonography studies including MCA velocity, fetal echocardiography may be helpful. A fetal karyotype should be obtained in most cases. With the availability of fluorescence in situ hybridization (FISH), rapid karyotyping can be performed on amniotic fluid. If infection is suspected, amniotic fluid can be sent for PCR testing or culture. Fetal blood can also be used for a rapid karyotype, and it can be sent for other tests, such as a complete blood count and platelet count, to rule out fetal anemia or thrombocytopenia. If blood is obtained, serologic studies and cultures can be performed on the specimen.

Fetal serum or amniotic fluid can be frozen or sent for other studies, such as screening for lysosomal storage diseases, if these are suspected. Although the deviation in optical density at 450 nm wavelength (ΔOD_{450}) values are increased in many cases of NIH,¹⁶⁵ this is not clinically useful information, so the study is not usually indicated. Amniotic fluid may be sent for lung-maturity studies if appropriate. A frozen sample of amniotic fluid may be useful for future viral DNA hybridization studies or oligosaccharide analysis if not ordered initially.

Because some test findings are not available promptly, numerous tests may need to be ordered before initial results are available. It is helpful to establish a connection with cooperative laboratory facilities

or, if these are not available locally, with reference laboratories to which specimens can be sent.

Management

Management issues are difficult to generalize because they depend on prognosis, gestational age, and presenting signs and symptoms. Before the fetus becomes viable, the prognosis should be explained to the parents, who should be given the option of terminating the pregnancy. If the underlying etiology is amenable to fetal therapy, this should be frankly discussed with the family, but, in general, the parents should be warned that diagnostic error is always possible and that the overall prognosis in NIH is still grim.

Many cases of NIH are detected during the third trimester. If the patient presents in preterm labor or if symptomatic hydramnios exists, difficult decisions need to be made about whether to administer tocolytic medications or to allow labor to continue. It may be warranted to continue tocolysis, as long as the mother is stable, while the fetal workup is being pursued. If a potentially reversible cause of hydrops is found, consultation with neonatology specialists may help guide counseling to the family about the advisability of prolonging the pregnancy and initiating fetal therapy versus proceeding with prompt delivery and postnatal treatment. If a fetal diagnosis with a poor prognosis seems fairly certain, a frank discussion with the family may lead to the discontinuation of tocolytic medication.

If the patient presents with or later shows signs of maternal compromise, such as preeclampsia or antenatal hemorrhage, management should be pursued without regard to fetal outcome, since it is so poor. Management decisions are particularly difficult in idiopathic cases with uncertain prognosis. Even though the overall prognosis is poor in idiopathic cases, every attempt should be made to prolong pregnancies diagnosed during the third trimester to 32 or 34 weeks' gestation, in order to maximize fetal survival, unless there are signs of fetal or maternal decompensation. If significant or symptomatic hydramnios is present, it may be treated with therapeutic amniocenteses, indomethacin, or, more conservatively, bed rest and conventional tocolytic therapy.

Fetal decompensation can be difficult to measure, but the usual biophysical parameters are nonetheless useful. If a fetal reactive heart rate tracing becomes abnormal, this should be interpreted as a sign of acute decompensation. Similarly, oligohydramnios, a decrease in fetal movement, and poor fetal tone are all ominous signs. Unless there is evidence that hydrops is resolving or that treatment has otherwise been effective, there does not seem to be any reason to prolong a pregnancy past 34 weeks' gestation or the attainment of a mature lung profile.

Huhta¹⁶⁶ suggested use of a cardiovascular scoring system to measure the degree of cardiovascular compromise using intracardiac, venous, and umbilical artery Doppler measurements. This method may be used longitudinally to monitor fetuses for decompensation in cases of hydrops.^{166,167}

Recurrence Risks

After the delivery of a fetus with NIH, investigation of the cause should continue in the nursery, if necessary. If the fetus is stillborn or dies during the early neonatal period, every attempt should be made to obtain a postmortem examination directed at finding the underlying cause of the problem. Without this information, counseling the patient and her family about future pregnancies is frustrating. Overall, recur-

rent hydrops fetalis is unusual, and for most families the prognosis is good for a normal pregnancy in the future. However, there are numerous case reports of recurrent pregnancies with hydropic fetuses.¹⁶⁸⁻¹⁷³ One must therefore be wary of reassuring families that idiopathic hydrops will not recur, and future pregnancies should be carefully monitored.

Delivery Considerations

Delivery of a fetus with hydrops should be attended by an experienced pediatric team prepared to deal with a sick neonate. Some authors have recommended the liberal use of cesarean section to avoid asphyxia and birth trauma, although no objective data support this approach.¹³⁶ Predelivery thoracentesis or paracentesis has also been advocated to enable immediate postnatal resuscitation or, in the case of a large fetal abdominal girth, to facilitate vaginal delivery.^{25,79,174,175} A recent series¹⁷⁶ showed increased survival among neonates born later in gestation with normal Apgar scores. Pleural effusion was also associated with a poorer chance for survival. No fetus born in their series before 30 weeks survived.

Immediate problems of the neonate are likely to center on respiratory support and fluid management. Virtually all neonates with hydrops require mechanical ventilation, and edema can make intubation difficult.^{177,178}

Postnatal drainage of pleural or peritoneal fluid may be required to maintain oxygenation. Some authors reserve these procedures for extreme cases, whereas others propose a more liberal use of fluid drainage.^{177,179,180} Fluid restriction, careful management of electrolytes, judicious use of albumin and diuretics, correction of anemia, and continuous assessment of intravascular volume are all important issues in the first few days of life.

Summary

Although there have been many advances in understanding of the causes of fetal NIH, it remains a difficult clinical problem. Many conditions have been associated with fetal hydrops, but few shed light on the pathophysiology of its development. Once the diagnosis of NIH is established, a careful search for causative fetal pathology should be undertaken. Unfortunately, the results of such a search may not be available at the time when difficult management decisions must be made. Recent advances in fetal therapy have increased the number of fetal conditions for which treatment is possible. However, the overall rates of morbidity in mother and fetus, and of mortality in the fetus, remain high.

Chapter 28

Pathogenesis of Spontaneous Preterm Labor

Roberto Romero, MD, and Charles J. Lockwood, MD

Preterm deliveries are those occurring between fetal viability and 37 completed weeks of gestation (menstrual age).¹ Delivery of a pre-viable fetus represents a spontaneous abortion rather than a preterm birth. The precise definition of “viability,” however, is a subject of debate because of the increased frequency of survival at very low gestational ages. Some neonates can survive if born around 24 weeks of gestation, but none at 20 weeks; therefore, we propose that preterm birth be defined as one that occurs between 24 and 36 6/7 weeks of gestation. This definition may need to be revised if future technologic advances allow substantial survival at less than 24 weeks of gestation.

A birth weight of 500 g has historically been used to define the lower limit of viability. However, this approach is limited because viable neonates born after 24 weeks may be affected by intrauterine growth restriction (IUGR) and have birth weights of less than 500 g. Conversely, some pre-viable infants may weigh more than 500 g. The threshold of 500 g is valuable if there is uncertainty about gestational age. An accurate definition of preterm birth has implications for the calculation of vital statistics and comparisons of the rates of preterm delivery among different countries and populations, an issue that is often overlooked.

Preterm births can be spontaneous or “indicated.” Spontaneous preterm labor can occur with either intact membranes or prelabor (premature) rupture of the fetal membranes (PROM). “Indicated” preterm births are those that result from induced preterm labor or preterm cesarean delivery for maternal or fetal indications, usually because of preeclampsia or IUGR or both. The mechanisms of disease responsible for these two conditions are discussed in other chapters of this text (see Chapter 5).

Of all preterm deliveries, some 25% (reported range, 18.7% to 35.2%) are indicated, and the remainder are spontaneous—45% (23.2% to 64.1%) from preterm labor with intact membranes and 30% (7.1% to 51.2%) from preterm labor after PROM.^{2,3} The rate of preterm delivery in the United States has climbed 14% since 1990; this has been attributed to an increased frequency of indicated preterm birth in singleton gestations, an increased number of multiple gestations, and an increased number of older parturients.⁴

Overview of the Mechanisms of Labor

The Common Pathway

The traditional view, which has dominated the study of preterm parturition, is that term and preterm labor are the same processes, albeit occurring at different gestational ages. Indeed, they do share a common pathway, which includes increased uterine contractility, cervical ripening, and membrane rupture.⁵ It has been proposed that the fundamental difference between term and preterm labor is that the former results from “physiologic activation” of this common pathway, whereas preterm labor results from a disease process (“pathologic activation”) that extemporaneously activates one or more of the components of the common pathway.⁶

The *common pathway of parturition* is defined as the anatomic, biochemical, immunologic, endocrinologic, and clinical events that occur in the mother and fetus in both term and preterm labor.⁶ Much clinical emphasis has been placed on the uterine components of the pathway (myometrial contractility, cervical ripening, and membrane rupture) (Fig. 28-1). However, there are systemic changes, such as an increase in the plasma concentration of corticotropin-releasing hormone (CRH) and in the caloric metabolic expenditures, that are also part of the common pathway.⁷⁻¹⁰

Activation of the uterine components of the common pathway of parturition may be synchronous or asynchronous. Synchronous activation results in clinical spontaneous preterm labor. Asynchronous activation results in a different phenotype. For example, predominant activation of the membranes leads to preterm PROM, that of the cervix to cervical insufficiency, and that of myometrium to preterm uterine contractions without cervical change or rupture of membranes (Fig. 28-2).

Spontaneous preterm labor with intact membranes, preterm PROM, and cervical insufficiency can be considered syndromes caused

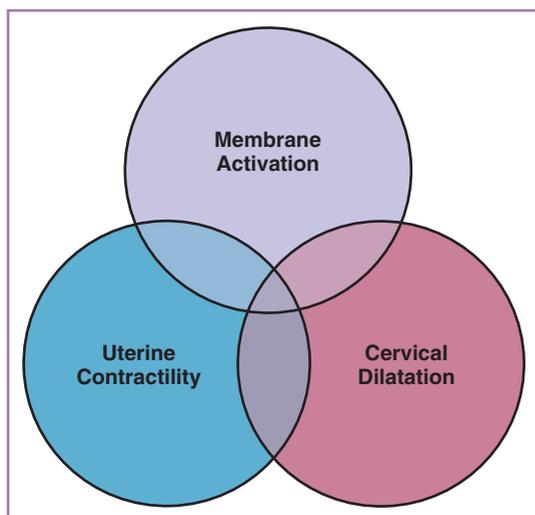

FIGURE 28-1 Uterine components of the common pathway of parturition (preterm and term). (From Romero R, Gomez R, Mazor M, et al: The preterm labor syndrome. In Elder MG, Romero R, Lamont RF (eds). Preterm Labor. New York: Churchill Livingstone, 1997, pp 29-49.)

by multiple etiologies with specific pathogenic pathways. This chapter reviews the pathophysiology of the common pathway of parturition and examines the pathologic mechanisms responsible for its activation.

Myometrial Contractility

Although myometrial contractility occurs throughout pregnancy, labor is characterized by a dramatic change in the pattern of uterine contractility, which evolves from “contractures” to “contractions.”⁹⁶ Nathanielsz and Honnabier¹¹ and Hsu and colleagues¹² defined *contractures* as epochs of myometrial activity lasting several minutes, associated with a modest increase in intrauterine pressure and fragmented bursts of electrical activity in the electromyogram. In contrast, *contractions* are epochs of myometrial activity of short duration associated with dramatic increases in intrauterine pressure and electromyographic activity. The switch from a predominant contracture pattern to a predominant contraction pattern occurs physiologically during normal labor¹³ or can be induced by pathologic events such as food withdrawal, infection, or intra-abdominal surgery.¹⁴⁻¹⁶

Increased cell-to-cell communication is thought to be responsible for the effectiveness of myometrial contractility during labor. Gap junctions develop in the myometrium just prior to labor and disappear shortly after delivery.¹⁷⁻²¹ Gap junction formation and the expression of the gap junction protein, connexin-43, in human myometrium is similar in both term and preterm labor.²²⁻²⁶ These findings suggest that the appearance of gap junctions and increased expression of connexin-43 may be part of the underlying series of molecular and cellular events responsible for the switch from contractures to contractions before the onset of parturition. Estrogen, progesterone, and prostaglandins have been implicated in the regulation of gap junction formation, and they also influence the expression of connexin-43.²⁷⁻²⁹ Lye and others have referred to a set of distinct proteins, called contraction-associated proteins, that are characteristic of this phase of parturition (see Chapter 5).^{24,30,31}

Lye and colleagues³² also proposed that the myometrium undergoes sequential phenotypic remodeling during pregnancy. Their studies

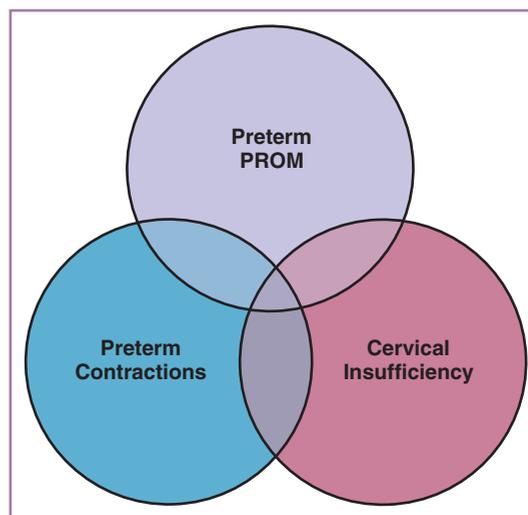

FIGURE 28-2 Clinical manifestations of preterm activation of the common pathway of parturition. Clinical manifestations depend on whether there is synchronous or asynchronous recruitment of the pathway. Cervical insufficiency is the presenting phenotype if activation of the cervix occurs in isolation. Prelabor rupture of membranes (PROM) occurs if decidua/membrane activation is the predominant pathway activated. Isolated activation of the myometrium results in preterm uterine contractions. Synchronous activation of the myometrium and the cervix results in the clinical presentation generally recognized as preterm labor with intact membranes. (From Romero R, Gomez R, Mazor M, et al: The preterm labor syndrome. In Elder MG, Romero R, Lamont RF (eds). Preterm Labor. New York: Churchill Livingstone, 1997, pp 29-49.)

were undertaken in rodents but have implications for humans. Three distinct stages of rat gestational myometrial development were recognized:

1. *Proliferative*, in which the number of myocytes increased, as demonstrated by greater proliferation cell nuclear antigen labeling and protein expression in early pregnancy. This phenotype coincided with a higher myometrial expression of antiapoptotic proteins (BCL2 and BCL2L1 [formerly BCL-xL]).
2. *Synthetic*, in which the myometrial cells underwent hypertrophy, as demonstrated by a higher protein/DNA ratio in the second half of pregnancy. This stage coincided with a higher secretion of extracellular matrix (ECM) proteins from the myocytes, in particular collagen I and collagen III, as well as a high concentration of caldesmon (a marker of synthetic phenotype)
3. *Contractile*, which occurred at the end of pregnancy and coincided with low myometrial expression of interstitial matrix proteins and high expression of components of the basement membrane (laminin and collagen IV).

α -Actin was expressed in the myometrium in early pregnancy, whereas γ -actin was highly expressed by myometrium with a contractile phenotype. The switch from a proliferative to a synthetic phenotype appeared to be regulated by caspase 3, and a decrease in progesterone was responsible for the switch from the synthetic to the contractile phenotype.³² This view is consistent with the proposal of Csapo about the importance of progesterone in the regulation of myometrial contractility at the onset of parturition.³³ Microarray experiments of myometrium in labor indicate an overexpression of genes involved in

control of inflammation (Romero et al., unpublished observations) This is consistent with other studies which used subtraction hybridization to identify genes differentially expressed during labor. Interleukin 8 (IL-8) and superoxide dismutase have been found to be differentially regulated.³⁴

Cervical Remodeling

The changes in the cervix include: (1) softening, (2) ripening, (3) dilatation, and, after delivery, (4) repair.³⁵ Sonographic studies have demonstrated that shortening of the cervix occurs before the dramatic increase in uterine contractility that characterizes term and preterm labor. Hence, the regulation of cervical remodeling has become important in the understanding of cervical insufficiency and spontaneous preterm labor.

The molecular and cellular bases for cervical remodeling during pregnancy and parturition are largely dependent on the regulation of extracellular matrix components.³⁵⁻⁴¹ Softening of the cervix begins in early pregnancy. The tensile strength of the softened cervix appears to be maintained by an increase in collagen synthesis and growth of the cervix. Cervical ripening is characterized by a decreased concentration of collagen and the dispersion of collagen fibrils. The latter has been attributed to glycosaminoglycans, such as decorin and hyaluronan, which promote hydration of cervical tissue and dispersion of the collagen fibers.³⁶ Dilation of the cervix is an inflammatory phenomenon in which there is an influx of macrophages and neutrophils and matrix degradation.⁴²⁻⁴⁴ Chemokines such as IL-8⁴⁵⁻⁴⁹ and S100A9^{50,51} attract inflammatory cells, which, in turn, release proinflammatory cytokines, including IL-1 β ^{52,53} and tumor necrosis factor- α (TNF- α),³⁵⁻⁵⁴ that can activate the nuclear factor (NF)- κ B signaling pathway. NF- κ B can block progesterone receptor-mediated actions.⁵⁵ Progesterone has been implicated in the regulation of cervical remodeling because (1) administration of antiprogestins to women in the mid-trimester and at term induces cervical ripening,^{35,56-60} and (2) the administration of progesterone-receptor antagonists such as mifepristone (RU-486) or onapristone (ZK 98299) to pregnant guinea pigs,^{61,62} old-world monkeys,⁶³ and *Tupaia belangeri* induces cervical ripening.³⁵ Cervical responsiveness to antiprogestins increases with advancing gestational age,³⁵ and the effects of antiprogestins in the cervix are not always accompanied by changes in myometrial activity.³⁵ Indeed, Stys and associates⁶⁴ demonstrated a dissociation between the effects of progesterone in the myometrium and those in the cervix. A frequent observation, in animals^{62,63} as well as in humans,⁶⁵ is that antiprogestins induce cervical ripening but not labor. Indeed, labor may be delayed by days or weeks, or it may not begin at all after cervical ripening has been accomplished in humans.³⁵ Collectively, these findings suggest that the cervix is a major site of progesterone action. This realization is important, because much of the emphasis in previous years has been on the effect of progesterone on the myometrium. Yet, recent randomized clinical trials suggest that progesterone may be helpful in preventing preterm birth in women with a short cervix.⁶⁶⁻⁶⁹

Decidual/Membrane Activation

We use the term *decidual/membrane activation* to refer to a complex set of anatomic and biochemical events that lead to separation of the lower pole of the fetal amniochorionic membranes from the decidua of the lower uterine segment and, eventually, to spontaneous rupture of the membranes and delivery of the placenta.

During pregnancy, the chorioamniotic membranes fuse with the decidua. In preparation for delivery, biochemical events take place to

allow separation and postpartum expulsion of the membranes. Fibronectins are a family of important extracellular matrix proteins. The available evidence suggests that degradation of a heavily glycosylated form of cellular fibronectin (i.e., fetal fibronectin) which is present at the chorionic-decidual interface leads to its release into cervical and vaginal secretions immediately before term and preterm parturition.⁷⁰⁻⁷³ Beyond proteolytic degradation of the decidual and amniochorionic extracellular matrix by matrix-degrading enzymes, PROM is also associated with amnion epithelial apoptosis and localized inflammation.⁷⁴ Therefore, these processes belong to the common terminal pathway of parturition.

Enzymatic activity of matrix metalloproteinases (MMPs) and other proteases has been implicated in the process of rupture of membranes and parturition with intact membranes (with and without infection).⁷⁵⁻⁷⁷ Histologic studies of membranes in women with term PROM indicate that membranes that rupture prematurely have a decreased number of collagen fibers, disruption of the normal wavy patterns of these fibers, and deposition of amorphous materials among them.⁷⁸ Similar changes have been observed in the membranes apposed to the cervix in women undergoing elective cesarean delivery at term with intact membranes. The implication is that, although spontaneous rupture of membranes normally occurs at the end of the first stage of labor, the process responsible for this phenomenon begins before the onset of labor.

Histologic studies of the site of rupture have demonstrated a zone of altered morphology (ZAM).^{79,80} A significant decrease in the amount of collagen type I, III, or V and an increased expression of tenascin have been reported in the ZAM. Tenascin is an extracellular matrix characteristically expressed during tissue remodeling and wound healing. Its identification in the membranes thus signifies the presence of injury and a wound healing-like response. Observations by Bell and colleagues^{81,82} suggested that changes in the ZAM are more extensive in the setting of preterm PROM. These morphologic and biochemical observations are consistent with the results of biophysical studies suggesting that rupture of membranes results from the application of acute or chronic stress on localized areas of the membranes that are weaker.

The precise mechanism of decidual/membrane activation remains to be elucidated. As noted, roles for extracellular matrix-degrading enzymes such as the MMPs and apoptosis have been proposed. Several studies have demonstrated increased availability of MMP-1 (interstitial collagenase),⁸³ MMP-8 (neutrophil collagenase),⁸⁴ MMP-9 (gelatinase-B),⁸⁵ and neutrophil elastase⁸⁶ in the amniotic fluid of women with preterm PROM, compared with women in preterm labor with intact membranes. Plasmin has also been implicated in this process,⁷³ because this enzyme can degrade type III collagen, fibronectin, and laminin.⁸⁷ Other MMPs are likely to be involved, but systematic studies have not been conducted to date.⁸⁸⁻⁹⁰ A role for tissue inhibitors of MMPs (TIMPs) has also been postulated.⁹¹

Prostaglandins as Key Activators of the Common Pathway of Parturition

A central question in the understanding of parturition is whether the signals responsible for activation of the common pathway are similar in term and preterm labor. Prostaglandins have been considered the key mediators for the onset of labor,⁹²⁻¹⁰⁷ because they can induce myometrial contractility,^{92,96,105,107} changes in extracellular matrix metabolism associated with cervical ripening,^{94,95,99,100,104} and decidual/membrane activation.⁵

Descriptive evidence traditionally invoked to support a role for prostaglandins in the initiation of human labor includes the following: (1) administration of prostaglandins can induce early or late termination of pregnancy (abortion or labor)^{103,108-118}; (2) treatment with indomethacin or aspirin can delay spontaneous onset of parturition in animals¹¹⁹⁻¹²²; (3) concentrations of prostaglandins in plasma and amniotic fluid increase during labor¹²³⁻¹³⁰; (4) intra-amniotic injection of arachidonic acid, the precursor of prostaglandins, induces abortion¹⁰¹; (5) amniotic fluid concentrations of prostaglandins increase before the onset of spontaneous labor at term in humans and nonhuman primates¹³¹; (6) expression of myometrial prostaglandin receptors increases in labor^{132,133}; and (7) labor is associated with increased cyclooxygenase-2 (COX-2) expression of messenger RNA (mRNA) and increased activity of this enzyme in amnion (a rate-limiting step in the production of prostaglandins). This increase in amniotic COX-2 activity is accompanied by decreased expression of the prostaglandin-metabolizing enzyme, 15-hydroxy-prostaglandin dehydrogenase (PGDH) in the chorion. This would allow prostaglandins produced in the amnion to traverse the chorion and reach the myometrium, where they can stimulate smooth muscle contractions.¹³⁴

The biochemical mechanisms by which prostaglandins activate the common pathway of parturition are the following: (1) prostaglandins directly promote uterine contractions by increasing sarcoplasmic and transmembrane calcium fluxes and through increased transcription of oxytocin receptors, connexin-43 (gap junctions), and the prostaglandin receptors EP₁ through EP₄ and FP^{27,135,136}; (2) prostaglandins induce synthesis of MMPs by fetal membranes and cells within the uterine cervix (as noted, MMPs have been implicated in the mechanisms of membrane rupture and also in cervical ripening)^{137,138}; and (3) prostaglandin E₂ (PGE₂) and PGF_{2α} increase the ratio of expression of the progesterone receptor (PR) isoforms, PR-A/PR-B.¹³⁹ This may induce a functional progesterone withdrawal. Figure 28-3 describes the molecular mechanisms implicated in the common pathway of parturition.

Spontaneous Preterm Parturition as a “Syndrome”

The current taxonomy of disease in obstetrics is based on the clinical presentation of the mother and not on the mechanisms of disease responsible for the clinical presentation. Neither the term “preterm labor with intact membranes” nor “preterm prelabor rupture of membranes” conveys information about the pathologic process that has led to untimely delivery. This situation is not unique to preterm parturition: it is also the case in preeclampsia, small for gestational age (SGA), fetal death, and other obstetric syndromes.

Generally, the diagnostic labels used in clinical obstetrics simply reflect a collection of symptoms and signs (e.g., abdominal pain due to uterine contractions, leakage of fluid) without information about the mechanisms of disease. The lack of recognition of this is responsible for the failure of any single diagnostic test or treatment to detect, cure, or prevent preterm delivery. To emphasize that preterm labor has multiple causes, we have used the word “syndrome,” which is defined as a combination of symptoms or signs that form a distinct clinical picture but can be generated by multiple etiologies. The features of the great obstetric syndromes have been described elsewhere.¹⁴⁰

We also make a distinction between preterm labor as a multifactorial disorder versus a syndrome. We are unaware of any disease in medicine that is unifactorial. For example, even sickle cell anemia, which is caused by the mutation of a single nucleotide, produces a wide range of clinical manifestations, and environmental factors such as infection or hypoxia can influence the phenotype caused by a single discrete genotype. The term “multifactorial” is often used in genetics to refer to common complex disorders in which the genetic predisposition is attributed to several genes and can be altered by environmental factors. Each of the causes of preterm parturition syndrome fits this definition of multifactorial. For example, in the case of infection, microorganisms can be considered an environmental factor, but the intensity and nature of the host inflammatory response is under genetic control. Thus, gene-environment interactions contribute to the phenotype of infection associated preterm parturition. The same is the case for vascular disease or hemorrhage, stress, and so on. The causes of preterm parturition syndrome are presented in Figure 28-4. The mechanisms of disease for each cause are in the following sections. The molecular signaling pathways implicated in four of these mechanisms are displayed in Figure 28-5.

The Spontaneous Preterm Parturition Syndromes

Infection and Inflammation

Infection is a frequent and important mechanism of disease in preterm delivery. Indeed, it is the only pathologic process for which an unequivocal causal link with preterm parturition has been established. Evidence for causality includes the following: (1) intrauterine infection or systemic administration of microbial products (bacterial endotoxin) to pregnant animals results in spontaneous preterm labor and birth¹⁴¹⁻¹⁵³; (2) extrauterine maternal infections (malaria,^{154,155} pyelonephritis,¹⁵⁶⁻¹⁶⁰ pneumonia,¹⁶¹⁻¹⁶³ and periodontal disease¹⁶⁴⁻¹⁶⁹) are associated with preterm delivery; (3) subclinical intrauterine infections are consistently associated with preterm labor and preterm birth¹⁷⁰; (4) pregnant

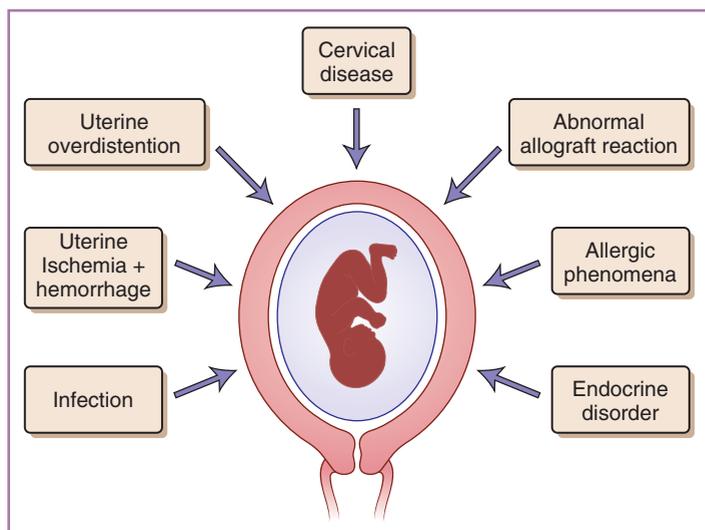

FIGURE 28-4 The preterm parturition syndrome. Multiple pathologic processes can lead to activation of the common pathway of parturition. (Modified from Romero R, Espinoza J, Mazor M, Chaiworapongsa T: The preterm parturition syndrome. In Critchely H, Bennett P, Thornton S (eds): *Preterm Birth*. London: RCOG Press, 2004, pp 28-60.)

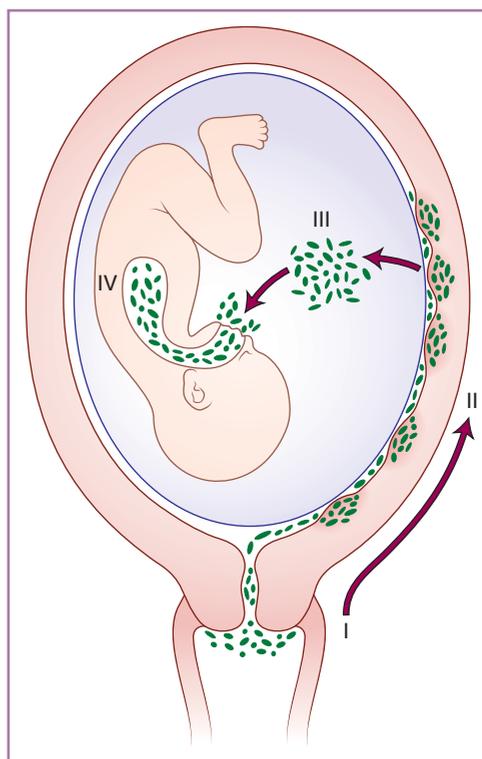

FIGURE 28-6 The pathway of ascending intrauterine infection. Stage I refers to a change in microbial flora in the vagina and/or cervix. In Stage II, microorganisms are located between the amnion and chorion. Stage III represents intra-amniotic infection, and Stage IV is fetal invasion. The most common sites for microbial attack are the skin and the fetal respiratory tract. (Reproduced with permission from Romero R, Mazor M: *Infection and preterm labor*. Clin Obstet Gynecol 31:553-584, 1988.)

women with intra-amniotic infection¹⁷¹⁻¹⁷³ or inflammation (defined as an elevation of amniotic fluid concentrations of proinflammatory cytokines^{174,175} and matrix-degrading enzymes¹⁷⁶ in the mid-trimester) are at risk for subsequent spontaneous preterm birth; (5) antibiotic treatment of ascending intrauterine infections can prevent preterm parturition in experimental models of chorioamnionitis^{149,177}; and (6) treatment of asymptomatic bacteriuria prevents preterm birth.^{178,179}

Because the amniotic cavity is sterile for bacteria in 99% of cases, detection of microorganisms in the amniotic cavity with either cultivation techniques or molecular microbiologic techniques defines microbial invasion of the amniotic cavity. Microorganisms or their products

can elicit an inflammatory response within the amniotic cavity: intra-amniotic inflammation. Inflammation of the chorioamniotic membranes, or histologic chorioamnionitis, can exist without clinical signs of infection (clinical chorioamnionitis). The stages of ascending intrauterine infection are displayed in Figure 28-6.

Microbiologic studies using cultivation techniques suggest that infection may account for 25% to 40% of all preterm births.^{180,181} Microbial invasion of the amniotic cavity (MIAC) is present in 12.8%¹⁸⁰ of women with preterm labor with intact membranes, in 32% of those with preterm PROM,¹⁸⁰ and in 51% of patients with acute cervical insufficiency.^{182,183} Patients with MIAC are more likely to deliver preterm neonates, have spontaneous rupture of membranes, and develop clinical chorioamnionitis than those with sterile amniotic fluid.¹⁸⁴ The most common organisms found in the amniotic fluid are genital mycoplasmas.^{185,186} It is believed that ascending infection is the most common source of microbial invasion of the amniotic cavity, although transplacental infections may also occur. The lower the gestational age at which a patient presents with preterm labor and preterm PROM, the higher the frequency of MIAC.^{187,188} Moreover, many of these infections appear to be chronic in nature, because they have been detected in women having mid-trimester amniocentesis for genetic indications.¹⁷¹⁻¹⁷³ Bacterial products such as endotoxin have also been detected in the amniotic cavity of women with preterm labor and preterm PROM.^{189,190} Endotoxin has powerful proinflammatory effects in maternal and fetal tissues.¹⁹¹⁻¹⁹³

Microorganisms are “sensed” by the innate components of the immune system,¹⁹⁴ which include (1) the soluble pattern recognition receptors (PRRs), lectin, and C-reactive protein; (2) transmembrane PRRs, which include scavenger receptors, C-type lectins, and Toll-like receptors (TLRs); and (3) intracellular PRRs, including Nod1 and Nod2, retinoic-induced gene type 1, and melanoma differentiation associated protein 5, which mediate recognition of intracellular pathogens (e.g., viruses).¹⁹⁵ The best-studied PRRs are the TLRs.¹⁹⁴ Ligation of TLR results in activation of NF- κ B, which, in turn, leads to the production of cytokines, chemokines, and antimicrobial peptides.¹⁹⁴ Because TLRs are crucial for the recognition of microorganisms, it could be anticipated that defective signaling through this pathway would impair bacteria-induced preterm labor. Consistent with this thesis, a strain of mice bearing a spontaneous mutation for TLR-4 was less likely to deliver preterm after intrauterine inoculation of heat-killed bacteria or administration of lipopolysaccharide than wild-type mice.^{151,196} In pregnant women, TLR-2 and TLR-4 are expressed in the amniotic epithelium¹⁹⁷ as well as in decidua.¹⁹⁸ Moreover, spontaneous labor that occurs at term or preterm and is complicated by histologic evidence of chorioamnionitis, regardless of the membrane status (intact or ruptured), is associated with increased mRNA expression of TLR-2 and TLR-4 in the chorioamniotic membranes.¹⁹⁷ These observations suggest that the innate immune system plays a role in parturition.

The Role of Proinflammatory Cytokines

Inflammation and its mediators, chemokines such as IL-8, the proinflammatory cytokines (IL-1 β , TNF- α), and other mediators (e.g., platelet activating factor, prostaglandins) are central to preterm parturition induced by infection. IL-1 was the first cytokine implicated in the onset of preterm labor associated with infection.¹⁹⁹ Evidence in support of this concept includes the following: (1) IL-1 is produced by human decidua in response to bacterial products²⁰⁰; (2) IL-1 α and IL-1 β stimulate prostaglandin production by human amnion and decidua²⁰¹; (3) IL-1 α and IL-1 β concentrations and IL-1-like bioactiv-

ity are increased in the amniotic fluid of women with preterm labor and infection²⁰²; (4) intravenous IL-1 β stimulates uterine contractions²⁰³; and (5) administration of IL-1 to pregnant animals induces preterm labor and delivery,²⁰⁴ and this effect can be blocked by the administration of its natural antagonist, the IL-1 receptor antagonist (IL-1ra).²⁰⁵

Evidence supporting the role of TNF- α in the mechanisms of preterm parturition is similar and includes the following: (1) TNF- α stimulates prostaglandin production by amnion, decidua, and myometrium¹⁴⁸; (2) human decidua can produce TNF- α in response to bacterial products^{206,207}; (3) amniotic fluid TNF- α bioactivity and immunoreactive concentrations are elevated in women with preterm labor and intra-amniotic infection²⁰⁸; (4) in women with preterm PROM and intra-amniotic infection, TNF- α concentrations are higher in the presence of labor²⁰⁸; (5) TNF- α can stimulate the production of MMPs,^{209,210} which have been implicated in membrane rupture^{85,211,212}; (6) TNF- α application to the cervix induces changes that resemble cervical ripening²¹³; (7) TNF- α can induce preterm parturition when administered systemically to pregnant animals^{214,215}; and (8) TNF- α and IL-1 β enhance IL-8 expression by decidual cells, and this chemokine is strongly expressed by term decidual cells in the presence of chorioamnionitis.²¹⁶ Figure 28-7 displays the mechanisms involved in preterm parturition in the setting of infection.

Other cytokines and chemokines (IL-6,^{187,217-221} IL-10,^{203,222,223} IL-16,²²⁴ IL-18,²²⁵ colony-stimulating factors,²²⁶⁻²²⁸ macrophage migration inhibitory factor,²²⁹ IL-8,^{228,230-234} monocyte chemoattractant protein-1,²³⁵ epithelial cell-derived neutrophil-activating peptide-78,²³⁶ and, regulated on activation, normal T-cell expressed and secreted (RANTES)²³⁷ have also been implicated in infection-induced preterm delivery. The redundancy of the cytokine network implicated in parturition is such that blockade of a single cytokine is insufficient to prevent preterm delivery in the context of infection. For example, preterm labor after exposure to infection can occur in knockout mice for the IL-1 type I receptor, suggesting that IL-1 is sufficient, but not necessary, for the onset of parturition in the context of intra-amniotic infection/inflam-

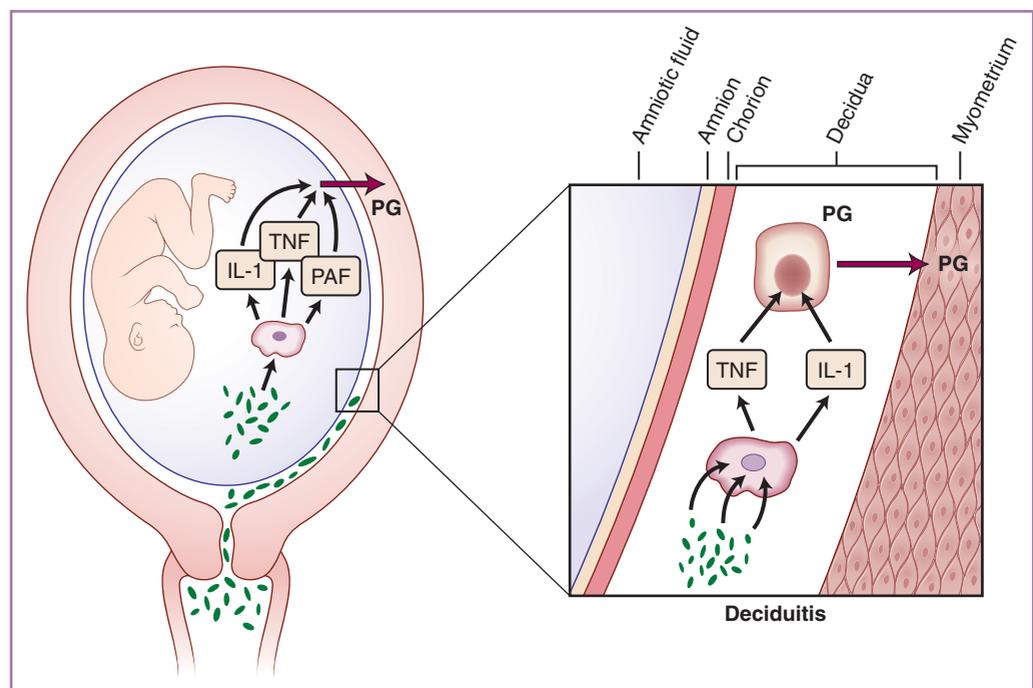

FIGURE 28-7 Cellular and biochemical mechanisms involved in initiation of preterm labor in cases of intrauterine infection. IL-1, interleukin-1; TNF, tumor necrosis factor/cachectin; PG, prostaglandins; PAF, platelet activating factor. mation.²³⁸ However, blockade of both signaling pathways (i.e., for IL-1 and TNF- α) in a double-knockout mice model was associated with a decreased rate of preterm birth after the administration of microorganisms.²¹⁵

Anti-inflammatory Cytokines and Preterm Labor

IL-10 is thought to be a key cytokine for the maintenance of pregnancy.²³⁹⁻²⁴¹ Its concentrations are increased in intra-amniotic inflammation,²⁴² suggesting that IL-10 may play a role in dampening the inflammatory response²⁴³⁻²⁴⁸ and may have therapeutic value.²⁴⁹⁻²⁵⁴ In a nonhuman primate model of intrauterine infection, pregnant rhesus monkeys ($n = 13$) were allocated to one of three interventional groups: (1) intra-amniotic IL-1 β infusion with maternal dexamethasone intravenously ($n = 4$); (2) intra-amniotic IL-1 β + IL-10 ($n = 5$); or (3) intra-amniotic IL-1 β administered alone ($n = 5$). Dexamethasone and IL-10 treatment significantly reduced IL-1 β -induced uterine contractility ($P < .05$). The amniotic fluid concentrations of TNF- α and leukocyte counts were also decreased by IL-10 treatment ($P < .05$).²⁰³ Furthermore, the administration of IL-10 in animal models of infection has been associated with improved pregnancy outcome.^{249,255}

Fetal Involvement in Intrauterine Infection

Carroll and Nicolaides²⁵⁶ found fetal bacteremia in 33% of fetuses with positive amniotic fluid cultures and in 4% of those with negative amniotic fluid cultures in the context of preterm PROM. Therefore, subclinical fetal infection is far more common than traditionally recognized. Recently, Goldenberg and colleagues²⁵⁷ reported that 23% of neonates born between 23 and 32 weeks of gestation had positive umbilical blood cultures for genital mycoplasmas.

Inflammation and Fetal Injury: The Fetal Inflammatory Response Syndrome

The fetal inflammatory response syndrome (FIRS) was initially described in pregnancies complicated by preterm labor and preterm PROM.^{258,259} It was defined as a fetal plasma concentration of IL-6 greater than 11 pg/mL.²⁵⁸ Fetuses with an elevated plasma IL-6 concentration had a higher rate of severe neonatal morbidity and a shorter cordocentesis-to-delivery interval than those with an IL-6 concentration lower than 11 pg/mL.²⁵⁹ These original findings were subsequently confirmed.²⁵⁹⁻²⁶² The histopathologic landmarks of FIRS are funisitis and chorionic vasculitis.²⁶³ The disorder can also be diagnosed by measurement of C-reactive protein concentrations in umbilical cord blood.²⁶⁴ Fetuses with FIRS have more systemic involvement, including hematologic abnormalities (neutrophilia), and a higher median nucleated red blood cell count than those without elevated IL-6.²⁶⁵ In addition, they have evidence of fetal stress, as determined by the fetal plasma ratio of cortisol to dehydroepiandrosterone sulfate (DHEAS),²⁶⁶ congenital fetal dermatitis,²⁶⁷ fetal cardiac dysfunction,²⁶⁸ involution of the thymus,²⁶⁹ and abnormalities of the fetal lung^{230,232,262,270-274} and brain.²⁷⁵⁻³⁰⁴

Among patients with preterm PROM, elevated fetal plasma IL-6 is associated with the impending onset of preterm labor, regardless of the inflammatory state of the amniotic fluid (Fig. 28-8).²⁵⁸ This suggests that the human fetus plays a role in initiating the onset of labor. However, maternal-fetal cooperation must occur for parturition to be completed. Fetal inflammation has been linked to the onset of labor in association with ascending intrauterine infection. However, systemic fetal inflammation may occur in the absence of labor if the inflammatory process does not involve the chorioamniotic membranes and decidua. Such instances may take place in the context of hema-

togenous viral infections or other disease processes (e.g., rhesus alloimmunization).³⁰⁵

Gene-Environment Interaction

A gene-environment interaction is said to be present when the risk of a disease (occurrence or severity) among individuals exposed to both the genotype and an environmental factor is either more severe or less severe than that which is predicted from the presence of either the genotype or the environmental exposure alone.^{306,307} Evidence in support of a gene-environment interaction in infection-related premature labor was reported by Macones and coworkers³⁰⁸ in a case-control study in which cases were defined as patients who had a spontaneous preterm delivery (<37 weeks) and controls as women who delivered after 37 weeks. The environmental exposure was clinically diagnosed bacterial vaginosis (symptomatic vaginal discharge, a positive whiff test, and clue cells on a wet preparation). The genotype of interest was TNF- α allele 2, given that carriage of this genotype had been demonstrated by the authors to be associated with spontaneous preterm birth in previous studies.³⁰⁹ The key observation was that patients with both bacterial vaginosis and the TNF- α allele 2 had an odds ratio of 6.1 (95% confidence interval [CI], 1.9 to 21) for spontaneous preterm delivery and that this odds ratio was higher than for patients with either bacterial vaginosis or carriage of the TNF- α allele alone, suggesting that a gene-environment interaction predisposes to preterm birth.^{308,310} Similar interactions may determine the susceptibility to intrauterine infection, microbial invasion of the fetus, and the likelihood of fetal injury.

Uteroplacental Vascular Disease and Decidual Hemorrhage

Vaginal bleeding in the first or second trimester is a risk factor for preterm birth. Bleeding in the first trimester alone is associated with an adjusted risk ratio of 2 (95% CI, 1.6 to 2.5) for preterm delivery.³¹¹ If vaginal bleeding is present in more than one trimester, the odds ratio for preterm PROM is 7.4 (95% CI, 2.2 to 25.6).³¹² Therefore, a disorder of uterine hemostasis that manifests clinically as bleeding places the patient at risk for preterm birth. The location of bleeding could be the decidua, specifically the interface between decidual parietalis and chorion or between the basal plate of the placenta and the decidua. The latter, when large enough, is known as abruptio placenta. The typical patient with vaginal bleeding who delivers preterm is a privately insured, white, older, parous, and college-educated patient.³¹³

The evidence in support of spiral artery vasculopathy and decidual hemorrhage as a mechanism of disease in spontaneous preterm delivery is the following: (1) abruptio placenta, a lesion of uteroplacental vascular origin is more frequent in women who deliver preterm with intact membranes^{314,315} or with PROM than in those who deliver at term³¹⁶⁻³¹⁸; (2) the frequency of SGA infants is increased in women who deliver after preterm labor with intact membranes and preterm PROM³¹⁹⁻³²⁴ (SGA has generally been attributed to a problem with the uterine vascular supply line, and this could account for both IUGR and abruption-associated preterm parturition); (3) vascular lesions in decidual vessels attached to the placenta have been reported in 34% of women with preterm labor and intact membranes and in 35% of those with PROM, but only in 12% of control patients (term gestations without complications) (such vascular lesions are associated with a mean odds ratio of 3.8 for preterm labor with intact membranes and 4 for PROM)³¹⁵; (4) women with preterm labor and intact membranes and those with preterm PROM have a higher percentage of failure of physiologic transformation in the myometrial segment of the spiral

	n	Procedure-to-delivery interval (median, range, days)

IV AF IL-6 ≤ 7.9 ng/mL FP IL-6 > 11 pg/mL 	5	0.75 (0.13–1)

FIGURE 28-8 Classification and procedure-to-delivery intervals of patients according to amniotic fluid (AF) and fetal plasma (FP) concentrations of interleukin-6 (IL-6). In the FP, the white color indicates a low concentration of IL-6, and the dark red color represents a high concentration. Likewise, the white color in the AF compartment indicates a low concentration of IL-6, and the gray color indicates a high concentration. (Reproduced with permission from Romero R, Gomez R, Ghezzi F, et al: A fetal systemic inflammatory response is followed by the spontaneous onset of preterm parturition. *Am J Obstet Gynecol* 179:186-193, 1998.)

arteries than women who deliver at term^{325,326}; (5) decidual hemosiderin deposition and retrochorionic hematoma formation is present in 37.5% of patients who deliver preterm after PROM (between 22 and 32 weeks of gestation) than in those who deliver at term (0.8%)³²⁷ (patients with preterm deliveries with intact membranes had decidual hemosiderin in 36% of cases); and (6) patients presenting with preterm labor and intact membranes who go on to have a preterm delivery are more likely to have an abnormal uterine artery velocimetry than patients with an episode of preterm labor who deliver at term.³²⁸⁻³³⁰

The mechanisms by which uteroplacental ischemia, decidual hemorrhage, or both may activate the common pathway of parturition include the generation of thrombin. Evidence in support of this mechanism has been summarized elsewhere³³¹ and includes the following: (1) because decidua is a rich source of tissue factor, the primary initiator of coagulation, hemorrhage into the decidua would generate substantial quantities of thrombin, explaining the strong association between abruption and disseminated intravascular coagulation³³²; (2) intrauterine administration of whole blood to pregnant rats stimulates myometrial contractility,³³³ but administration of heparinized blood does not (heparin blocks the generation of thrombin)³³³; (3) fresh whole blood stimulates myometrial contractility in vitro, and this effect is partially blunted by incubation with hirudin, a thrombin inhibitor³³³; (4) thrombin stimulates myometrial contractility in a dose-dependent manner³³³; (5) thrombin stimulates the production of MMP-1,³³⁴ urokinase-type plasminogen activator (uPA), and tissue-type plasminogen activator (tPA) by decidualized endometrial stromal

cells in culture³³⁵ (MMP-1 can digest collagen directly, whereas uPA and tPA catalyze the transformation of plasminogen into plasmin, which in turn can degrade type III collagen and fibronectin,³³⁶ important components of the extracellular matrix of the chorioamniotic membranes and decidua³³⁷); (6) thrombin/antithrombin (TAT) complexes, a marker of in vivo generation of thrombin, are increased in the plasma³³⁸ and amniotic fluid³³⁹ of patients with preterm labor and preterm PROM; (7) an elevation of plasma TAT complex concentration in the second trimester is associated with subsequent preterm PROM³⁴⁰; and (8) the presence of retroplacental hematoma detected by ultrasound examination in the first trimester is associated with adverse pregnancy outcomes, including preterm delivery and fetal growth restriction.³⁴¹

Additional evidence providing biologic plausibility for a role of thrombin is that the production of MMP-3 mRNA and protein by term decidual cells is normally inhibited by progesterins. However, thrombin reverses this inhibition by interacting with the protease-activated receptor type 1 (PAR-1).³⁴² This is important, because MMP-3 can degrade extracellular matrix located in the decidua and fetal membranes, but it can also activate MMP-1 and MMP-9, which can degrade, respectively, fibrillar collagen and gelatin. Thrombin also binds to PARs and increases expression of MMP-1 mRNA and proteins by decidual cells.³³⁴

Histologic examination of placentas with abruption frequently show evidence of inflammation.^{343,344} Neutrophils in the decidua colocalize with areas of fibrin deposition, suggesting a link between inflam-

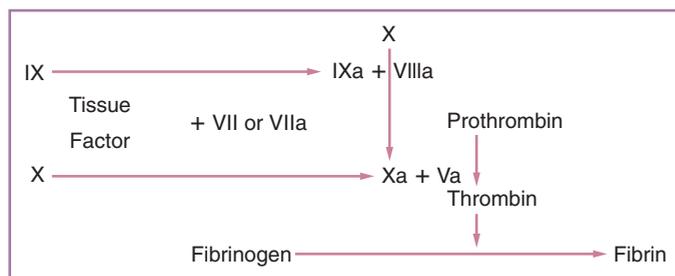

FIGURE 28-9 Tissue factor generates thrombin. The decidua is a rich source of tissue factor, the primary initiator of clotting. Disruption of spiral arteries and/or arterioles permits factor X or IX to be activated by the action of factor VII when complexed with tissue factor. Factor IXa combines with its cofactor VIIa to generate factor Xa indirectly. In either case, Xa binds to its cofactor to convert prothrombin to thrombin, which cleaves fibrinogen to fibrin.

mation and thrombin generation. Thrombin increases IL-8 mRNA and protein expression by decidual cells. IL-8 is a potent neutrophil chemokine that is capable of attracting neutrophils to the areas of bleeding.³⁴⁴ Inasmuch as neutrophils are a rich source of MMP-8, MMP-9, elastase,³⁴⁵ and reactive oxygen radicals,³⁴⁶⁻³⁴⁸ these products can contribute to extracellular matrix degradation in the decidual/membrane interface and to membrane rupture.

IL-11 has been demonstrated in the decidua of patients with abruption and preterm PROM. Thrombin induces IL-11 production (mRNA and protein) by decidual cells,³⁴⁹ and IL-11 can induce PGE₂ production.³⁴⁹ Therefore, this cytokine provides a link between thrombin generation, inflammation, activation of PARs, and the common pathway of parturition. Figures 28-9 and 28-10 describe the molecular mechanisms implicated in hemorrhage- or vascular-induced preterm labor.

Maternal and Fetal Stress

Maternal stress of exogenous or endogenous origin is modestly associated with an increased risk for preterm delivery.³⁵⁰⁻³⁵⁴ The nature and timing of the stressful stimuli can range from a heavy workload to anxiety and depression.^{355,356} African-American women with elevated scores for depression have an adjusted odds ratio for preterm delivery of 1.96 (95% CI, 1.04 to 3.72).³⁵⁷ The absence of similar findings in Hispanic and non-Hispanic white populations suggests an ethnic disparity in the effect of stress in the United States.

The stressful insult could occur in the pre-conceptional period or during pregnancy. Starvation before pregnancy leads to spontaneous preterm delivery in sheep.³⁵⁸ The precise mechanism whereby stress induces parturition is not known. However, a role for CRH has been proposed. This hormone was originally identified in the hypothalamus but is expressed by the placenta.³⁵⁹ The maternal plasma CRH concentrations increase during the second half of pregnancy and peak during labor, whereas serum concentrations of the CRH binding protein decline during the third trimester.^{360,361}

Smith and colleagues^{360,361} demonstrated that the trajectory of CRH serum concentration changes identify women destined for preterm, term, and post-term delivery. The mechanisms regulating the serum concentration and trajectory of CRH have been described as “a placental clock.” Because CRH maternal plasma concentrations are elevated in both term and preterm parturition, it would appear that CRH is part of the common pathway of labor.

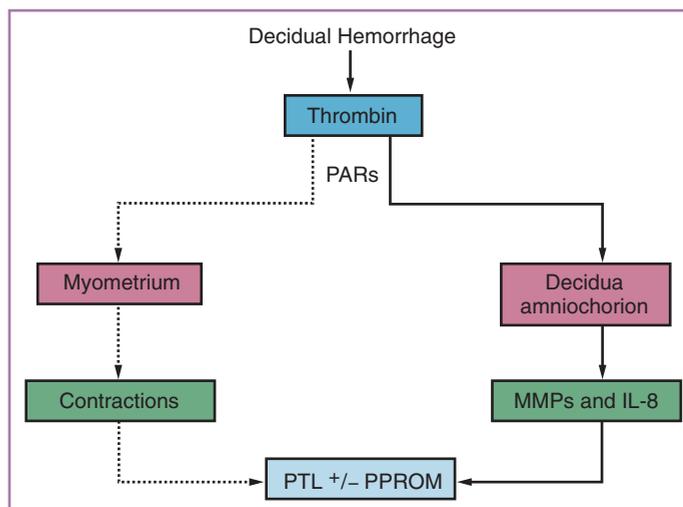

FIGURE 28-10 Mechanisms implicated in abruption-associated preterm labor and delivery. IL-8, interleukin 8; MMPs, matrix metalloproteinases; PARs, protease-activated receptors; PTL, preterm labor; PPROM, preterm premature rupture of membranes.

The mechanisms through which CRH activates the common pathway of parturition include the following: (1) increased production of PGE₂ by amnion, chorion, and placental cells, but not by decidual cells³⁶²⁻³⁶⁴; (2) increased production of PGE_{2α} by amnion, decidua, and placental cells, but not by chorion³⁶²⁻³⁶⁴; (3) increased expression of MMP-9 by chorion and amnion³⁶⁵; (4) stimulation of the release of adrenocorticotropin (ACTH) from the pituitary gland to drive fetal cortisol production³⁶⁶ (this establishes a feed-forward cycle, because cortisol stimulates production of CRH by the placenta and fetal membranes)³⁵⁹; (5) induction of the synthesis of fetal DHEAS by the fetal adrenal zone³⁶⁷⁻³⁶⁹ (DHEAS serves as a source for estrogens,³⁶⁷ which in turn enhance the expression of the oxytocin receptor, COX-2, prostaglandin receptors, and connexin-43)³⁷⁰⁻³⁷⁷; (6) cortisol produced in response to CRH can increase amnion COX-2 expression while inhibiting chorionic PGDH expression³⁷⁸⁻³⁸¹ (resulting in a net bioavailability of prostaglandins); and (7) CRH inhibits progesterone production by the placenta.³⁸² Figures 28-11 and 28-12 illustrate the molecular mechanisms for stress-associated preterm labor.

As noted, CRH has been implicated in the mechanisms of spontaneous parturition at term. Therefore, this specific pathway may operate in normal term labor as well as in preterm labor. In the former case, placental CRH expression reflects maturation of the fetal hypothalamic-pituitary-adrenal axis; in the latter, it reflects physiologically stressful events occurring at later gestational ages. It may be surmised that some cases of preterm labor occurring close to term resort to the physiologic mechanisms used in term labor after fetal maturation has been accelerated by stressful stimuli.

Uterine Overdistention

Patients with müllerian duct abnormalities,³⁸³ polyhydramnios,^{384,385} or multiple gestations³⁸⁶ are at increased risk for spontaneous preterm labor and delivery. The frequency of preterm delivery in multifetal gestations is 17%, and the mean gestational age at delivery decreases as a function of the number of fetuses: 35.3 weeks for twins, 32.2 weeks for triplets, and 29.9 weeks for quadruplets.⁴ Myometrial stretch has been implicated as a key mechanism driving these preterm deliveries.

However, the importance of stretch as a mechanism of activation of the common pathway of parturition is not restricted to the myometrium. Indeed, stretch may play a role in cervical remodeling and membrane rupture.³⁸⁷

How does stretch activate the common pathway of parturition? Intra-amniotic pressure remains relatively constant during gestation, despite the continued growth of the fetus, placenta, and uterus.^{388,389} This stability of pressure has been attributed to progressive myometrial relaxation caused by the effects of progesterone³⁹⁰ and nitric oxide.³⁹¹ Stretch, however, can induce increased myometrial contractility,³⁹² prostaglandin release,³⁹³ expression of connexin-43,²⁶ and increased oxytocin receptors in pregnant and nonpregnant human myometrium.³⁹⁴ The gene expression of these stretch-induced contraction-associated proteins (CAPs) during pregnancy is inhibited by progesterone.²⁶

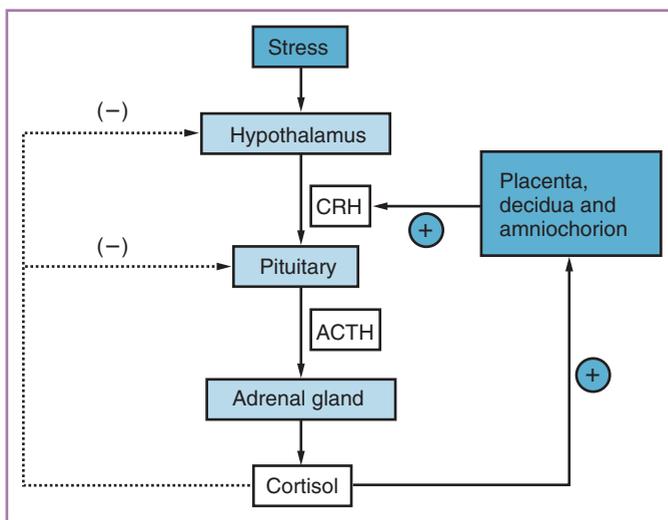

FIGURE 28-11 The fetal hypophysis-pituitary-adrenal-placental axis in pregnancy. ACTH, corticotropin; CRH, corticotropin-releasing hormone.

Mechanical stress in smooth muscle induces activation of integrin receptors³⁹⁵ and stretch-activated calcium channels,^{396,397} phosphorylation of platelet-derived growth factor receptor,³⁹⁸ and activation of G proteins.^{398,399} Mechanical force, once sensed, leads to activation of protein kinase C and mitogen activated protein kinases, increased gene expression of FOS (c-fos) and JUN (c-jun), and enhanced binding activity of transcription factor AP-1, which drives transcription of multiple parturition-associated genes.^{24,400-404} Other effects of physical forces relevant to myometrium include increased expression of COX-2, superoxide dismutase, and nitric oxide synthase. The precise nature of the sensing mechanisms of pressure/tension in the myometrium is yet to be determined.

Stretch can also affect the chorioamniotic membranes, which are distended by 40% at 25 to 29 weeks, 60% at 30 to 34 weeks, and 70% at term.⁴⁰⁵ Stretching of the membranes in vitro induces histologic changes characterized by elongation of the amnion cells and increased production of collagenase activity and IL-8,^{406,407} and stretching of amnion cells in culture results in increased production of PGE₂.⁴⁰⁸ Studies using an in vitro cell culture model for fetal membrane distention revealed upregulation of proinflammatory genes, including IL-8 and pre-B-cell colony-enhancing factor (visfatin).⁴⁰⁹ Distention of fetal membrane in vitro results in overexpression of four genes, namely IL-8, interleukin enhancer binding factor 2 (ILF2), huntingtin-interacting protein 2, and an interferon-stimulated gene encoding a 54-kDa protein.⁴¹⁰ Collectively, these observations suggest that mechanical forces associated with uterine overdistention may result in activation of mechanisms leading to membrane rupture.

Premature cervical ripening is also a feature of patients with multiple gestations, as well as those with certain müllerian duct anomalies (e.g., incompetent cervix in diethylstilbestrol [DES]-exposed daughters). IL-8,^{45,411,412} MMP-1,¹⁰⁴ prostaglandins,^{137,413,414} and nitric oxide⁴¹⁵ have been implicated in the control of cervical ripening. Inasmuch as these mediators are produced in response to membrane stretch, they may exert part of their biologic effects in parturition by stimulating extracellular matrix degradation of the cervix.

Figure 28-13 describes the mechanisms by which stretch may activate the common pathway of parturition. It is possible, however, that patients with multiple gestations represent a heterogeneous group.

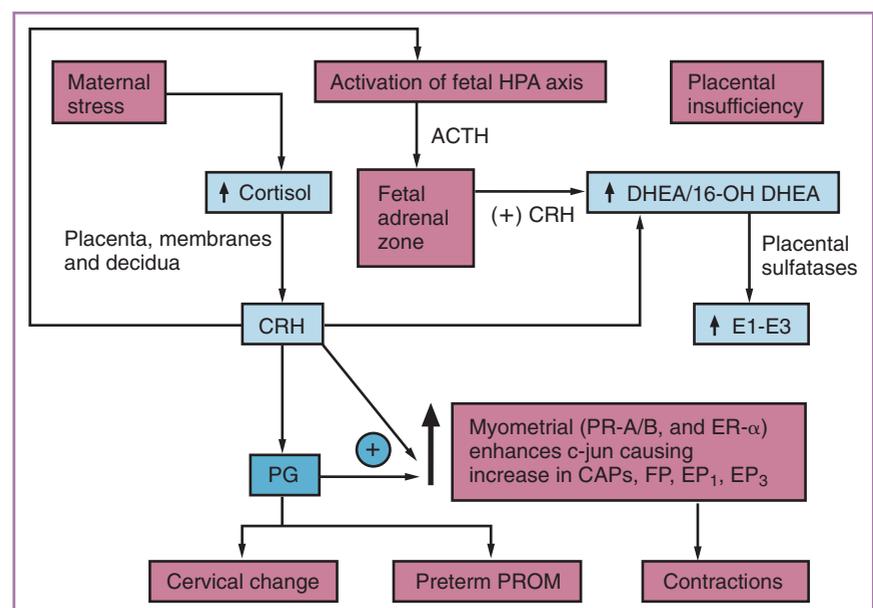

FIGURE 28-12 Proposed pathways by which stress can induce preterm labor. ACTH, corticotropin; CAPs, contraction-associated proteins; CRH, corticotropin-releasing hormone; DHEA, dehydroepiandrosterone; E1-E3, estrone, estradiol, and estriol; EP₁ and EP₃, prostaglandin E receptors types 1 and 3; ER- α , estrogen receptor- α ; FP, prostaglandin F receptor; HPA, hypophysis-pituitary-adrenal; PG, prostaglandins; PR, prostaglandin receptor; PROM, premature rupture of membranes.

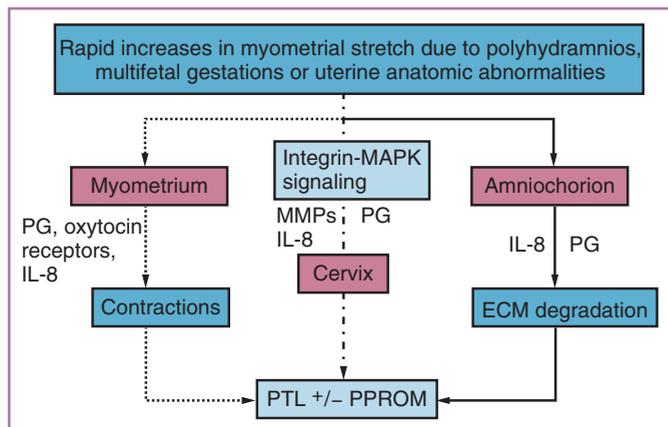

FIGURE 28-13 Proposed mechanisms by which stretch can induce preterm labor. ECM, extracellular matrix; IL-8, interleukin 8; MAPK, mitogen-activated protein kinase; MMPs, matrix metalloproteinases; PG, prostaglandins; PTL, preterm labor; PPROM, preterm premature rupture of membranes.

Some such patients have preterm labor associated with infection.⁴¹⁶⁻⁴¹⁸ Others have abnormalities of trophoblast invasion leading to vascular pathology, with or without fetal growth disorders, causing stress or decidual hemorrhage–mediated preterm deliveries. These separate mechanisms of disease may operate alone or in conjunction with uterine overdistention to activate the components of the common pathway.

Allergic Phenomena

Another potential mechanism of disease in preterm labor is an immunologically mediated phenomenon induced by an allergic mechanism. We have previously proposed that an allergic-like immune response (type I hypersensitivity) may be associated with preterm labor.⁴¹⁹ The term “allergy” refers to disorders caused by the response of the immune system to an otherwise innocuous antigen.⁴²⁰ This “allergen” cross-links immunoglobulin E (IgE) bound to high-affinity receptors on uterine mast cells, causing degranulation of these cells. The products of degranulation initiate inflammation.⁴²¹

Evidence in support of the possibility that an allergic-like phenomenon may operate in preterm labor includes the following: (1) the human fetus is exposed to common allergens such as house-dust mite, which has been detected in amniotic fluid in the mid-trimester of pregnancy and in umbilical cord blood⁴²²; (2) allergen-specific reactivity has been shown in umbilical cord blood at birth and as early as 23 weeks of gestation⁴²³; (3) pregnancy is traditionally regarded as a T helper 2 (T_H2) state that favors the production of IgE; (4) the human uterus contains mast cells, the effector cells of allergy⁴²⁴; (5) products of mast cell degranulation (i.e., histamine and prostaglandins) may induce myometrial contractility^{425,426}; (6) pharmacologic degranulation of mast cells induces myometrial and cervical contractility^{427,428}; (7) incubation of myometrial strips from sensitized and nonsensitized animals with an anti-IgE antibody increases myometrial contractility⁴²⁸; (8) human myometrial strips obtained from women known to be allergic to ragweed demonstrate increased myometrial contractility when challenged in vitro by the allergen, and, moreover, the sensitivity of the myometrial strips of nonallergic women can be transferred passively by preincubation of the strips with human serum (Robert Garfield, University of Texas, Galveston, personal communication); (9)

nonpregnant guinea pigs sensitized with ovalbumin and then challenged with this antigen demonstrate increased uterine tone⁴²⁸; (10) traditional descriptions of animals dying of anaphylactic shock have demonstrated enhanced uterine contractility when autopsy was performed immediately after death; (11) severe latex allergy in a pregnant woman after vaginal examination with a latex glove was followed by regular uterine contractions⁴²⁹; (12) human decidua contains immune cells capable of identifying local foreign antigens, including macrophages, B cells, T cells,^{430,431} and dendritic cells⁴³²; and (13) we have identified a subgroup of patients with preterm labor who have eosinophils in the amniotic fluid as the predominant white blood cell⁴¹⁹ (under normal circumstances, white blood cells are not present in amniotic fluid; the presence of eosinophils therefore suggests an abnormal immune response, and perhaps they are the markers of an allergic-like response in preterm labor). The antigen eliciting an abnormal immunologic response remains to be identified. Recent evidence suggests that administration of ovalbumin to sensitized pregnant guinea pigs can induce preterm labor and delivery and that this phenomenon can be prevented with treatment with either cromolyn sodium or antihistaminics.⁴³³

Cervical Disorders

Cervical insufficiency is traditionally considered a cause of mid-trimester abortion. However, accumulating evidence suggests that it can produce a wide spectrum of disease,⁴³⁴ including the well-recognized recurrent pregnancy loss in the mid-trimester, some forms of preterm labor (presenting with bulging membranes in the absence of significant uterine contractility or rupture of membrane), and probably precipitous labor at term. Cervical disease may be the result of a congenital disorder (i.e., hypoplastic cervix or DES exposure in utero), surgical trauma (i.e., conization resulting in substantial loss of connective tissue) or traumatic damage of the structural integrity of the cervix (i.e., repeated cervical dilation).⁴³⁵

Cervical insufficiency in the mid-trimester can be considered an example of asynchronous activation of the mechanisms that induce cervical remodeling. Indeed, it is likely that most cases of “cervical insufficiency” reflect not primary cervical disease leading to premature remodeling but other pathologic processes, such as infection, which has been reported in 50% of patients presenting with acute cervical insufficiency,¹⁸³ or recurrent decidual hemorrhage. The reader is referred to a detailed review of this condition and the role of cervical cerclage in the prevention of preterm birth.⁴³⁶

Hormonal Disorders: Suspension of Progesterone Action

Progesterone has been considered central to pregnancy maintenance.⁴³⁷ Progesterone promotes myometrial quiescence, downregulates gap junction formation, inhibits cervical ripening, and decreases the production of chemokines (i.e., IL-8) by the chorioamniotic membranes, which is thought to impede decidual/membrane activation.^{65,438-440} Progesterone is considered important for pregnancy maintenance in humans, because inhibition of progesterone action can result in parturition. Administration of progesterone receptor antagonists (i.e., mifepristone or onapristone) to pregnant women, nonhuman primates,⁴⁴¹ and guinea pigs⁶⁵ can induce labor or cervical change or both.⁴³⁷ Therefore, a suspension of progesterone action is believed to be important for the onset of parturition in humans.

In many species, a progesterone withdrawal (a drop in serum progesterone concentration) occurs before spontaneous labor.⁴⁴²

However, in humans, nonhuman primates, and guinea pigs, a progesterone withdrawal has not been demonstrated (see Young⁴⁴³ for a description of the comparative physiology of parturition in mammals).

The mechanism by which, in humans, progesterone action is suspended in the setting of sustained high circulating concentrations of progesterone has eluded discovery. Six potential mechanisms have been posited to explain this paradox: (1) reduced bioavailability of progesterone by binding to a high-affinity protein^{444,445}; (2) increased cortisol concentration in late pregnancy, which may compete with progesterone for binding to the glucocorticoid receptor⁴⁴⁶; (3) conversion of progesterone to an inactive form within the target cell before it interacts with its receptor^{447,448}; (4) quantitative and qualitative changes in progesterone receptor isoforms (PR-A, PR-B, PR-C)⁴⁴⁹⁻⁴⁵²; (5) changes in progesterone receptor coregulators⁴⁵³; and (6) a functional progesterone withdrawal through NF- κ B.⁴⁵⁴⁻⁴⁵⁶

Progesterone's actions are mediated by multiprotein complexes, including progesterone receptors, modifying factors (co-regulators and adaptors), and effector proteins (RNA-polymerase, chromatin-remodeling proteins, and RNA-processing factors). In addition, non-genomic mechanisms have recently been proposed.⁴⁵³

There is evidence supporting the view that a "functional progesterone withdrawal" occurs locally in intrauterine tissues during human parturition in both term and preterm gestation.^{453,457-463} The changes in the ratio of estrogen and progesterone activity could activate the three tissue components of the common pathway of parturition, including myometrium, cervix, and decidual-amniochorionic membranes directly or indirectly through prostaglandin or oxytocin and its receptor systems.^{437,450,451,453,457-469} However, the signal eliciting the onset of these hormonal functional changes in human parturition remains to be determined.

The interest in progestins to prevent preterm delivery has been rekindled by several randomized clinical trials, suggesting that progestins may prevent preterm delivery.⁴⁷⁰ The initial trials were conducted in women with a previous preterm delivery and used either vaginal progesterone⁴⁷¹ or 17 α -hydroxyprogesterone caproate.⁶⁷ Subsequently, vaginal progesterone was reported to reduce the rate of preterm birth by 40% in women with a short cervix (≤ 15 mm).⁶⁸ A post hoc analysis of another trial was supportive of this concept.^{66,472} The precise mechanisms by which exogenous progestins reduce the rate of preterm birth are unknown. It is possible that exogenous progesterone inhibits cervical remodeling in the mid-trimester of pregnancy through the mechanisms outlined earlier in this chapter.

Summary

It is becoming increasingly evident that preterm labor, preterm PROM, and cervical insufficiency are syndromes caused by multiple pathologic processes leading to increased myometrial contractility, cervical remodeling, and/or membrane activation. The clinical presentation depends on the nature and timing of the insults affecting the various components of the uterine common pathway of parturition. This view has important implications for understanding the biology of preterm parturition, as well as its diagnosis, treatment, and prevention.

Chapter 29

Preterm Labor and Birth

Jay D. Iams, MD, Roberto Romero, MD, and Robert K. Creasy, MD

Preterm birth is the principal unsolved problem in perinatal medicine. In 2005, one of every eight births in the United States was preterm—more than 525,000 infants. Advances in care have improved outcomes for preterm infants, but prematurity is still the most common underlying cause of perinatal¹ and infant² morbidity and mortality. Surviving infants may experience lifelong consequences, including neurodevelopmental, respiratory, gastrointestinal, and other morbidities. The rate of preterm birth has risen by more than one third since the 1980s, even as the perinatal mortality rate has decreased.

Preterm births are preceded by numerous clinical conditions that fall into two broad categories, according to whether one or more steps of the parturitional process (cervical ripening, membrane and decidual activation, and coordinated uterine contractility) has or has not begun. The first group, often called *spontaneous preterm births*, includes preterm labor with intact membranes, preterm premature rupture of the membranes (pPROM) before labor begins, preterm cervical effacement or insufficiency, and some instances of uterine bleeding of uncertain origin. The second group, called *indicated preterm births*, comprises preterm births that are medically initiated because of maternal or fetal compromise. These categories are sometimes indistinct in clinical practice but are useful to organize intervention strategies. The pathophysiology of preterm parturition is discussed in Chapter 28. This chapter addresses the overall problem of preterm birth, including the epidemiology and burden of disease for all preterm neonates and specific care for the clinical syndrome of preterm labor. Clinical care for pregnancies complicated by cervical insufficiency or pPROM is discussed in Chapters 30 and 31, respectively. Newborn and childhood complications of preterm birth are discussed in Chapter 58.

The Problem of Preterm Birth

Definitions

A birth before 259 days (37 weeks) from the first day of the last normal menstrual period, or 245 days after conception, is commonly defined as *preterm*. The appropriate lower limit of gestational age separating preterm birth from spontaneous abortion is controversial and varies from 20 weeks or earlier in the United States to 23 to 24 weeks in Europe.³ The 20-week boundary was derived historically from quickening, the first signs of fetal movement, but pathologic and epidemiologic studies suggest that 16 to 17 weeks may be a more appropriate boundary, in that pregnancies ending between 16 and 20 weeks

are associated with increased risk of preterm birth in subsequent pregnancies.⁴⁻⁷

Infants who weigh less than 2500 g at birth, regardless of gestational age, are designated as *low birth weight* (LBW). Infants who weigh less than 1500 g are called *very low birth weight* (VLBW), and those below 1000 g are *extremely low birth weight* (ELBW).

LBW and preterm infants have in the past been considered together, but advances in pregnancy dating increasingly allow outcomes related to gestational age to be distinguished from outcomes related to birth weight. This is important, because perinatal and infant morbidities vary substantially according to gestational age and maturity as well as birth weight (see also Chapters 34 and 58).⁸ The current dual system, wherein obstetric data are recorded by gestational age but neonatal and infant data are analyzed by birth weight, has been identified as an impediment to optimal care by the Institute of Medicine.⁹ Data relating outcomes to percentiles of weight for gestational age are needed to identify and understand the causes and consequences of both prematurity and abnormal growth and to allow the fetal and neonatal patient to receive optimal care before and after birth.

The proportion of LBW infants who are preterm versus term varies among developed and underdeveloped nations.¹⁰ In underdeveloped countries, LBW infants are commonly growth restricted due to chronic maternal illness and/or malnutrition regardless of their gestational age (see Chapter 34). In developed nations, the majority of LBW infants are preterm. Indeed, some preterm infants weigh more than 2500 g at birth.⁸

Incidence of Preterm and Low-Birth-Weight Infants

Preterm Birth

Births before 37 weeks in the United States have increased by one third over the last 25 years. The rate was 9.4% in 1981, 10.6% in 1990, 12.7% in 2005, and 12.8% in 2006.¹¹

Approximately 75% of preterm births occur between 34 and 36 weeks (Fig. 29-1). Although these late preterm infants experience significant morbidity, the great majority of perinatal mortality and most serious morbidity occurs among the 16% of preterm infants (<3.5% of all births) who are born before 32 weeks' gestation.

Low Birth Weight

Rates of LBW have increased in parallel with the rising preterm birth rate. The overall LBW rate, including singleton and multiple gestations of all races, was 6.7% in 1984, 7.7% in 2001, and 8.2% in 2005. The

incidence of VLBW births (<1500 g) increased from 1.16% in 1981, to 1.27% in 1990, and to 1.49% in 2005, related primarily to the increase in multiple gestations.¹¹

There is substantial international variation in the LBW rate (Fig. 29-2), owing not only to differences in the actual rates but also to limitations in collecting data and to variations in the definitions and methods used to ascertain birth information.

Ascertainment of Preterm Birth and Low Birth Weight

Reported rates of preterm birth and, to a lesser extent, LBW are influenced by factors that must be understood to use this data

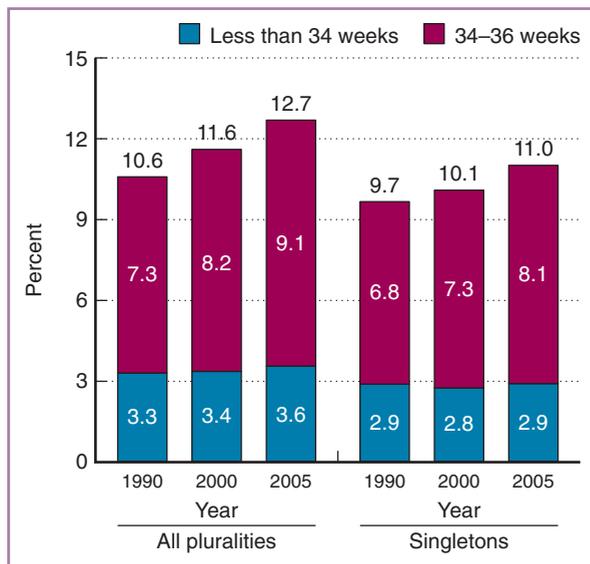

FIGURE 29-1 Preterm birth rates for all births and for singletons only: United States, 1990, 2000, and 2005. (From Hamilton BE, Martin JA, Sutton PD, et al: Births: Final data for 2005. Natl Vital Stat Rep 56[6]:4, 2007.)

appropriately: the variability of definitions, and the prevalence of ultrasound.

Available data are influenced by definitions of preterm and LBW that vary internationally and within the United States, where definitions may differ by state. The lower boundary of gestational age is usually 20 weeks in the United States, but it varies from 20 to 24 weeks in reports from other countries.¹²⁻¹⁴ The definition of LBW is universally accepted as a birth weight of less than 2500 g, but the lower boundary of 500 g is variable and in practice may be affected by cultural and religious beliefs and whether the infant shows signs of life.

Determination of gestational age by ultrasound measurement of fetal structures has superior accuracy over other methods when used in the first 12 to 20 weeks of pregnancy (see discussion by G. Alexander in reference 9, pp. 604-643). As the availability and quality of prenatal ultrasound services has increased, the distribution of gestational age has shifted to the left, reducing the number of post-term births and providing a corresponding increase in deliveries before 37 weeks of gestation (Fig. 29-3).

Rising Incidence of Preterm Birth

Regardless of the definitions chosen and the methods used to determine gestational age, the true incidence of preterm birth has increased in developed countries. There are two major reasons for the increase: the increased number of late preterm births (between 34 and 36 weeks' gestation) and the increased number of multifetal gestations.

In 1990, 7.3% of births occurred between 34 and 36 weeks; that rate has risen steadily, to 9.1% in 2005. In addition to the rise related to improved gestational dating by ultrasound, there has been a true increase in the number of preterm births between 34 and 36 weeks that are intentional or indicated (see earlier discussion). These indicated preterm births are the result of a decision to end the pregnancy for medical or obstetric reasons¹⁵ (Fig. 29-4; see Fig. 29-6).

Increased multifetal gestations are related to fertility therapies.¹⁶⁻¹⁸ Rates of preterm birth for infants born in multifetal pregnancies between 1990 and 2004 are shown in Figure 29-5. The rise in preterm births related to fertility therapies is discussed later in this chapter and in Chapter 25.

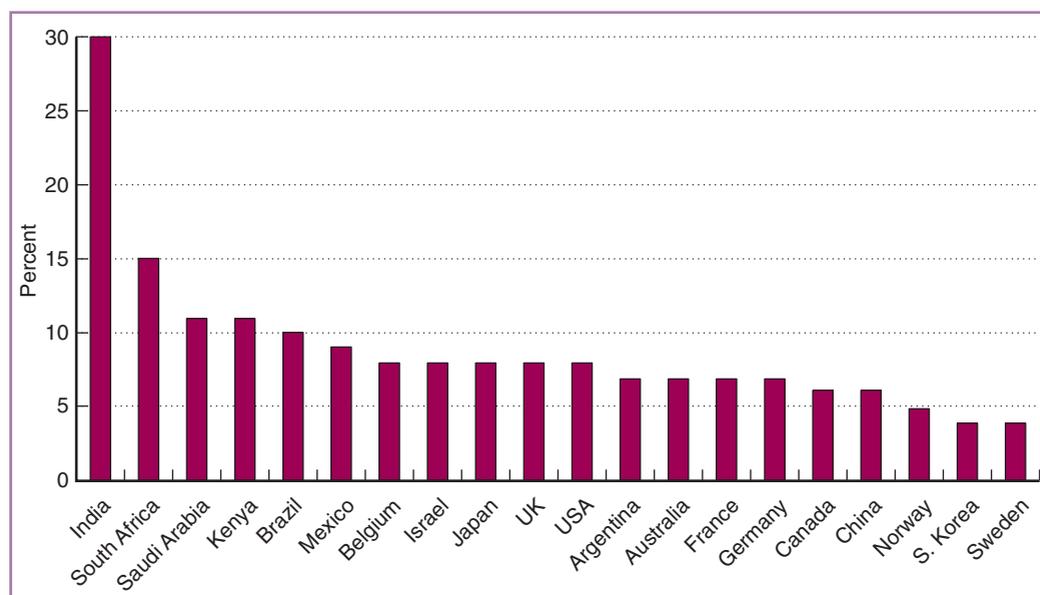

FIGURE 29-2 Percentage of low-birth-weight infants, by country. (Data from 2002 [latest available] from World Health Organization, http://www.who.int/whosis/database/core/core_select_process.cfm [accessed November 5, 2007].)

The Clinical Presentations of Preterm Birth

Preterm birth has been called “multifactorial” because of the numerous obstetric and medical conditions that accompany it. Traditional obstet-

ric taxonomy has not distinguished the *clinical presentations* of preterm parturition (e.g. preterm labor, pPROM, cervical insufficiency, amnionitis and/or vaginal bleeding) from *causative mechanisms* such as infection, hemorrhage, uterine distention, trauma, or fetal compromise, or from *risk factors* (e.g., multiple gestation, preeclampsia, abruptio

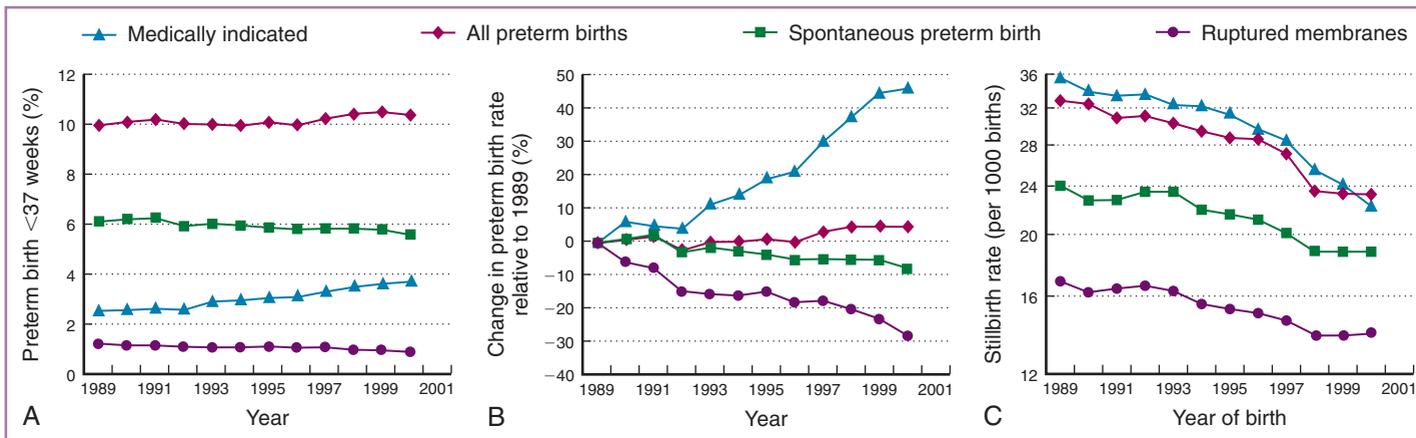

FIGURE 29-6 Temporal changes in singleton preterm births (<37 weeks) overall and in preterm births resulting from ruptured membranes, medically indicated preterm labor, and spontaneous preterm labor in the United States and in stillbirths, all races, 1989-2000. **A**, Rates in each group by year. **B**, The percentage change in rates relative to 1989. **C**, Temporal trends in stillbirth rates. (Adapted from Ananth CVP, Joseph KSM, Oyelese YM, et al: Trends in preterm birth and perinatal mortality among singletons: United States, 1989 through 2000. *Obstet Gynecol* 105:1084-1091, 2005.)

placentae, placenta previa, fetal growth restriction, maternal diabetes, hypertension, pyelonephritis). Designation of a clinical presentation such as preterm labor and pPROM as separate pathogenic entities has impaired understanding of the pathways leading to preterm birth. It is more useful to understand preterm birth in the two broad categories mentioned—as the result of preterm pathologic initiation of one or more steps in the parturitional process, or as a means to resolve maternal or fetal risk related to continuing the pregnancy.

The concept of spontaneous versus indicated preterm birth offered by Meis and colleagues is consistent with this distinction.¹⁹ Indicated preterm deliveries, which account for about 25% of preterm births in the United States, follow medical or obstetric conditions that would create undue risk for the mother (e.g., maternal sepsis, hypoxia), the fetus (e.g., poorly controlled maternal diabetes, intrauterine growth restriction), or both (e.g., maternal hypertension, placenta previa or abruption) if the pregnancy were to continue. The most common diagnoses preceding an indicated preterm birth are preeclampsia (40%), fetal distress (25%), intrauterine growth restriction (10%), placental abruption (7%), and fetal demise (7%).^{19,20} Other common causes include pregestational and gestational diabetes, renal disease, Rh sensitization, and congenital malformations.^{21,22}

Spontaneous preterm births, on the other hand, follow preterm labor, pPROM, or related diagnoses such as cervical insufficiency or amnionitis when labor begins in the absence of overt maternal or fetal illness that would otherwise require delivery. Risk factors associated with spontaneous preterm birth include genital tract colonization and infection, nonwhite race, multiple gestation, bleeding in the second trimester, low pre-pregnancy weight, and a history of previous spontaneous preterm birth.²³ Approximately 75% of preterm births are spontaneous.^{19,24,25}

The distinction between indicated and spontaneous preterm births is not always clear but provides a framework for evaluation of trends and causes of preterm delivery. For example, an increase in indicated preterm births accounts for much of the recent rise in late preterm births and in the overall preterm birth rate in the United States (Fig. 29-6A,B). This increase has been accompanied by a decline in fetal mortality (see Fig. 29-6C), especially after 28 weeks, suggesting that the increased rate of preterm births may reflect improved prenatal care.

Consequences of Preterm Birth

(See Also Chapter 58)

Definitions of Perinatal and Infant Mortality

The *perinatal mortality rate* is the total of fetal deaths after 20 weeks' gestation plus neonatal deaths through the first 28 days of life, per 1000 births (live births + fetal deaths) after 20 weeks' gestation.¹ Preterm birth is the leading cause of perinatal and infant mortality for infants born to women of all races and ethnic backgrounds, and particularly for non-Hispanic black women.^{2,26}

The *infant mortality rate* is the number of deaths of live-born infants before 1 year of age per 1000 live births. Figure 29-7 displays the relative contribution of prematurity-related conditions to overall infant mortality in 2004 according to maternal race or ethnicity.²⁶ Infant mortality increases markedly as gestational age and birth weight decline. In 2001, 41% of all infants born alive before 28 weeks of gestation died within 1 year, compared with 5% of those born at 28 to 31 weeks, 1% of those born at 32 to 35 weeks, and 0.3% of those born at term.²⁷

Despite the rise in the rate of preterm birth between 1990 and 2004, fetal and infant mortality rates declined over the same time interval (Fig. 29-8). The decline in perinatal mortality was related primarily to a decrease in fetal deaths after 28 weeks' gestation, corresponding to an increased rate of indicated preterm birth during this time (see Fig. 29-6). Fetal deaths account for more than half of perinatal deaths. In the United States in 2004, there were 25,655 fetal deaths (50.3% between 20 and 27 weeks, and 49.7% after 27 weeks), and 18,602 neonatal deaths (79.8% before 7 days and 20.2% between 7 and 28 days after birth).¹

Factors Affecting Perinatal, Infant, and Childhood Mortality and Morbidity

(See Also Chapter 58)

DATA COLLECTION

Reports of survival and morbidity vary according to the denominator employed. Obstetric data sets include all living fetuses at entry to

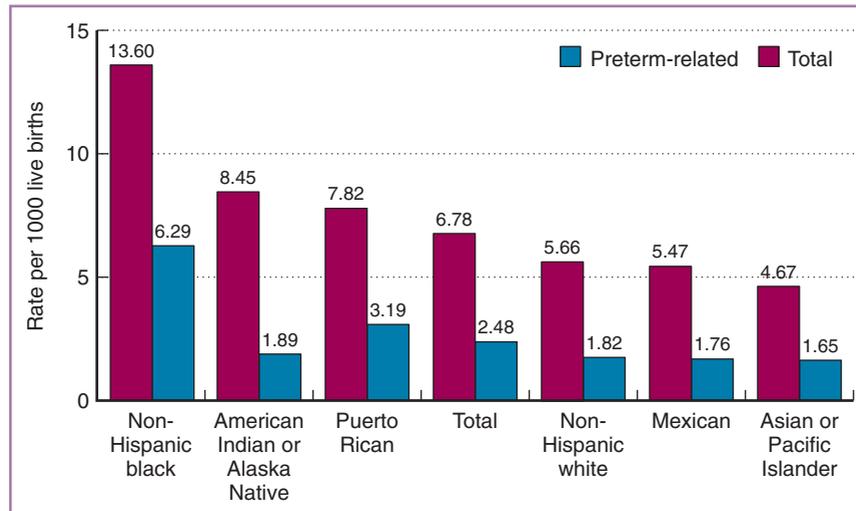

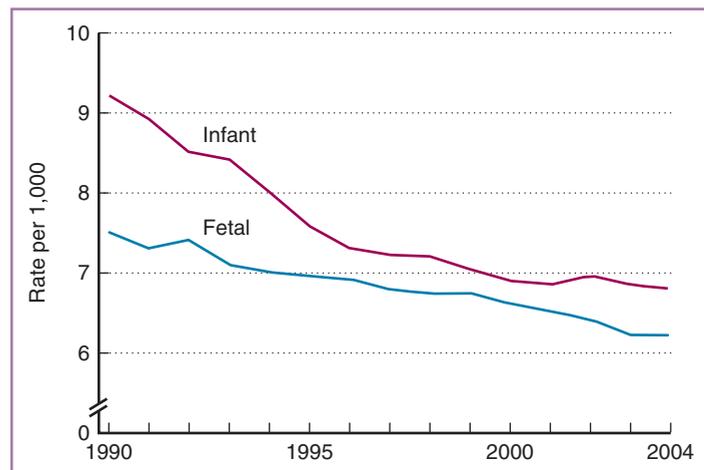

FIGURE 29-7 Total and preterm-related infant mortality rates by race or ethnicity of mother: United States, 2004. Preterm-related deaths are those in which the infant was born preterm (<37 completed weeks of gestation) and the underlying cause of death was assigned to one of the following categories from the *International Classification of Diseases, Tenth Revision*: K550, P000, P010, P011, P015, P020, P021, P070-Po73, P102, P220-229, P250-279, P280, P281, P360-P369, P520-P523, P77. The categories of American Indian or Alaska Native and Asia or Pacific Islander include persons of Hispanic and non-Hispanic origin. (From MacDorman M, Callaghan WM, Mathews TJ, et al: Trends in Preterm-Related Infant Mortality by Race and Ethnicity: United States, 1999-2004. National Center for Health Statistics, 2007. Available at <http://www.cdc.gov/nchs/products/pubs/pubd/hestats/infantmort99-04/infantmort99-04.htm> [accessed February 28, 2008].)

FIGURE 29-8 Fetal and infant mortality rates: United States, 1990-2004. The infant mortality rate is the number of infant deaths per 1000 live births. The fetal mortality rate is the number of fetal deaths occurring after 20 weeks' gestation per 1000 births (live births + fetal deaths). (From MacDorman MF, Munson ML, Kirmeyer S: Fetal and Perinatal Mortality—United States, 2004. Natl Vital Stat Rep 56[3]:1-19, 2007.)

the obstetric suite,²⁸ whereas neonatal data sets exclude intrapartum and delivery room deaths and thus report rates based on newborns admitted to the nursery.^{29,30} Rates of survival and morbidity at the same gestational age and/or birth weight are therefore somewhat higher in neonatal data sets and in data from tertiary care centers.

GESTATIONAL AGE

Before delivery, gestational age is the strongest predictor of survival and morbidity for the infant. The perinatal mortality rate is strongly related to gestational age at birth, especially between 22 and 32 weeks, as was shown in data from one large center in Figure 29-9.³¹ Although mortality declines sharply after 32 weeks, infants born between 32 and 36 weeks still have increased rates of adverse outcomes. A French study

of outcomes at 5 years of age for infants born between 30 and 34 weeks found a progressive decline in rates of perinatal mortality and neonatal morbidity with advancing gestational age at birth. Rates of cerebral palsy and cognitive impairment at 5 years of age also declined with advancing gestational age at birth.³²

Neonatal mortality rates at 34, 35, and 36 weeks were 1.1, 1.5, and 0.5 per 1000 live births, respectively, compared with 0.2 per 1000 live births at 39 weeks, in a report from Parkland Hospital.³³ Five percent of infants born at 34 weeks required neonatal intensive care, compared with 2% of those born at 35 weeks, 1.1% at 36 weeks, 0.6% at 37 weeks, and 0.5% at 39 weeks. More than three quarters of late preterm births followed preterm labor or ruptured membranes, with the remainder caused by obstetric complications.

FIGURE 29-9 Survival by gestational age among live-born resuscitated infants. Results of a community-based evaluation of 8523 deliveries, 1997-1998, Shelby County, Tennessee. Curves smoothed by 2-point average. (From Mercer BM: Preterm premature rupture of the membranes. *Obstet Gynecol* 101:178, 2003, Figure 1.)

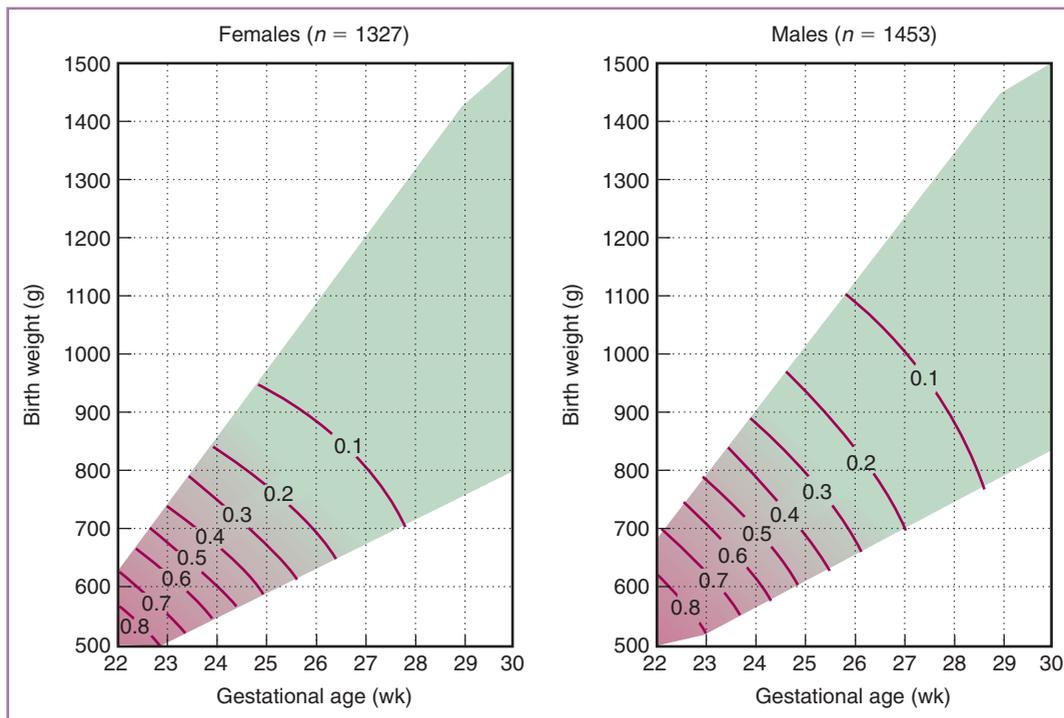

FIGURE 29-10 Estimated mortality risk by birth weight and gestational age based on singleton infants born in National Institute of Child Health and Human Development (NICHD) Neonatal Research Network centers between January 1, 1995, and December 31, 1996. Numeric values represent age- and weight-specific mortality rates and are expressed as decimal fractions (e.g., 0.7 = 70%). (From Lemons JA, Bauer CR, Oh W, et al: Very low birth weight outcomes of the National Institute of Child Health and Human Development Neonatal Research Network, January 1995 through December 1996. *NICHD Neonatal Research Network. Pediatrics* 107:E1, 2001. Used with permission of the American Academy of Pediatrics.)

BIRTH WEIGHT

After delivery, birth weight and gender can be combined with gestational age to predict mortality, as shown in Figure 29-10 for infants born alive between 22 and 30 weeks' gestation.²⁹ A recent study combined gestational age, birth weight, gender, treatment with antenatal steroids, and multiple versus singleton gestation to generate improved estimates of neonatal outcomes for infants with birth weights of 400-1000 grams.³⁴

Very Low Birth Weight Infants. Regionalized care for high-risk mothers and infants, antenatal fetal treatment with glucocorticoids, neonatal administration of exogenous pulmonary surfactant, and improved ventilator technology have produced survival rates that now exceed 90%, and survival without major morbidity in more than 80% of infants born at 28 weeks' gestation or weighing 1000 g at birth.

Rates of survival with and without morbidity for VLBW infants (500 to 1500 g) born into tertiary neonatal intensive care units in the

FIGURE 29-11 Changes in mortality, morbidity, and morbidity-free survival over time. Comparison of mortality, morbidity, and morbidity-free survival for very low birthweight infants cared for in twelve National Institute of Child Health and Human Development (NICHD) Neonatal Research Network Centers in 1990-1991, 1995-1996, and 1997-2000 by 250-g birth weight intervals, based on the total number of singleton infants born in the centers. (From Fanaroff AA, Stoll BJ, Wright LL, et al; NICHD Neonatal Research Network: Trends in neonatal morbidity and mortality for very low birthweight infants. *Am J Obstet Gynecol* 196:147.e1-147.e8, 2007.)

United States did not change appreciably from 1990 to 2000 (Fig. 29-11).³⁵

Extremely Low Birth Weight Infants. Increasing attention has been paid to infants born at the perivable thresholds of age (22 to 25 weeks) and weight (400 to 600 g). In a study of singleton births between 1991 and 1996, 56.1% of 406 infants born at 24 weeks and 68% of 454 infants born at 25 weeks survived to hospital discharge.³⁰ Data from the Vermont Oxford and National Institute of Child Health and Human Development (NICHD) Neonatal Research Networks indicate that rates of survival and morbidity for infants born between 23 and 25 weeks' gestation are unlikely to improve any further. Survival rates for babies born into the tertiary nurseries of the NICHD Neonatal Research Network between 1996 and 2000 improved from 20% to 30% at 23 weeks but only marginally at 24 weeks (from 58% to 60%) and 25 weeks (from 75% to 80%).³⁶ In the Vermont Oxford data, mortality and morbidity declined steadily between 1991 and 1995 for infants weighing 501 to 1500 g but did not change between 1995 and 1999.³⁷ The American Academy of Pediatrics³⁸ and the American College of Obstetricians and Gynecologists (ACOG)³⁹ issued joint statements on perinatal care at the limits of viability in 2002, with recommendations based on the data reported by Lemons and colleagues in 2001²⁹ (see also Chapter 58).

Survival among infants born weighing less than 500 g is rare. A Vermont Oxford Network study reported that 48% of 4172 infants with birth weights between 401 and 500 g and a mean gestational age of 23.3 weeks died in the delivery room.⁴⁰ Among the 17% who survived to hospital discharge, the mean gestational age was more than 25 weeks, and significant morbidity was universal. Notably, the risk of neonatal mortality does not exceed 50% for babies of any ethnicity or race until the gestational age at birth is less than 24 weeks and birth weight is less than 500 g.⁴¹

MATERNAL RACE

Perinatal deaths vary significantly by maternal race and ethnicity. The perinatal mortality rate in 2004 for infants born to non-Hispanic black women in the United States was 20.3 (per 1000 live births + fetal deaths), compared with 10 for all other racial and ethnic groups (Fig. 29-12).¹

The relationship of maternal race to risk of neonatal mortality is complex. African-American infants have a greater overall perinatal mortality rate than do whites or Hispanics. This higher risk is related to increased risk of stillbirth at all gestational ages and increased risk of neonatal mortality for infants born at term and post-term. However, neonatal mortality rates for black preterm and LBW infants are lower than for other ethnic groups.⁴¹

OTHER FACTORS

Mortality rates for preterm and VLBW infants are lower if the child is female (odds ratio [OR], 0.42; 95% confidence interval [CI], 0.29 to 0.61), is growth restricted (OR, 0.58; CI, 0.38 to 0.88), or was treated with antenatal corticosteroids (OR, 0.52; CI, 0.36 to 0.76), compared with infants at the same gestational age who are male, were normally grown, or did not receive antenatal steroids.^{42,43} Intrauterine infection adversely influences survival and morbidity.⁴³ Mortality rates also vary among neonatal intensive care units, despite similar care practices and patient demographics.⁴⁴ Therefore, local statistics are preferred when counseling patients.

Perinatal Morbidity

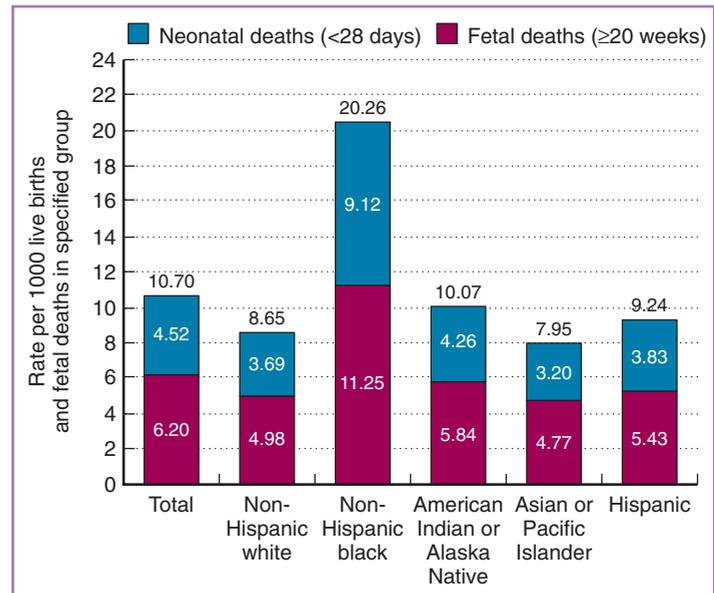

Preterm infants are at risk for specific diseases related to the immaturity of various organ systems and the cause and circumstances of preterm birth. Common complications in premature infants include respiratory distress syndrome (RDS), intraventricular hemorrhage (IVH), bronchopulmonary dysplasia (BPD), patent ductus arteriosus (PDA), necrotizing enterocolitis (NEC), sepsis, apnea, and retinopathy of prematurity (ROP).

The frequency of major morbidity rises as gestational age decreases, especially before 32 weeks. There is wide geographic variation in the frequency of neonatal morbidities, especially for VLBW infants.⁴⁴ Typical rates for the most common morbidities among survivors are shown according to gestational age in Figure 29-13, from a single center,³¹ and by birth weight in Table 29-1, from a tertiary care network.³⁵

Long-Term Outcomes

Major neonatal morbidities related to preterm birth that carry lifetime consequences include chronic lung disease, grades III and IV IVH,

FIGURE 29-12 Perinatal mortality rates, definition II, by race and Hispanic origin of mother: United States, 2004. Rates for non-Hispanic white, non-Hispanic black, and Hispanic categories exclude data from Oklahoma, which did not report Hispanic origin for fetal deaths. Rates for subtotals do not add exactly to totals because of slight differences in the denominators used for rate computations. (From MacDorman MF, Munson ML, Kirmeyer S: Fetal and Perinatal Mortality—United States, 2004. *Natl Vital Stat Rep* 56[3]:1-19, 2007.)

NEC, and vision and hearing impairment. Increased rates of cerebral palsy, neurosensory impairment, reduced cognition and motor performance, academic difficulties, and attention deficit disorders are reported for preterm infants and rise in frequency as the gestational age at birth declines.^{28,45-47} Approximately one third of cerebral palsy cases have been attributed to early preterm birth (<32 weeks of gestation).⁴⁸ A study of 308 surviving infants born before 25 weeks found that almost all had some disability at age 6 years: 22% had severe neurocognitive disabilities (cerebral palsy, IQ >3 standard deviations below the mean, blind, or deaf), 24% had moderate disability, 34% had mild disability, and 20% had no neurocognitive disability.⁴⁷

Health care workers regularly overestimate the likelihood and severity of neurologic morbidity in infants born preterm.⁴⁹ This is important, because these expectations may adversely influence outcomes (Figs. 29-14 and 29-15).^{50,51}

Self-esteem among prematurely born infants followed to adolescence does not differ from that among persons born at term. Although

24% of 132 adolescents who weighed less than 1 kg at birth had significant sensory deficits, they did not differ from controls of normal birth weight in their self-perception of global self-worth, scholastic or job competence, or social acceptance.⁵²

Epidemiology and Risk Factors for Preterm Birth

Spontaneous preterm birth is similar to other multifactorial disorders, such as cancer or heart disease, wherein multiple endogenous and exogenous risk factors interact to cause disease. In the case of spontaneous preterm birth, such interaction generates the premature and often asynchronous initiation of one or more steps in parturition. Thus, the risk factors for preterm labor are similar to those for pPROM and cervical insufficiency.

TABLE 29-1 PERCENTAGE OF VERY-LOW-BIRTH-WEIGHT INFANTS SURVIVING WITH SELECTED NEONATAL MORBIDITIES*

Maternal Characteristics

Familial Risk

Studies showing familial risk patterns suggest that there is a genetic predisposition for preterm birth. Women whose sisters have had a preterm birth have a 1.8-fold higher risk of preterm delivery,⁵³ and grandparents of women who deliver preterm are more likely to have been preterm themselves than the grandparents of women who deliver at term.⁵⁴ Genetic association studies have discovered polymorphisms in several genes in the mother and the fetus associated with spontaneous preterm birth⁵⁵⁻⁵⁷ and LBW.⁵⁸ Gene-environment interaction was identified in a study wherein neither maternal bacterial vaginosis (BV) nor maternal carriage of an allele of the tumor necrosis factor- α (TNF- α) gene was associated with spontaneous preterm birth if present

alone, but the combination significantly increased risk of preterm birth.⁵⁹ Another study demonstrated that a polymorphism in the interleukin 6 (IL-6) gene was related to an increased risk of spontaneous preterm birth in African-American women with BV but was not linked to preterm birth risk in African-American women who did not have BV or in Caucasian women regardless of BV status.⁵⁵ An interaction between maternal smoking and a genetic polymorphism that increases the likelihood of LBW has also been identified.⁵⁸ These studies support a role for gene-environment interactions in the pathogenesis of spontaneous preterm birth. Studies to date have employed the candidate gene approach to study DNA variants of biologically suspected genes, but these are being replaced by whole genome association studies which hold promise for improved understanding of the genetic basis of preterm birth and its sequelae.^{60,61}

Data from Behrman RE, Stith Butler A (eds); Institute of Medicine Committee on Understanding Preterm Birth and Assuring Healthy Outcomes: *Preterm Birth: Causes, Consequences, and Prevention*. Washington, DC: National Academies Press, 2007.

Education and Economic Status

Low socioeconomic and educational status, low or high maternal age, and single marital status are correlated with an increased risk of preterm birth.^{62,63} The rate of preterm birth declines with advancing education for all ethnic groups but remains higher among non-Hispanic blacks at all educational levels (Table 29-2).

Race and Ethnic Background

Rates of preterm birth are almost twofold higher among black (African-American, and Afro-Caribbean) women (16% to 18%) than in Asian, Hispanic, and white women in the United States and Great Britain. Preterm births before 32 weeks are also significantly increased in black women compared with women from other racial or ethnic groups (Fig. 29-16).⁶⁴

Rates of preterm and LBW infants remain higher for black women, compared with white, Asian, or Hispanic women, after controlling for social disadvantage⁶⁵ and education. Remarkably, preterm birth rates are higher for well-educated, non-Hispanic black women than for poorly educated, non-Hispanic white, Asian, or Hispanic women (see Table 29-2).

Rates of preterm birth among Arab-American women are the same or lower than among non-Hispanic white women, despite increased socioeconomic risk.⁶⁶ Rates of preterm delivery among black women born outside the United States are generally lower than among African-American women or among Afro-Caribbean women living in the

United Kingdom,⁶⁷ suggesting a risk induced or enhanced by residence in the United States or Britain. Acute or short-term stress in pregnancy has a weak relationship to the risk of preterm birth, but chronic stress, such as might be experienced by persons of color, has a stronger link to preterm birth (see later discussion).

Maternal Behaviors and Environment

Maternal smoking is related to poor pregnancy outcomes such as growth restriction, placental abruption, infant mortality, and preterm birth, but the relationship to preterm birth is modest.⁶⁸⁻⁷⁰ A population-based study of more than 300,000 singleton births found a dose-related association between spontaneous preterm birth and smoking more than 10 cigarettes per day (OR, 1.7).⁷¹ Smoking is important because of its high prevalence (20% to 25% of pregnant women smoke) and the potential for successful intervention.⁷² The mechanisms by which smoking is related to preterm birth are unclear, but nicotine and carbon monoxide are vasoconstrictors that decrease uteroplacental blood flow. The observed decrease in fetal weight is not surprising.

Substance abuse may be linked to preterm birth risk through concurrent exposure to lifestyle-related risk factors such as limited prenatal care, nutritional deficits, genital tract infections, and cigarette smoking. Marijuana has not been independently related to preterm birth. Initial reports associating cocaine with preterm birth due to abruption may have been influenced by ascertainment bias; the magnitude of the risk of preterm birth among cocaine users is now con-

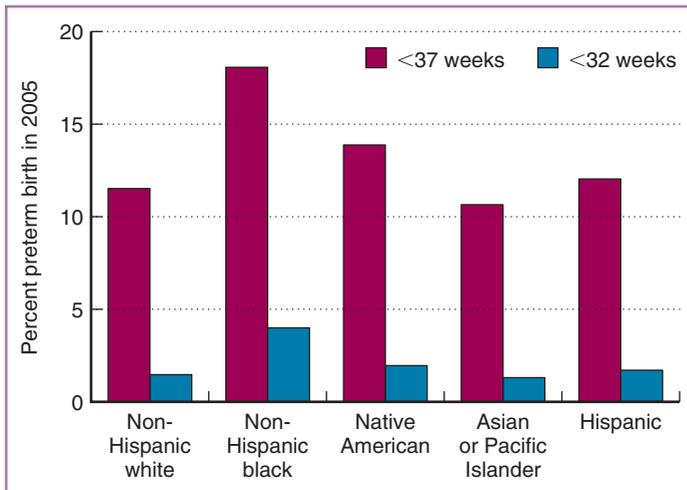

FIGURE 29-16 Rates of preterm birth, by race/ethnicity of mother: United States, 2005. (From Hamilton BE, Martin JA, Ventura SJ: Births: Preliminary data for 2005. Health E-Stats. Natl Vital Stat Rep 55, 2006.)

sidered uncertain.⁹ Maternal alcohol consumption has a complex association with preterm birth, with some studies showing no relationship or even a modest reduction in the rate of preterm birth among light drinkers^{20,73} and others confirming an increased risk related to regular and heavy alcohol intake.^{73,74}

Psychological Factors

Stress during pregnancy is a topic of great public interest, but evidence to address this concern is inadequate. Studies relating preterm birth risk to stress in pregnancy suffer from methodologic variation but generally report a modest relationship, with relative risks (RR) of 1.3 to 1.4 for stressful life events such as death of a family member, loss of employment, or divorce.^{75,76} Stress is often accompanied by other known risk factors, such as socioeconomic disadvantage, smoking, or African-American ethnicity. Lu and Chen found that adding stress to a statistical model of risk factors for preterm birth in 33,542 women had little effect on the observed relationship between race and preterm birth; they concluded that stressful life events, even events immediately preceding or during pregnancy, do not significantly contribute to racial and ethnic disparities in preterm birth.⁷⁷ Evidence that *chronic* stress is related to preterm birth risk is more robust⁷⁸ and suggests that stress may increase risk by altering immunologic function.⁷⁹⁻⁸³ Chronic stress related to racism is a potential explanation for the disparity in preterm birth rates between African-American or Afro-Caribbean women and women of other ethnic backgrounds.⁸³

Depression before and during pregnancy is being recognized as a risk factor for adverse pregnancy outcomes including preterm birth. Clinical depression occurs in as many as 15% to 35% of women. The reported relationship between depression and risk of preterm birth is modest (less than twofold).^{84,85} Risk factors for depression are similar to those related to preterm birth and include non-Hispanic black race, young age, limited education, and exposure to stressful life events.⁸⁶ Depressed mood has been reported to correlate with reduced natural killer cell activity and increased plasma concentrations of proinflammatory cytokines,⁸⁷ so alterations in immune response may partially mediate the relationship between depression and preterm birth.

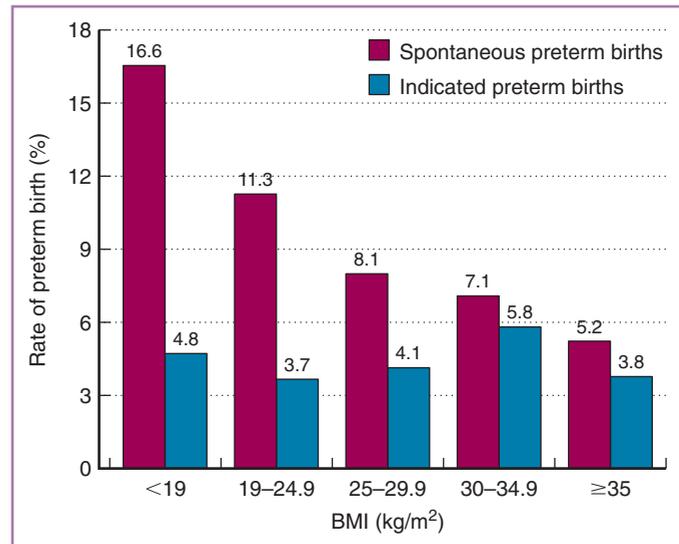

FIGURE 29-17 Comparison of rates of spontaneous and indicated preterm birth by maternal body-mass index (BMI). (Adapted from Hendler I, Goldenberg RL, Mercer BM, et al: The Preterm Prediction Study: Association between maternal body mass index [BMI] and spontaneous preterm birth. Am J Obstet Gynecol 192:882-886, 2005.)

Maternal Physical Activity

Work and physical activity have been studied in relation to risk of preterm birth, with conflicting results. Although rates of preterm birth are lower in women who are employed compared with those who are unemployed, the risk among employed women may be increased by work that is physically demanding or stressful. In a European study, the risk of preterm birth was not related to employment per se but was increased among women who worked more than 42 hr/wk (OR, 1.33; CI, 1.1 to 1.6) or who were required to stand for more than 6 hr/day (OR, 1.26; CI, 1.1 to 1.5).⁸⁸ Work while standing was associated with preterm birth (OR, 1.56; CI, 1.04 to 2.60) in a study from Guatemala,⁸⁹ but this finding was not observed by researchers from North Carolina, where the risk of preterm birth was higher in women who worked nights compared with those who worked days.⁹⁰ There are no data to relate specific work tasks to preterm birth risk.

Coitus during pregnancy commonly leads to a transient increase in uterine activity⁹¹ and is an opportunity to acquire genital tract infections, but self-reported sexual activity was not related to the risk of preterm birth in a study of women with a prior preterm birth.⁹² The practice of douching before or during pregnancy has been suggested to increase the risk of preterm birth, but the association is confounded by the higher prevalence of BV in African-American women, who are more likely to practice douching.^{93,94}

Nutritional Status

The risk of preterm birth has been related to maternal nutritional status during pregnancy, as measured by body mass index (BMI), nutritional intake, and serum markers of nutritional status.⁹⁵⁻⁹⁷ For example, a low pre-pregnancy BMI is associated with higher risks of spontaneous preterm birth, whereas obesity may be protective (Fig. 29-17).⁹⁵ One study found that a low BMI was more strongly related to preterm birth risk among African-American and Hispanic women than among white women.⁹⁸

Women with low serum iron, folate, or zinc levels have more preterm births than those with measurements in the normal range.⁹⁷ The mechanisms by which maternal nutritional status might influence preterm birth risk are unclear but may involve effects on uterine blood flow or resistance to infection.^{97,99,100}

Infections

(See Also Chapter 28)

GENITAL TRACT INFECTION AND COLONIZATION

The risk of preterm birth related to infection is sometimes considered as a risk that is acquired during pregnancy—an accurate concept for extragenital infections such as pyelonephritis or pneumonia, but one that does not fully apply to genital tract colonization and infection. Pre-pregnancy colonization of the upper and lower genital tract and the maternal immune response to that colonization are increasingly recognized as important aspects of infection-related risk of preterm birth. The correlation between genital tract infection and preterm birth has long been recognized,¹⁰¹ but the pathways by which infection leads to preterm birth have not, until recently, been understood to involve activation of the innate immune system. Microorganisms are recognized by pattern-recognition receptors such as Toll-like receptors, which, in turn, elicit the release of inflammatory chemokines and cytokines such as IL-8, IL-1 β , and TNF- α . During intrauterine infection, microbial products and proinflammatory cytokines stimulate the production of prostaglandins and other inflammatory mediators as well as matrix-degrading enzymes. Prostaglandins stimulate uterine contractility, and degradation of extracellular matrix in the fetal membranes leads to pPROM.^{60,102} The contribution of infection to preterm birth has been estimated to be 25% to 40% based on microbiologic studies, but this may be an underestimate, because intrauterine infection is difficult to detect with conventional culture techniques. For example, molecular microbiologic studies based on the polymerase chain reaction (PCR) have revealed evidence of *Ureaplasma urealyticum* in amniotic fluid samples with negative cultures.¹⁰³⁻¹⁰⁶

Intrauterine colonization and infection can occur in the decidua, the chorioamniotic space, or the amniotic cavity. Because microbial colonization is more common in the chorioamnion than within the amniotic cavity, amniotic fluid cultures underestimate the contribution of infection to preterm birth. However, bacteria are known to be present in the chorioamnion in women who deliver healthy infants at term,¹⁰⁷ indicating that bacteria in the chorioamnion do not always generate an inflammatory response that leads to preterm labor and birth. The most common pathway by which microorganisms gain access to the choriodecidual and amniotic cavity is probably ascent from the vagina and the cervix, but the timing of this spread is uncertain. It may occur before or during pregnancy.¹⁰⁸ Regardless of when colonization occurs, intrauterine inflammation is postulated to cause clinical symptoms, such as vaginal discharge, cervical effacement, ruptured membranes, or labor, only when microbial counts increase as the membranes try to adhere to the decidua in the second trimester.^{61,102} This phenomenon is consistent with the strong association between increased concentrations of fetal fibronectin, the choriodecidual “glue,” in vaginal fluid between 13 and 22 weeks’ gestation, with spontaneous preterm birth in the second trimester.¹⁰⁹ The microorganisms most commonly recovered from the amniotic cavity and chorioamnion are genital mycoplasma species, especially *U. urealyticum*, and other organisms of low virulence, consistent with the chronicity of intrauterine infections and the frequent lack of overt clinical signs of infection.¹⁰²

SPECIFIC INFECTIONS

BV, an alteration in the microbial ecosystem of the vagina, is a clinical correlate of lower and upper tract infection. BV is diagnosed clinically by the presence of clue cells, a vaginal pH greater than 4.5, a profuse white discharge, and a fishy odor when the vaginal discharge is exposed to potassium hydroxide.¹¹⁰ BV in pregnancy has been consistently associated with an increased risk of preterm birth, but apparently only as a marker, because eradication of BV from the genital tract of pregnant women does not consistently reduce the likelihood of preterm birth.^{111,112} BV is more commonly detected in African-American women, and is more strongly related to preterm birth in African-American women than in women of other racial or ethnic backgrounds.¹¹³ This association is unrelated to differences in sexual behaviors.¹¹⁴ Moreover, eradication of BV does not reduce the risk of preterm birth in either African-American or white women.^{112,115}

Trichomonas vaginalis is present in 3.1% of women of reproductive age, and it is more common in African-American women (13%) than in other groups.¹¹⁶ It has been associated with a modest increase in the risk of preterm birth (RR, 1.3) in some studies¹¹⁷ but not in all.¹¹⁸

Sexually transmitted infections, including *Chlamydia trachomatis* (in the presence of a maternal immune response),¹¹⁹ syphilis, and gonorrhea, confer an increased risk of preterm birth of approximately twofold,¹²⁰ but eradication of these organisms does not reduce that risk, again suggesting involvement of host factors.

Clinical markers of genital tract infection that correlate with an increased risk of preterm birth include the detection of BV and an increased level of fetal fibronectin in cervicovaginal fluid after 22 weeks’ gestation.¹²¹

Extragenital infections including pyelonephritis, asymptomatic bacteriuria, pneumonia, and appendicitis are associated with preterm birth.^{122,123}

PERIODONTAL DISEASE

Maternal periodontal disease has been linked to an increased risk of preterm birth,¹²⁴ but the basis for the association is uncertain.¹²⁵ It most likely results from shared variations in the inflammatory response to microorganisms in the oral and genital tracts.¹²⁶⁻¹²⁹ Goepfert and colleagues demonstrated that, after adjusting for other factors, periodontal disease was not related to increased intrauterine bacterial colonization, histologic chorioamniotitis, or cord blood cytokine levels.¹³⁰

The biologic pathway explaining the relationship between periodontal disease and preterm birth is unknown. Variations in host response to microbial colonization related to genetic polymorphisms or concurrent environmental exposures, or both, have been proposed as contributors to the disparate rates of preterm birth among ethnic groups, particularly in relation to infection-driven preterm birth,^{58,131} and may apply to other inflammation at extragenital sites, such as periodontal inflammation.

Reproductive History

Prior Spontaneous Preterm Birth

Although most women who experience a preterm birth will deliver at term in subsequent pregnancies, the recurrence risk for spontaneous preterm birth is twofold or higher. This yields an actual risk that ranges from 15% to 20% to more than 50% to 60% when maternal race, ethnicity, and the number and gestational age of prior preterm deliveries are considered.^{4,132-137} The recurrence risk rises in women of all races as the number of prior preterm births increases, with a twofold rise

TABLE 29-3 RISK OF PRETERM BIRTH IN SUBSEQUENT PREGNANCIES

Not preterm		4.4
Preterm		17.2
Not preterm	Not preterm	2.6
Preterm	Not preterm	5.7
Not preterm	Preterm	11.1
Preterm	Preterm	28.4

From Bakkeiteig LS, Hoffman HJ: Epidemiology of preterm birth: Results from a longitudinal study of births in Norway. In Elder MG, Hendricks CH (eds): *Preterm Labor*. London, Butterworths, 1981, p. 17.

for each prior preterm birth.²³ The most recent birth is the most predictive, as was demonstrated in a Norwegian study (Table 29-3).

The risk increases further as the gestational age of the index preterm birth declines, especially with gestational age before 32 weeks.⁴⁹ A prior preterm birth as early as 16 to 18 weeks has been found to confer an increased risk in subsequent pregnancies.^{7,9,138}

The risk of recurrence is almost twofold higher for non-Hispanic black women than for any other group. Adams and colleagues related maternal race and gestational age of the initial preterm birth to recurrence risk.¹³⁷ If the first preterm birth occurred before 32 weeks, the risk of recurrent preterm birth was 28% for white women but 36% for African-American women.

When multiple risk factors occur in African-American women, recurrence rates approximating 50% have been reported.^{139,140} In a placebo-controlled trial of 17 α -hydroxyprogesterone caproate (17P) to reduce the risk of preterm birth, 54% of women in the placebo arm delivered before 37 weeks, and 30.7% delivered before 35 weeks. The mean gestational age at delivery in the qualifying pregnancy was 31.3 \pm 4.2 weeks; 46% of subjects had more than one prior preterm birth, and 59% were African-American.¹³⁹ In another study of 611 women with one (75%) or more (25%) prior preterm births, 40% delivered before 37 weeks, and 25% delivered before 35 weeks of gestation. One quarter of the subjects in this trial were African-American.¹⁴⁰ These rates are consistent with prior studies showing a 1.5- to 2-fold increased risk for each risk factor (African-American race, more than one prior preterm birth, and gestational age <32 weeks)^{4,7,9,135} and with prior observational studies.¹⁴¹

The mechanisms of recurrence are not clear but have been related to short cervix,¹³⁵ infection,¹⁴² and short inter-pregnancy interval. After adjusting for confounding variables, a short interval between pregnancies is associated with a twofold increased risk of preterm birth.¹⁴³⁻¹⁴⁵ A short interpregnancy interval is more common among women whose first birth was preterm.

Prior preterm birth of twins confers an increased risk of preterm birth in a subsequent singleton pregnancy that is related to the gestational age at delivery of the index twin pregnancy.^{136,146,147} Menard and coworkers¹⁴⁶ studied the outcome of singleton pregnancies after a twin pregnancy and found a 40% risk of preterm birth in a subsequent singleton gestation if the twin birth occurred before 30 weeks' gestation, a modestly increased risk when the twin birth was at 30 to 33 weeks, and no increased risk if the twin birth occurred between 33 and 37 weeks. Facco and colleagues¹⁴⁷ found a fivefold increased risk of preterm birth in women who had previously delivered preterm twins, compared with women whose twin pregnancy was delivered at term.

Prior Indicated Preterm Birth

Women with indicated preterm births also have an increased risk of another indicated preterm birth, because the underlying condition (e.g., maternal diabetes, hypertension) often persists.^{4,148} Unexplained fetal growth restriction can also be recurrent.^{149,150}

Uterine Anomalies

Women with müllerian duct fusion anomalies have an increased risk of pregnancy loss, with clinical presentations that vary according to uterine anatomy, cervical involvement, and placental implantation site.^{151,152} Preterm births are reported in 25% to 50% of pregnancies among women with uterine malformations.^{153,154} Among 246 pregnancies in 130 women with uterine anomalies, 20.3% were delivered preterm, 8.5% delivered in the second trimester, and 25% were first trimester losses.¹⁵⁴ The preterm birth rate was particularly increased (approximately 35%) in women with bicornuate, didelphys, or arcuate uteri, compared to those with septate or subseptate uteri (approximately 15%) in this report. Müllerian fusion anomalies may involve the cervix as well as the uterine cavity, so the clinical presentation may include cervical insufficiency, bleeding related to abnormal placental implantation, and preterm labor. Clinical presentations leading to preterm birth in a study of 61 women with uterine anomalies included preterm labor in 39%, pPROM in 13.7%, and abruption in 5.9%.¹⁵⁵ Prenatal exposure to diethylstilbestrol is associated with an increased risk of preterm labor and birth related to the typical T-shaped uterine anomaly.¹⁵⁶

Pregnancy Termination

A history of elective abortion has been related to an increased risk of preterm birth in subsequent pregnancies.¹⁵⁷⁻¹⁵⁹ In one study, a history of elective abortion was associated with an increased risk for subsequent preterm birth between 22 and 32 weeks of gestation (OR, 1.5; CI, 1.1 to 2.0). Women with more than one elective termination had a higher risk, especially for preterm births before 28 weeks' gestation.¹⁵⁹ Another case-control survey of 2938 preterm and 4781 term births in 10 countries reported that women with a history of induced abortions were significantly more likely to have a subsequent spontaneous preterm delivery. A prior elective abortion did not affect the risk of subsequent indicated preterm birth. The risk of preterm birth increased with the number of abortions, and the strength of the association increased with decreasing gestational age at birth.¹⁵⁸ In another study of 12,432 women, rates of preterm delivery were compared according to the occurrence and number of previous induced abortions; other risk factors were controlled. Previous induced abortion was associated with an increased risk of preterm birth (OR, 1.4; CI, 1.1 to 1.8), and the risk of preterm delivery increased with the number of previous induced abortions (OR, 1.3; CI, 1.0 to 1.7 for one previous abortion, and OR, 1.9; CI, 1.2 to 2.8 for two or more).¹⁶⁰

The magnitude of the risk of preterm birth related to elective abortion is small but appears to be real. The association could be related to cervical injury but may also be the result of colonization of the upper genital tract. This possibility was suggested by a study that compared subsequent pregnancy outcomes in women who had a prior surgical versus medical abortion and found no difference in the rate of subsequent preterm birth between the two groups.¹⁶¹ No comparison was made with preterm birth in women without a history of pregnancy termination.

Cervical Surgery

Women treated for cervical intraepithelial neoplasia (CIN) with a loop electrosurgical excision procedure (LEEP), or with cervical conization

using either laser or cold knife, have an increased risk of later preterm birth. The largest studies of this relationship have come from Scandinavian registries in which long term follow-up is possible.¹⁶²⁻¹⁶⁴ Among 8210 women treated surgically for CIN between 1986 and 2003, the risk of preterm birth before 37 weeks of gestation was increased after cervical conization (RR, 1.99; CI, 1.81 to 2.20), as were the risks for birth between 28 and 31 weeks (RR, 2.86; CI, 2.22 to 3.70) and before 28 weeks (RR, 2.10; CI, 1.47 to 2.99). Risks of LBW and perinatal death were also increased after conization (RR, 2.06; CI, 1.83 to 2.31, and RR, 1.74; CI, 1.30 to 2.32, respectively). A Danish cohort of 11,088 women was monitored from 1991 through 2004; of 14,982 deliveries in the cohort, 542 occurred between 21 and 37 weeks. The rate of preterm birth was 3.5% in women with no previous LEEP and 6.6% in women previously treated with LEEP (OR, 1.8; CI, 1.1 to 2.9). A smaller study from a colposcopy clinic in New Zealand reported an increased risk of pPROM after treatment for CIN, particularly with laser procedures.¹⁶⁵

Current Pregnancy Characteristics

Bleeding

Vaginal bleeding related to placental abruption or previa often leads to preterm delivery, but first- and second-trimester bleeding of uncertain origin is also significantly associated with subsequent spontaneous preterm birth, especially if the bleeding is recurrent or persistent.^{166,167} The mechanism by which bleeding is associated with preterm birth occurring weeks later is uncertain, but it is one of several observations suggesting that injury at the maternal-fetal interface increases the risk of later preterm birth (see Chapter 28). For example, an increase in maternal serum α -fetoprotein not explained by structural fetal anomalies is a marker of fetomaternal bleeding that confers an increased risk of preterm birth¹⁶⁸⁻¹⁷⁰; this suggests that occult placental hemorrhage may lead to eventual preterm delivery presenting as pPROM, growth restriction, or concealed abruption. First-trimester bleeding in singleton pregnancies after assisted reproductive technology (ART) has been associated with an increased risk of preterm birth. In a review of 1432 singleton pregnancies conceived after ART, women with first-trimester bleeding had increased rates of pPROM (OR, 2.44; CI, 1.38 to 4.31), preterm birth before 37 weeks (OR, 1.64; CI, 1.05 to 2.55), and before 32 weeks preterm birth (OR, 3.05; CI, 1.12 to 8.31).¹⁷¹

Similarly, the rate of preterm birth is increased when one fetus in a multifetal gestation is lost, a finding noted among surviving singletons in multifetal gestation conceived by in vitro fertilization (IVF)¹⁷² but not in spontaneously conceived pregnancies.¹⁷³ The risk of preterm birth is increased further in higher-order multiple gestations intentionally reduced to twins compared with spontaneous twins.¹⁷⁴ These reports suggest that disturbance of the intrauterine environment in the first or early second trimester is associated with increased subsequent risk of preterm parturition.

Assisted Reproductive Technologies

Preterm birth is more common in pregnancies conceived after ovulation induction and ART, including IVF and gamete and zygote intrafallopian transfer, frozen embryo transfer, and donor embryo transfer.¹⁷⁵ The increased rate of preterm birth after ART is observed in singleton as well as multifetal pregnancies. A review of pregnancy outcome of singletons conceived after in vitro fertilization found increased rates of perinatal mortality (OR, 2.40; CI, 1.59 to 3.63), preterm birth before 37 weeks' gestation (OR, 1.93; CI, 1.36 to 2.74) and before 33 weeks' gestation (OR, 2.99; CI, 1.54 to 5.80), as well as increased rates of VLBW (OR, 3.78; CI, 4.29 to 5.75), small for gestational age (OR, 1.59;

CI, 1.20 to 2.11), and congenital malformations (OR, 1.41; CI, 1.06 to 1.88), compared with spontaneously conceived singleton infants.¹⁷⁶ Other meta-analyses have drawn similar conclusions: perinatal mortality, preterm birth, LBW and VLBW, and small for gestational age are all increased approximately twofold for singleton infants born after IVF.¹⁷⁷⁻¹⁷⁹ A review of 27 studies found a threefold increased risk of birth before 32 weeks in singleton pregnancies conceived after IVF (RR, 3.27; CI, 2.03 to 5.28).¹⁸⁰

Medical stimulation of ovulation (e.g., with clomiphene) is associated with an increased rate of multifetal gestation but was not, until recently, linked to an increased rate of preterm birth in singletons. Ombelet and associates¹⁸¹ reported a threefold increase in births of infants before 32 weeks and weighing less than 1500 g, and a twofold increase in births before 37 weeks and weighing less than 2500 g, among women who conceived after controlled ovarian stimulation compared with spontaneous conception. The mechanisms for this observation are not known.

Multiple Gestation

(See Also Chapter 25)

Multifetal gestations have a sixfold increased risk of preterm delivery compared with singleton pregnancies. The risk increases with fetal number. Between 15% and 20% of all preterm infants are the product of the 2% to 3% of pregnancies that are multifetal. Almost 60% of twins are born preterm, most often after spontaneous labor or pPROM before 37 weeks' gestation. The remainder deliver preterm because of maternal or fetal conditions such as preeclampsia or growth restriction. Almost all higher-multiple gestations deliver preterm. Rates of preterm and LBW in multifetal pregnancies in 2004 are shown in Table 29-4.

The risk of early birth rises with the number of fetuses, suggesting uterine overdistention and fetal signaling as potential pathways to early initiation of labor. Nevertheless, many women with twins deliver after 37 weeks of gestation, suggesting that uterine stretch or distention is variably accommodated according to maternal characteristics including cervical length, physical activity, uterine tone, and other risk factors.¹⁸²⁻¹⁸⁵

The rate of preterm birth in twins has increased since 1990 (Fig. 29-18).¹¹ Rates of preterm birth were similar for twin pregnancies resulting from ART ($n = 231$) compared with spontaneously conceived twins ($n = 430$).¹⁸⁶

Uterine Factors

UTERINE VOLUME

Increased uterine volume caused by excessive amniotic fluid or multiple gestation is a strong risk factor for preterm birth, conferring a relative risk of 6 or greater.¹⁹

UTERINE CONTRACTIONS

Uterine contraction frequency is related to the risk of preterm birth.^{91,187,188} However, uterine contractions do not predict preterm birth well in singletons because of the wide variation in contraction frequency in normal pregnancy and the large overlap in contraction frequency between women who do and do not deliver preterm.¹⁸⁸ Newman and colleagues reported similar results in a study limited to twins.¹⁸⁵

CERVICAL LENGTH

Digital examination is the traditional method used to detect cervical maturation and changes that predict preterm birth. As labor

TABLE 29-4 PERCENTAGE OF PRETERM AND LOW-BIRTH-WEIGHT BIRTHS BY NUMBER OF FETUSES

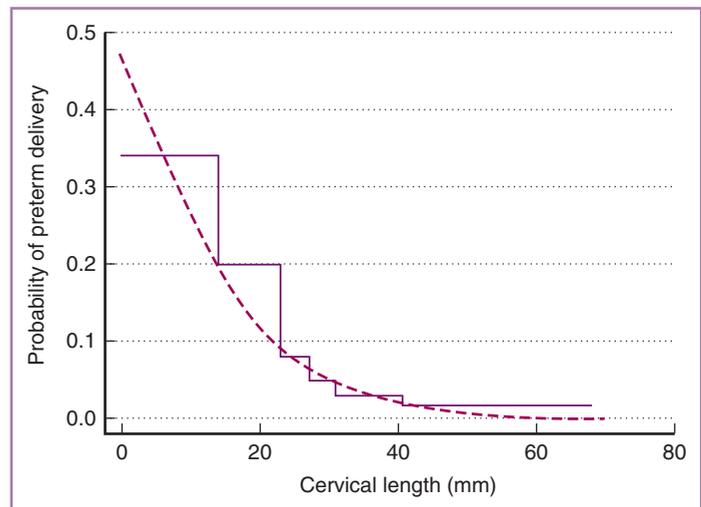

FIGURE 29-19 Probability of spontaneous preterm delivery based on cervical length. Estimated probability of spontaneous preterm delivery before 35 weeks of gestation from the logistic-regression analysis (dashed line) and observed frequency of spontaneous preterm delivery (solid line) according to cervical length measured by transvaginal ultrasonography at 24 weeks. (From Iams JD, Goldenberg RL, Meis PJ, et al: The length of the cervix and the risk of spontaneous premature delivery. N Engl J Med 334:567-573, 1996.)

approaches, the cervix shortens, softens, rotates anteriorly, and dilates. Although emphasis is usually placed on dilation, softening and shortening were the features of the digital examination that most strongly correlated with preterm delivery in a study of 589 nulliparous women.¹⁸⁹ A short cervix detected by ultrasonography is a risk factor for spontaneous preterm delivery¹⁹⁰⁻¹⁹³ (Fig. 29-19).¹⁹¹

The predictive value of cervical length measurements is influenced by the gestational age at measurement. Cervical effacement in normal parturition begins at about 32 weeks, limiting the utility of cervical length measurements thereafter to excluding preterm labor in women with symptoms. Cervical length measurements before 14 to 15 weeks have no relationship to risk of preterm birth.¹⁹⁴ Cervical length in the second trimester has been most studied. The 50th, 10th, and 3rd percentiles between 16 and 22 weeks are approximately 40, 30, and 25 mm^{192,195} when measured endovaginally with a standardized technique¹⁹⁶; between 22 and 32 weeks, these percentile values are 35, 25, and 15 mm, respectively.^{191,193} In an observational study of 2915 women,¹⁹¹ a cervical length of 25 mm or less (the 10th percentile) at 22 to 24 weeks' gestation was associated with an RR of 6.5 (CI, 4.5 to 9.3) for preterm birth before 35 weeks and an RR of 7.7 (CI, 4.5 to 13.4) for preterm birth before 32 weeks. Serial measurements improve

predictive value, but additional observations of funneling and dynamic changes do not.^{197,198}

The RR and positive predictive value of cervical length measurements below the 5th percentile are influenced only slightly by a prior history of preterm birth^{199,200} but such a history increases the predictive value for longer cervical lengths.^{196,201,202} Berghella and associates²⁰³ published regression analyses that demonstrate variation in predictive value of cervical length by gestational age in women with a prior preterm birth. Figure 29-20 displays the likelihood of preterm birth before 32 weeks in a woman with a previous preterm birth.²⁰⁴

Cervical insufficiency due to congenital cervical weakness, surgery, or trauma is characterized by ultrasonographic evidence of cervical shortening that is indistinguishable from cervical effacement caused by preterm activation of parturition, so the relative contribution of biophysical versus biochemical causes of short cervix and subsequent preterm birth is not clear (see Chapter 30). Regardless of cause, cervical

FIGURE 29-20 Predicted probability of delivery before 32 weeks of gestation, by cervical length (mm) and time of measurement (week of pregnancy), in women with a prior preterm birth. (From Berghella V. Gestational age at cervical length measurement and incidence of preterm birth. *Obstet Gynecol* 110:311-317, 2007.)

effacement or shortening detected by digital or ultrasound examination indicates an increased risk of preterm birth that rises as cervical length decreases.

Interventional Strategies

Efforts to prevent the morbidity and mortality associated with preterm birth may be categorized as *tertiary* (initiated after the process of parturition has begun, with a goal of preventing delivery or improving outcomes for preterm infants), *secondary* (aimed at eliminating or reducing risk in women with known risk factors), or *primary* (directed to all women before or during pregnancy to prevent and reduce risk).

Most obstetric care for preterm birth has been focused on tertiary interventions such as regionalized perinatal care, tocolysis, antenatal corticosteroids, antibiotics, and optimal timing of indicated preterm birth. These measures are intended to reduce the burden of prematurity-related illness and have minimal, if any, effect on the incidence of preterm birth. Chapter 23 describes appropriate use of antenatal glucocorticoids as a tertiary strategy to reduce perinatal morbidity and mortality regardless of the clinical presentation leading to preterm birth. This section describes clinical management of preterm labor. Chapters 30, 31, and 34 address clinical management of the related conditions of cervical insufficiency, pPROM, and fetal growth restriction, respectively.

Treatment of symptomatic preterm labor is directed at arresting labor long enough to transfer the mother to the appropriate hospital for delivery and to allow administration of corticosteroids, two interventions that consistently have been shown to reduce perinatal mortality and morbidity. Other interventions directed at reducing neonatal and infant morbidity and mortality include predelivery antibiotics and neuroprotectants.

Diagnosis of Preterm Labor

Diagnosis and treatment of preterm labor is challenging, because the sequence and timing of events that precede preterm labor are incompletely understood. Because the progression from subclinical preterm parturition to overt preterm labor is often gradual, standard criteria for the diagnosis of preterm labor (uterine contractions accompanied by cervical change) lack precision. The result is overdiagnosis in as many as 40% of women diagnosed with preterm labor and enrollment of women who are not in labor into trials of agents to arrest preterm labor.²⁰⁵ Moreover, women who were treated to prevent or arrest preterm labor and were thought to have been treated successfully may not have required treatment at all; the true result of treatment is confidently known only for those whose treatment was unsuccessful. Reliable studies of methods to prevent or arrest preterm labor will not be possible until more accurate diagnostic criteria are established.

Preterm labor must be considered whenever abdominal or pelvic symptoms occur after 16 to 20 weeks' gestation. Limitation of this diagnosis to women presenting after 20 weeks is a historical custom at odds with epidemiologic and biologic evidence reviewed previously. Symptoms including pelvic pressure, increased vaginal discharge, backache, and menstrual-like cramps occur commonly during normal pregnancy, and they suggest preterm labor more by their persistence than their severity. Contractions may be painful or painless, depending on the resistance offered by the cervix. Contractions against a closed, uneffaced cervix are likely to be painful, but recurrent pressure or tightening may be the only symptoms when cervical effacement precedes the onset of contractions.²⁰⁶ The traditional criteria—persistent uterine contractions accompanied by dilation and/or effacement of the cervix—are reasonably accurate if the contraction frequency is six or more per hour and cervical dilation is 3 cm or greater and/or effacement is 80% or greater, or if membranes rupture or bleeding occurs.^{207,208} When lower thresholds for contraction frequency and cervical change are used, false-positive diagnosis is common,^{205,207} but sensitivity does not necessarily increase.²⁰⁹ Accurate diagnosis of early preterm labor is difficult, because the symptoms²¹⁰ and signs⁹¹ of preterm labor occur commonly in normal women who do not deliver preterm, and because digital examination of the cervix in early labor (<3 cm dilation and <80% effacement) is not highly reproducible.²¹¹⁻²¹³

Women with symptoms whose cervical dilation is less than 2 cm and/or whose effacement is less than 80% present a diagnostic challenge. In a clinical trial to identify women with true preterm labor, 179 women with preterm contractions and minimal cervical dilation were randomly assigned to receive either intravenous hydration and observation without intervention or observation after a single dose of 0.25 mg subcutaneous terbutaline.²¹⁴ Intravenous hydration did not decrease preterm contractions. Women whose contractions recurred despite transient cessation after terbutaline were more often found to be in preterm labor, leading the authors to conclude that a single dose of subcutaneous terbutaline is an efficient method of identifying true preterm labor.

Diagnostic accuracy can be improved by transvaginal sonographic measurement of cervical length and/or testing for fetal fibronectin in cervicovaginal fluid.²¹⁵⁻²²⁰ Both tests improve diagnostic accuracy by reducing false-positive diagnosis. Transabdominal sonography has poor reproducibility for cervical measurement and should not be used clinically without confirmation by a transvaginal ultrasound,²²¹ but a cervical length of 30 mm or more by endovaginal sonography suggests that preterm labor is unlikely in symptomatic women if the examination is properly performed. Similarly, a negative fibronectin test in

women with symptoms before 34 weeks' gestation and cervical dilation of less than 3 cm can also reduce the rate of false-positive diagnosis if the result is returned promptly and the clinician is willing to act on a negative test result by not initiating treatment.^{213,216,220}

Clinical markers for high risk of imminent preterm delivery in women with symptoms include ruptured membranes, vaginal bleeding, and cervical dilation beyond 2 cm.²²² Among women with intact membranes, no bleeding, and cervical dilation less than 3 cm, the combination of a positive fibronectin test and a sonographic cervical length of less than 30 mm predicted increased risk of delivery within 48 hours (26%); the risk was less than 7% if only one or neither test is positive.²²³ The presence of debris or "sludge" in amniotic fluid near the internal os on transvaginal sonography has also been associated with increased risk of delivery within 48 hours²²⁴ and with intra-amniotic infection²²⁵ in women with symptoms of preterm labor.

Management of Preterm Labor

Treatments to Reduce Morbidity and Mortality REGIONALIZATION OF CARE

Regionalization of perinatal care reduces morbidity and mortality for preterm infants, especially those born before 32 weeks of gestation^{226,227} (see Chapter 58).

ANTENATAL CORTICOSTEROIDS

As discussed in Chapter 23, antenatal treatment with glucocorticoids has been shown to reduce perinatal mortality and morbidity in appropriately conducted trials and in clinical practice. Current guidelines support a single course of antenatal steroids for women at risk of preterm birth. Optimal implementation of antenatal steroid treatment is complicated by difficulty in judging the imminence of preterm birth. Because benefit is maximized by a full course of treatment and is conferred for a period of weeks after treatment, we favor administration of betamethasone or dexamethasone as soon as there is a demonstrated risk of preterm birth in the current pregnancy. We do not administer steroids solely because of a historical risk factor such as prior preterm birth, but we do consider giving steroids at the first evidence of preterm parturition after 24 weeks in the current pregnancy (e.g., bleeding, cervical change demonstrated by digital or ultrasound examination, positive test for fetal fibronectin) in women with multiple gestation or prior preterm birth. We believe that the advantage of assured receipt of steroids outweighs the likelihood that the benefit of treatment will wane before delivery.

ANTIBIOTICS

Women with preterm labor should be treated with antibiotics to prevent neonatal group B streptococcal (GBS) infection (see Chapter 38). Because preterm infants have an increased risk of neonatal GBS infection, compared to infants born at term, intrapartum prophylaxis with penicillin or ampicillin is recommended.²²⁸ There is also evidence that infants born to women with pPROM have reduced perinatal morbidity when antepartum antibiotic prophylaxis has been administered (see Chapter 31).^{23,229} Antibiotic therapy for women with preterm labor with intact membranes has not been effective in prolonging pregnancy or reducing morbidity²³⁰⁻²³⁴ and should be limited to prophylaxis of GBS transmission or treatment of a specific pathogen.

NEUROPROTECTANTS

Phenobarbital given to the mother does not reduce neonatal IVH when given alone or in combination with vitamin K.²³⁵⁻²³⁷

Antenatal maternal treatment with magnesium has been inconsistently associated in observational studies with reduced rates of IVH, cerebral palsy, and perinatal mortality in premature infants.²³⁸⁻²⁴³ A randomized, placebo-controlled trial of antenatal magnesium conducted in 1062 women and infants delivered before 30 weeks' gestation found significantly lower rates of gross motor dysfunction and non-significant trends toward reduced rates of mortality and cerebral palsy in surviving infants in the treated group at 2 years of age.²⁴⁴ There were no significant adverse effects in infants exposed to antenatal magnesium sulfate. A randomized comparison of magnesium to placebo given before preterm birth as a neuroprotectant to 573 women and their 688 fetuses reported no evidence of harm related to magnesium.²⁴⁵ Another randomized, double-masked, placebo-controlled trial conducted in 2241 women with imminent preterm birth (91% with pPROM) before 32 weeks' gestation found a 55% reduction (RR, 0.45; CI, 0.23 to 0.87) in cerebral palsy at age 2 years among survivors who received antenatal magnesium just before delivery; 95.6% of the enrolled infants were followed-up.²⁴⁶ The rate of death before 2 years was similar in magnesium- versus placebo-treated infants (RR, 1.12; CI, 0.85 to 1.47). These data suggest that there may be a role for prenatally administered magnesium sulfate as a neuroprotectant for infants born before 32 weeks' gestation.

Contraindications to Arrest of Labor

Maternal contraindications to tocolysis include hypertension, bleeding, and cardiac disease. Preterm labor accompanied by maternal hypertension may occur in response to fetal stress or distress, uterine ischemia, or occult placental abruption. Vaginal bleeding may occur because of cervical effacement and dilation but is rarely more than spotting. Because thrombin stimulates uterine contractions, both placenta previa and abruption may be accompanied by uterine contractions. Tocolysis is always contraindicated when hemorrhage is significant, but if bleeding is modest and believed to occur in response to contractions, tocolysis may be considered to achieve time for corticosteroids in the setting of extreme prematurity. Such treatment should be undertaken only in hospitals with experience and appropriate laboratory and consultative support, because even low doses of β -mimetic agents and calcium channel blockers may impair the maternal cardiovascular response to hypotension, and prostaglandin inhibitors affect maternal platelet function. Cardiac disease is a contraindication because of the risks of tocolytic drugs in these patients.

Fetal contraindications to tocolysis include gestational age of 36 weeks or more, fetal demise or lethal anomaly, chorioamnionitis, and evidence of acute or chronic fetal compromise.

Tocolytic Therapy

GOALS OF TOCOLYSIS

Tocolytic agents act to inhibit uterine muscle contractions after the parturitional process is well established and therefore have limited opportunity to prevent preterm birth. The goal of tocolysis is to reduce neonatal morbidity and mortality by delaying delivery long enough to allow administration of corticosteroids and maternal in utero transport to an appropriately equipped hospital. Tocolytic drugs are used for this purpose in women with risk of imminent preterm birth due to active preterm labor and, in selected instances, in women with pPROM.

The appropriate benchmark to assess the efficacy of tocolytic agents is improved health outcome for infants born to women with preterm parturition, but most studies have insufficient power to assess the effect of treatment on this end point. One placebo-controlled trial of transdermal nitroglycerin treatment for preterm labor before 28 weeks

reported a significant decrease in composite neonatal morbidity in infants born to treated mothers,²⁴⁷ but such trials are uncommon, so meta-analyses and surrogate end points (e.g., delay in delivery) are more commonly used to assess efficacy and safety. The Cochrane Collaboration (<http://www.cochrane.org> [accessed February 28, 2008]) regularly conducts meta-analyses of tocolytic drugs; the most recent Cochrane Review concluded that calcium channel blockers such as nifedipine and the oxytocin antagonist atosiban can delay delivery by 2 to 7 days with a favorable ratio of risk to benefit.^{248,249} The Cochrane analyses concluded that β -mimetic drugs can delay delivery by 48 hours but have greater side effects than other agents,²⁵⁰ that magnesium sulfate is ineffective,²⁵¹ and that there are insufficient data regarding cyclooxygenase (COX) inhibitors to support conclusions.²⁵²

These reviews form the basis for clinical algorithms, but they are limited by the design and size of the original research studies. For example, a randomized trial²⁵³ of nifedipine (an agent listed as potentially effective in the Cochrane Review) versus magnesium sulfate (an agent listed as ineffective) illustrates the issues that complicate interpretation of the literature on tocolysis:

1. Randomized trials most often compare two agents to one another, not to placebo, in the belief that placebo treatment is unacceptable.
2. Contraction frequency and cervical change determined by digital examination are the standard entry criteria, but these characteristics have low specificity and sensitivity, and thus lead to the enrollment of women who will deliver at term without treatment in as many as 40% of instances.^{205,207,208}
3. The sample size is too small to address health outcomes such as rates of neonatal or infant morbidity, so a surrogate end point, such as prolongation of pregnancy, is used.

These issues so complicate interpretation of this trial²⁵³ that the results have been interpreted to show that nifedipine is superior to magnesium (same efficacy, fewer side effects, and shorter neonatal intensive care unit stay) and that magnesium has efficacy that is “equal” to that of nifedipine. Neither may be true. Rather, the most appropriate interpretation of this and other comparative studies of tocolytics is that, because parturition is a gradual process with an accelerated phase of active labor, it is extremely difficult for researchers to identify the appropriate population and equally difficult to identify the appropriate moment to use tocolysis. Selection of the “best” tocolytic drug is therefore probably less important than selecting the patient for whom labor would otherwise progress to delivery.

CHOOSING A TOCOLYTIC AGENT

The key process in actin-myosin interaction, and therefore in contraction, is myosin light-chain phosphorylation. This reaction is controlled by myosin light-chain kinase (MLCK). The activity of tocolytic agents is related to regulation of the interactions of this enzyme with calcium and with cyclic adenosine monophosphate (cAMP). Calcium is essential for the activation of MLCK and binds to the kinase as calmodulin-calcium complex. Intracellular calcium levels are the product of calcium influx across the cell membrane and release of calcium from intracellular storage sites. Depolarization leads to calcium influx through specific calcium channels that are voltage dependent. This is the site of action of the calcium channel blockers. Calcium can also enter through voltage-independent mechanisms, most notably the calcium-magnesium-adenosine triphosphatase (Ca^{++} , Mg^{++} -ATPase) system. Magnesium ions may interact here to compete with calcium for the voltage-dependent channels. Calcium is stored within cells in

the sarcoplasmic reticulum and in mitochondria. Progesterone and cAMP promote calcium storage at these sites, whereas prostaglandin $\text{F}_{2\alpha}$ ($\text{PGF}_{2\alpha}$) and oxytocin stimulate calcium release. Cyclic AMP directly inhibits MLCK function via phosphorylation. Levels of cAMP are increased by the action of adenylate cyclase, which is stimulated by β -mimetic agents. Thus, β -mimetic tocolytics act through adenylate cyclase to increase cAMP, which inhibits MLCK activity, both by direct phosphorylation and by reducing intracellular free calcium through inhibiting calcium release from storage vesicles. The β -mimetics also interact with surface receptors on the trophoblast to increase cAMP, which in this tissue increases production of progesterone.

Smooth muscle cells contract in a coordinated and effective manner by intercellular communication via gap junctions. Estrogens and progesterone regulate the formation of gap junctions and the concentration of oxytocin receptors.

Tocolytic drugs may be safely used when standard protocols are followed. Selection of the appropriate tocolytic requires consideration of the efficacy, risks, and side effects to identify the optimal agent for each patient. No tocolytic drug is currently approved in the United States for the indication of arresting labor. Drugs marketed for other indications, such as asthma (β -agonists), hypertension (calcium channel blockers), and anti-inflammatory/analgesic agents (nonsteroidal anti-inflammatory drugs [NSAIDs]) are used as tocolytics within rules of the U.S. Food and Drug Administration (FDA) that allow physicians to prescribe medications for “off-label” use.

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers, marketed to treat hypertension, angina, and arrhythmias, are increasingly being used as tocolytic agents. The pharmacologic effect likely occurs by inhibition of the voltage-dependent channels of calcium entry into smooth muscle cells, acting to decrease intracellular calcium and to decrease release of stored calcium from intracellular storage sites. Nifedipine is the calcium blocker most commonly used as a tocolytic agent. Calcium channel blockers are rapidly absorbed after oral administration. Pharmacokinetics in pregnancy are similar to those in the nonpregnant state. Nifedipine appears in plasma within a few minutes after oral administration, reaches peak concentrations at 15 to 90 minutes, and has a half-life of 81 minutes.²⁵⁴ Placental transfer occurs within 2 to 3 hours after administration of oral nifedipine. The duration of action in the mother of a single dose is up to 6 hours. There are no placebo-controlled trials of calcium channel blockers as tocolytics. The Cochrane Collaboration meta-analyses support the use of calcium channel blockers as short-term tocolytics over other available agents because of their relatively greater contraction suppression and fewer side effects than other agents in 12 reported trials.²⁴⁸ Rates of birth occurring within 7 days after treatment (RR, 0.76; CI, 0.60 to 0.97) and before 34 weeks' gestation (RR, 0.83; CI, 0.69 to 0.99) were significantly reduced with calcium channel blockers, as were the rates of neonatal morbidities, including respiratory distress (RR, 0.63; CI, 0.46 to 0.88), NEC (RR, 0.21; CI, 0.05 to 0.96), IVH (RR, 0.59; CI, 0.36 to 0.98), and jaundice (RR, 0.73; CI, 0.57 to 0.93), when compared with treatment with other tocolytics. Fewer women treated with calcium channel blockers ceased treatment due to adverse drug reactions (RR, 0.14; CI, 0.05 to 0.36).

Maternal Effects. Hypotension and headache are the most common side effects of nifedipine. Pretreatment with fluids may reduce the incidence of maternal side effects such as headache (20%), flushing (8%), dizziness, and nausea (6%). Most side effects are mild, but myocardial infarction was documented in a healthy young woman 45 minutes after a second dose of nifedipine.²⁵⁵ Nifedipine is less likely

to be discontinued because of maternal side effects than either magnesium sulfate or β -mimetic agents.^{248,253,256} Simultaneous or sequential use of calcium channel blockers with β -mimetics is not recommended because of effects on heart rate and blood pressure. Concurrent administration of magnesium with calcium channel blockers may cause skeletal muscle blockade.²⁵⁷ As with other tocolytics, maternal pulmonary edema has been reported.²⁵⁸

Fetal Effects. Early studies in animals reported fetal hypotension, but a study in women treated with calcium channel blockers for preterm labor revealed no changes in the fetal middle cerebral artery, renal artery, ductus arteriosus, umbilical artery, or maternal vessels.²⁵⁹ There is one report of fetal death in a patient treated with nifedipine for tocolysis.²⁶⁰ Oei, in summarizing the European experience with nifedipine, advised the following precautions: “calcium channel blockers should not be combined with intravenous β -agonists. Secondly, intravenous nicardipine or high oral doses of nifedipine (≥ 150 mg/day) should be avoided in cases of cardiovascular compromised pregnant women and/or multiple gestations. In all cases, blood pressure should be monitored and cardiocography recorded during the administration of immediate release Tablets, and chewing the Tablets should be avoided.”²⁶¹

Treatment Protocol. When used as a tocolytic, nifedipine is commonly given orally as a 10- to 20-mg initial dose, repeated every 3 to 6 hours until contractions are rare, then followed by long-acting formulations of 30 or 60 mg every 8 to 12 hours for 48 hours while antenatal steroids are being administered. Serious maternal and fetal side effects are more likely with short-acting preparations when the drug is initiated, and they are more likely in women with hypertension or other cardiovascular disorders. The long-acting preparations have fewer side effects, but headache and hypotension still occur.

Summary of Calcium Channel Blockers. Nifedipine has been used increasingly as a tocolytic because significant maternal and fetal side effects are uncommon and oral administration is convenient. However, efficacy is not established by placebo-controlled trials, and the ideal dosage regimen is not clear. Nifedipine should not be combined with magnesium or β -mimetics, and it should be avoided in the presence of intrauterine infection, maternal hypertension, or cardiac disease.

CYCLOOXYGENASE INHIBITORS

Prostaglandin synthesis is reduced by inhibition of COX by NSAIDs. Prostaglandins mediate the final pathways of uterine muscle contraction, causing an increase in free intracellular calcium levels in myometrial cells and increased activation of MLCK. Gap junction formation is enhanced by prostaglandins. Prostaglandins given to pregnant women can ripen the cervix or induce labor, depending on the dosage and route of administration. COX, also known as prostaglandin synthase, converts arachidonic acid to prostaglandin G_2 . Prostaglandin synthesis is increased when the COX-2 form of this enzyme is induced by cytokines, bacterial products such as phospholipases and endotoxins, and corticosteroids.

NSAIDs vary in activity, potency, and side effects. Indomethacin, the NSAID most often used as a tocolytic, crosses the placenta. Unlike aspirin, indomethacin binds reversibly to COX, so that inhibition lasts only until the drug is excreted. Umbilical artery serum concentrations equal maternal levels within 6 hours after oral administration. The half-life in the mother is 4 to 5 hours; it is 15 hours in a full-term infant but is significantly longer in preterm infants.

The Cochrane Review concluded that indomethacin administration was associated with a significant reduction in births before the 37th week, as well as increased gestational age and increased birth

weight, but noted that there were insufficient data to determine fetal safety.²⁵²

Maternal Effects. Prostaglandin inhibition has multiple side effects because of the abundance of prostaglandin-mediated physiologic functions. Serious maternal side effects are uncommon when the agent is used in a brief course of tocolysis. Gastrointestinal side effects such as nausea, heartburn, and vomiting are common but usually mild. Less common but more serious complications include gastrointestinal bleeding, prolonged bleeding time,²⁶² thrombocytopenia, and asthma in aspirin-sensitive patients. Prolonged treatment with NSAIDs can lead to renal injury, especially if other nephrotoxic drugs are used. Hypertensive women uncommonly experience an acute increase in blood pressure after taking indomethacin. The antipyretic effect of an NSAID may obscure a clinically significant fever. Maternal contraindications to indomethacin tocolysis include renal or hepatic disease, active peptic ulcer disease, poorly controlled hypertension, asthma, and coagulation disorders.

Fetal and Neonatal Effects. Although the maternal side effect profile is mostly benign, serious fetal and neonatal complications of COX inhibitors can occur if the drugs are used outside established protocols. In actual practice, such complications have been rare, but treatment guidelines must be followed carefully. The major fetal side effects are constriction of the ductus arteriosus, oligohydramnios, and neonatal pulmonary hypertension. Ductal constriction may occur because the formation of prostacyclin and PGE_2 , which maintain ductal vasodilation, is inhibited by indomethacin.²⁶³ Transient ductal constriction has been reported in as many as 50% of fetuses of women treated with indomethacin before 32 weeks of pregnancy, usually after several days of therapy. This typically resolves within 24 hours after the medication is discontinued without sequelae.^{264,265} However, persistent ductal constriction and irreversible right-sided heart failure have been reported.²⁶⁶

Primary pulmonary hypertension in the neonate, a potentially fatal illness, has been associated with fetal exposure to NSAIDs²⁶⁷ including ibuprofen, naproxen, aspirin, and indomethacin. Although maternal indomethacin treatment within 16 hours of birth was blamed for a single case of neonatal pulmonary hypertension,²⁶⁸ neither a case-control series in which 75 exposed fetuses were matched with 150 controls²⁶⁹ nor a literature review and meta-analysis that compared outcomes in 1621 infants treated with indomethacin in utero with 4387 unexposed infants found significant differences in neonatal morbidity when maternal indomethacin therapy was used in protocols that limited use to 48 hours or less taken before 32 weeks' gestation.^{270,271} This reassuring information does not mitigate the potential fetal risks of NSAID treatment for longer than 48 hours before 32 weeks or for any duration after 32 weeks, nor the risks associated with prolonged or repeated maternal-fetal exposure to NSAIDs at any time during pregnancy.

Oligohydramnios may accompany indomethacin tocolysis, because indomethacin inhibits the normal prostaglandin inhibition of antidiuretic hormone and also exerts direct effects on fetal renal blood flow. These effects are dose related and reversible, but they are not inconsequential: Neonatal renal insufficiency and death after several weeks of antenatal maternal treatment has been reported.²⁷² Sulindac is an NSAID that has less placental transfer than indomethacin, but amniotic fluid index, hourly fetal urine production, and ductal blood flow were equally reduced in a randomized comparison of sulindac, indomethacin, and nimesulide, another NSAID.²⁷³

Other complications, including NEC, small-bowel perforation, PDA, jaundice, and IVH, have been observed when indomethacin was used in a clinical setting only after other agents had failed and without

limit on the duration or gestational age of treatment.²⁷⁴ No association with IVH has been reported in studies where standard protocols were used.^{269,270,275}

Because of the effect of NSAIDs on fetal urine production and amniotic fluid volume, indomethacin has been used when preterm labor is associated with polyhydramnios.²⁷⁶ Uterine activity and pain associated with degenerating uterine fibroids in pregnancy also respond well to indomethacin.

Fetal contraindications to the use of indomethacin include growth restriction, renal anomalies, chorioamnionitis, oligohydramnios, ductal dependent cardiac defects, and twin-twin transfusion syndrome.

Treatment Protocol. Indomethacin is well absorbed orally. The usual regimen is a 50-mg oral loading dose followed by 25 to 50 mg by mouth every 6 hours. Therapy is limited to 48 hours and to pregnancies before 32 weeks' gestation because of concern about side effects described earlier.

Amniotic fluid volume and fetal renal anatomy should be assessed before indomethacin is used for tocolysis. Treatment beyond 48 hours may be considered in extraordinary circumstances but requires surveillance of amniotic fluid volume and ductal flow. Repeated courses should be avoided if possible. Treatment should be discontinued if delivery is imminent.

Summary of Indomethacin. Indomethacin is an effective tocolytic agent that is generally well tolerated by the mother. Concern about fetal side effects has appropriately limited the use of indomethacin to brief courses of therapy in patients with preterm labor before 32 weeks' gestation.

OXYTOCIN ANTAGONISTS

Oxytocin stimulates contractions in labor at term by inducing conversion of phosphatidylinositol to inositol triphosphate, which binds to a protein in the sarcoplasmic reticulum, causing release of calcium into the cytoplasm. Oxytocin receptor antagonists compete with oxytocin for binding to receptors in the myometrium and decidua, to prevent or reduce calcium release. The oxytocin receptor antagonist, atosiban, inhibits spontaneous and oxytocin-induced contractions but does not affect prostaglandin-induced contractions. Maternal side effects are uncommon, because oxytocin receptors are located only in the uterus and breast. Oxytocin antagonists cross the placenta but do not affect fetal cardiovascular or acid-base status.

Atosiban was evaluated in a randomized, placebo-controlled trial in which 531 women with preterm labor between 200/7 and 336/7 gestational weeks were treated with either intravenous and subcutaneous atosiban or intravenous and subcutaneous placebo.²⁷⁷ Women in either study arm with persistent contractions and progressive cervical change 1 hour after entry were treated openly with a tocolytic agent of the clinician's choice. The interval from enrollment to delivery did not differ between the two groups (26 versus 21 days, $P = .6$). However, among 424 women who enrolled after 28 weeks' gestation, those treated with atosiban were more likely to remain undelivered without requiring an alternate tocolytic at 24 hours (73% versus 58%; OR, 1.93; CI, 1.30 to 2.86), at 48 hours (67% versus 56%; OR, 1.62; CI, 1.62 to 2.37), and at 7 days (62% versus 49%; OR, 1.70; CI, 1.17 to 2.46). There were no differences in pregnancy prolongation for subjects enrolled between 20 and 28 weeks. The FDA did not approve atosiban because of an unexpected finding of more perinatal deaths among infants born to women enrolled into the atosiban arm before 26 weeks. It is not clear whether the difference in outcomes was related to the drug or to an inexplicably larger number of women with gestational age less than 26 weeks who were randomized to the atosiban arm. As in other placebo-controlled tocolytic trials, the rate of "suc-

cessful" treatment in the placebo group was greater than 50%, indicating the difficulty in distinguishing active preterm labor from preterm parturition.

In another trial that compared subcutaneous infusions of atosiban with placebo infusion,²⁷⁸ there were no differences in the rates of preterm birth before 28, 32, or 37 weeks' gestation, but the interval from the start of maintenance infusion therapy to the first recurrence of preterm labor was longer for the atosiban group. An international study group compared the efficacy and side effect profile of atosiban with those of ritodrine.²⁷⁹ Efficacy in delaying delivery for 48 hours (about 85% for both drugs) and for 7 days (about 75% for both drugs) was similar, but cardiovascular side effects were much less common for atosiban (4%) than for ritodrine (84%).

The most recent Cochrane Review noted that atosiban treatment was associated with an increased number of infants born weighing less than 1500 g in the treatment group, compared with the group receiving placebo (RR, 1.96; CI, 1.15 to 3.35; 2 trials, 575 infants) but resulted in fewer maternal drug reactions requiring alternative treatment (RR, 0.04; CI, 0.02 to 0.11; 4 trials, 1035 women). Evidence for the efficacy of atosiban to improve infant outcomes was deemed insufficient.²⁴⁹

Atosiban is widely used in Europe. In an open, randomized trial of atosiban compared with routinely used tocolytic agents conducted in 585 women, prolongation of pregnancy for 48 hours was equal in both groups, but significantly more women receiving atosiban remained undelivered at 48 hours without requiring an alternative tocolytic (77.6% versus 56.6%; $P < .001$). Maternal side effects were less common in women receiving atosiban.²⁸⁰

Summary of Atosiban. Atosiban has minimal side maternal effects and efficacy that is comparable to that of other tocolytics. Although it is commonly used in Europe, it was not approved by the U.S. FDA due to concerns about fetal outcomes in women treated before 26 weeks that may or may not have been related to the drug.

NITRIC OXIDE DONORS

Nitric oxide (NO) acts to maintain normal smooth muscle tone. NO is synthesized during the oxidation of L-arginine to L-citrulline, a reaction catalyzed by nitric oxide synthase (NOS). The interaction between NO and soluble guanylyl cyclase (sGC) links extracellular stimuli of NO formation to synthesis of cyclic guanosine 3',5'-monophosphate (cGMP) in target cells. The increase in cGMP content in smooth muscle cells activates MLCK, which causes smooth muscle relaxation. NO donors such as nitroglycerin inhibit spontaneous oxytocin- and prostaglandin-induced activity.

Glyceryl trinitrate (GTN) has been studied as an acute uterine relaxant to allow uterine manipulation for external cephalic version or ex utero fetal surgery and also as a tocolytic agent. Studies of GTN as a tocolytic have produced mixed results. Intravenous GTN was less effective in arresting contractions and had more side effects than magnesium sulfate in a study of 31 subjects.²⁸¹ In a randomized trial that compared transdermal GTN with ritodrine in 245 women with preterm labor, 74% of participants in both treatment arms delivered after 37 weeks.²⁸² Treatment was discontinued in 25% of the GTN group due to maternal hypotension. Headache was frequent, occurring in 30% of GTN-treated women. The Cochrane Review summarized four randomized trials that compared NO to placebo, no treatment, or other tocolytics and found that NO treatment of preterm labor was associated with fewer deliveries before 37 weeks, but there were insufficient data to assess newborn outcomes.²⁸³

A subsequent randomized trial compared β -mimetic tocolysis with GTN plus rescue β -mimetic tocolysis for persistent contractions in 235 women at 24 to 35 weeks' gestation in whom preterm parturition was

confirmed by a positive finding of cervicovaginal fetal fibronectin or ruptured membranes. There was no significant difference in the time to delivery using Kaplan-Meier curves ($P = .451$).²⁸⁴ In another placebo-controlled trial of NO tocolysis before 28 weeks, also published since the Cochrane Review, composite neonatal morbidity was significantly reduced in infants born to mothers treated with NO.²⁴⁷ This is one of the few studies to report improved neonatal outcome, but these studies are insufficient to recommend NO donors until additional, larger studies are reported.

Headache and hypertension are the most commonly reported maternal side effects. Fetal side effects are uncommonly reported but might be expected because of the drug's effect on maternal blood pressure. Kahler and colleagues investigated maternal and fetal blood flow with Doppler ultrasound in women treated for preterm labor with GTN patches at a dosage of 0.8 mg/hr and found no effect on blood flow in any fetal organ.²⁸⁵

Summary of Nitric Oxide. Nitric oxide donors have not been widely used for tocolysis but deserve further investigation. Current data do not support use outside clinical trials.

MAGNESIUM SULFATE

Pharmacology. Magnesium acts by competition with calcium either at the motor end plate (reducing excitation by affecting acetylcholine release and sensitivity at the motor end plate)²⁸⁶ or at the cell membrane (reducing calcium influx into the cell at depolarization). Myometrial contractility is inhibited when maternal serum levels of magnesium are 5 to 8 mg/dL.²⁸⁷ Deep tendon reflexes may be lost when concentrations reach 9 to 13 mg/dL, and respiratory depression defects occur at 14 mg/dL. Magnesium is excreted almost entirely by the kidney, with at least 75% of the infused dose of magnesium (for the treatment of preeclampsia) excreted during the infusion and at least 90% excreted within 24 hours.²⁸⁸ As magnesium is reabsorbed in the loop of Henle by a transport-limited mechanism, the glomerular filtration rate affects excretion significantly. Increases in maternal serum magnesium also result in maternal hypocalcemia (the total calcium level falling by approximately 25%) and an increase in parathyroid hormone but no change in maternal phosphate or calcitonin level. Hypocalcemia is usually asymptomatic. Magnesium ions cross the placenta rapidly, with fetal and newborn levels increasing proportionately with maternal levels.²⁸⁹ The mean half-life of neonatal hypermagnesemia secondary to maternal therapy may be as long as 40 hours.²⁸⁸

Evidence to support magnesium sulfate as an effective tocolytic is weak.^{290,291} The Cochrane Library reviewers found no significant advantage regarding the rates of delivery within 48 hours or before 34 or 37 weeks in studies of women treated with magnesium.²⁵¹ Two small, randomized trials compared magnesium with nifedipine²⁵³ and celecoxib;²⁹² both found no difference in the percentage of women who delivered within 48 hours.

Despite the limited evidence of benefit, magnesium has been a common choice because of its familiarity and presumed safety relative to β -mimetics and other tocolytics. This rationale for choosing magnesium sulfate has been challenged by reviews that emphasized the paucity of data to support any benefit²⁹³⁻²⁹⁶ and by concerns about fetal safety (discussed later). Direct evidence of improved fetal, neonatal, and/or infant outcomes attributable to magnesium tocolysis is absent, and indirect support from comparative trials and secondary analyses is weak.^{251,290,293,295,296}

Maternal Effects. Magnesium has a low rate of serious maternal side effects, but flushing, nausea, vomiting, dry mouth, headache, blurred vision, generalized muscle weakness, diplopia, and shortness

of breath occur, together with maternal sense of loss of control. Chest pain and pulmonary edema have been reported with a frequency similar to that seen with β -mimetics.²⁹⁷ If renal function is impaired (and magnesium excretion is thus reduced), hypermagnesemia leading to respiratory impairment is more likely. Theoretically, high serum magnesium concentrations could alter the amount of muscle relaxant needed during general anesthesia. Magnesium should not be used as a tocolytic in women with myasthenia gravis. Hypocalcemia may be asymptomatic, or it may manifest as hand contractures.²⁹⁸ Prolonged treatment has been associated with maternal osteoporosis.²⁹⁹ Neuromuscular blockade is possible if magnesium is used concurrently with nifedipine tocolysis.

Neonatal Effects. Magnesium crosses the placenta and achieves serum levels comparable to maternal levels, but serious short-term neonatal complications are uncommon if the duration of maternal therapy does not exceed 48 hours. Neonatal lethargy, hypotonia, and respiratory depression may occur. Prolonged magnesium tocolysis has also been associated with neonatal bone demineralization.³⁰⁰

The Magnesium Sulfate Controversy. Large studies (described earlier) that demonstrated the neuroprotectant benefits of magnesium sulfate have overcome and refuted an early report about possible adverse neonatal and infant effects of antenatal magnesium treatment.²⁴¹ This report described 9 infant deaths among 85 infants born to 75 mothers: three deaths, occurring at 41, 96, and 141 days of life, were attributed to sudden infant death syndrome; one infant died of congenital anomalies at 24 days of life; two deaths occurred in a twin pair born at 26 weeks with the twin-twin transfusion syndrome (an in utero death in the donor twin and neonatal death at 3 days of age in the recipient twin); another infant, one of twins born at 25 weeks, died at 260 days of age; another born at 33 weeks died at 16 days of age in the emergency department; and another died in the delivery room of a subepicardial bleed. Subsequent randomized trials, however, have enrolled more than 30 times as many subjects without evidence of increased neonatal or infant mortality related to magnesium and have demonstrated a reduction in moderate to severe cerebral palsy in surviving infants.^{238,243-246,300,301}

Treatment Protocol. Magnesium sulfate must be given parenterally to achieve serum levels above the normal range. Therapeutic dosage regimens are similar to those used for intravenous seizure prophylaxis of preeclampsia. The customary clinical protocol for magnesium sulfate begins with a loading dose of 4 to 6 g magnesium sulfate in 10% to 20% percent solution (60 mL of 10% magnesium sulfate in 5% dextrose in 0.9% normal saline) given over 30 minutes.²⁹⁷ This is followed by a maintenance dose of 2 g/hr (40 g of magnesium sulfate added to 1 L 5% dextrose in 0.9% normal saline or Ringer lactate at 50 mL/hr). The intravenous rate is increased by 1 g/hr until the patient has fewer than one contraction per 10 minutes or until a maximum dose of 4 g/hr is reached. Some centers choose 3 g/hr as the upper limit. Intravenous fluids are restricted to 125 mL/hr. Fluid status should be followed closely. Deep tendon reflexes and vital signs, including respiratory rate, should be recorded hourly. Magnesium levels may be obtained to answer safety concerns, but the infusion should be reduced or stopped without waiting for drug level results if respiration or urine output declines. Calcium gluconate should be readily available to reverse the effects of magnesium.

Once contractions have decreased to fewer than 1 every 10 to 15 minutes or have ceased, the infusion may be discontinued without first tapering the infusion rate. Magnesium is sometimes continued until an arbitrary end point is reached (e.g., 12 hours after contractions ceased) or until a steroid course is completed, but this approach is unsupported by data.

If renal function is normal, magnesium is excreted rapidly in the urine. Magnesium should be administered cautiously in women with evidence of renal impairment, such as oliguria or serum creatinine levels higher than 0.9 mg/dL. Magnesium sulfate should not be used in patients with myasthenia gravis, because the magnesium ion competes with calcium.

Summary of Magnesium Sulfate. Magnesium sulfate is a familiar agent, but its tocolytic efficacy is poor. Magnesium may be a useful choice if the diagnosis of preterm labor is early and uncertain and in patients in whom other agents are contraindicated (e.g., those with insulin-dependent diabetes).

β-MIMETIC TOCOLYTICS

β-Sympathomimetic drugs, including terbutaline, ritodrine, and others, have been widely used as tocolytics. These agents act to relax smooth muscle in the bronchial tree, blood vessels, and myometrium through stimulation of the β-receptors. β-Receptors are divided into β₁ and β₂ subtypes. The β₁-receptors are largely responsible for the cardiac effects, while β₂-receptors mediate smooth muscle relaxation, hepatic glycogen production, and islet cell release of insulin. Variable ratios of β₂- to β₁-receptors occur in body tissues. Stimulation of β₁-receptors in the heart, vascular system, and liver accounts for the side effects of these drugs. The most commonly used β-mimetic in the United States is terbutaline (marketed as a drug for asthma), but others, including albuterol, fenoterol, hexoprenaline, metaproterenol, nylidrin, orciprenaline, and salbutamol, are used in other countries. Although ritodrine was approved by the FDA for tocolysis in 1980, it did not achieve wide use because of frequent maternal side effects and is no longer marketed. Terbutaline has a rapid effect when given subcutaneously (3 to 5 minutes). Published protocols often employ subcutaneous administration, with a usual dose of 0.25 mg (250 μg) every 4 hours.³⁰²

A single subcutaneous dose of terbutaline to arrest contractions during the initial evaluation of preterm contractions may aid in the diagnosis of preterm labor. In one study,²¹⁴ women whose contractions persisted or recurred after a single subcutaneous dose were more likely to have true preterm labor; those whose contractions ceased were probably not in labor. In a Cochrane Database analysis of 1332 women enrolled into 11 randomized, placebo-controlled trials of β-mimetic drugs, treated subjects were less likely to deliver within 48 hours (RR, 0.63; CI, 0.53 to 0.75), but not within 7 days.²⁵⁰ Perinatal and neonatal mortality and perinatal morbidity were not reduced by β-mimetic treatment in this analysis. Side effects requiring change or cessation of treatment were frequent. Other reviews have reported similar conclusions.³⁰³

Maternal side effects of the β-mimetic drugs are common and diverse due to the abundance of β-receptors in the body. Maternal tachycardia, chest discomfort, palpitation, tremor, headache, nasal congestion, nausea and vomiting, hyperkalemia, and hyperglycemia are significantly more common in women treated with β-mimetics.²⁵⁰ Most side effects are mild and of limited duration, but serious maternal cardiopulmonary and metabolic complications have been reported.

Cardiopulmonary Complications of β-Mimetics. The β-mimetic agents can produce a mild (5 to 10 mm Hg) fall in diastolic blood pressure, and the extensive peripheral vasodilatation may make it difficult for the patient to mount a normal response to hypovolemia. Exclusion of women with any history of heart disease or significant hemorrhage and limitation of infusion rates to maintain maternal heart rate at less than 130 beats/min are important steps to avoid cardiac complications. Symptomatic arrhythmias and myocardial ischemia have occurred during β-agonist tocolytic therapy; myocardial

infarction leading to death has been reported.³⁰⁴ Tocolysis should be discontinued and oxygen administered whenever a woman reports chest pain during tocolytic therapy. Premature ventricular contractions, premature nodal contractions, and atrial fibrillation noted in association with β-mimetic therapy usually respond to discontinuation of the drug and oxygen administration. Baseline or routine electrocardiograms before or during treatment are not helpful. Nonetheless, an electrocardiogram is indicated if there is no response to oxygen and cessation of β-mimetic therapy. Pulmonary edema has been reported with all tocolytics, including β-mimetic therapy. Restriction of the duration of treatment to less than 24 hours, maintenance of careful attention to fluid status, and detection of complicating conditions such as intrauterine infection may reduce this risk.

Metabolic Complications. β-Mimetic agents induce transient hyperglycemia and hypokalemia during treatment. Measurement of glucose and potassium before therapy is initiated and on occasion during the first 24 hours of treatment may be appropriate to identify significant hyperglycemia (>180 mg/dL) or hypokalemia (<2.5 mEq/L.). These metabolic changes are mild and transient, but prolonged treatment (>24 hours) may rarely induce significant alterations in maternal blood sugar, insulin levels, and energy expenditure.³⁰⁵ The risk of abnormal glucose metabolism is further increased by simultaneous treatment with corticosteroids. Other agents should probably be chosen for women with pregestational diabetes, and, in most cases, for those with gestational diabetes as well.

Neonatal Effects. Neonatal hypoglycemia, hypocalcemia, and ileus may occur after treatment with β-mimetics and can be clinically significant if the maternal infusion is not discontinued 2 hours or more before delivery.

Given their potential for clinically significant side effects and the availability of alternative choices, the β-sympathomimetic agents should not be used in women with known or suspected heart disease, severe preeclampsia or eclampsia, pregestational or gestational diabetes requiring insulin, or hyperthyroidism. These drugs are contraindicated if suspected preterm labor is complicated by maternal fever, fetal tachycardia, leukocytosis, or other signs of possible chorioamnionitis.

Long-term or maintenance use of β-mimetic drugs has been advocated to suppress contractions and thereby prevent preterm labor, but tachyphylaxis or desensitization of the adrenergic receptor occurs after prolonged exposure to β-agonists, so that increasing dosages are required to sustain a response.

Continuous subcutaneous infusion of terbutaline has been reported to have fewer side effects at lower doses than oral administration.³⁰⁶ Although these protocols suppressed contractions, they had no effect on rates of preterm birth or perinatal morbidity in randomized, placebo-controlled trials.^{307,308} The Cochrane Review did not support terbutaline infusion to prolong pregnancy,³⁰⁹ nor did the most recent ACOG practice bulletin.²¹⁸

Summary of β-Mimetic Tocolysis. β-Mimetic drugs were once commonly used as tocolytics but are being replaced by agents with better safety and side effect profiles. Terbutaline has relatively few serious side effects when given as a single subcutaneous injection of 0.25 mg to facilitate maternal transfer or to initiate tocolysis while another agent with a slower onset of action is being given. Long-term oral or subcutaneous treatment has not been shown in controlled trials to reduce either prematurity or neonatal morbidity.

CLINICAL USE OF TOCOLYTIC DRUGS

Tocolytic therapy is employed in several clinical circumstances. In caring for a woman with active contractions and advanced cervical effacement with the goal of arresting labor to allow time for maternal

transfer, antenatal steroids, and GBS prophylaxis, treatment with subcutaneous terbutaline or oral nifedipine may stop contractions promptly, after which nifedipine may be continued or another agent started. Treatment may be continued at least until contractions occur less frequently than four times per hour without additional cervical change. If labor has been difficult to stop in a patient with complete cervical effacement, acute treatment may be continued for 48 hours while steroid therapy is completed.

If contractions persist despite therapy, the wisdom of tocolytic treatment should be reevaluated. If cervical dilation has progressed beyond 4 cm, treatment should be discontinued in most instances. Persistent contractions despite ongoing tocolysis raise the possibility of placental abruption or intra-amniotic infection. Amniocentesis should be considered.

If fetal well-being can be confirmed (by a normal fetal biophysical profile including normal fluid volume, or by amniocentesis showing a negative amniotic fluid Gram stain, and/or normal amniotic fluid glucose), the accuracy of the original diagnosis should be reconsidered, remembering that significant effacement, softness, and development of the lower uterine segment are the features of the digital examination that most reliably indicate preterm labor. If a fibronectin swab was collected before therapy was begun, it should be sent for analysis. A positive fibronectin test is not confirmatory, but a negative result, if collected before performance of a digital examination, suggests that preterm birth is unlikely (4%) within 2 weeks.^{216,223} Alternately, a transvaginal cervical ultrasound examination may be performed. A cervical length of 30 mm or more essentially excludes the diagnosis of preterm labor except in cases of acute abruption.²¹⁵

Initiating treatment with a second agent is often considered when contractions persist. Serum levels are not clinically helpful to adjust the dose of tocolytics. A change to a second agent or combination therapy with multiple agents may slow contractions, but this approach often results in increased side effects as well. Sustained treatment with multiple tocolytics increases the risk of significant side effects and should in general be avoided.

Care after Acute Treatment for Preterm Labor

Continued suppression of contractions after acute tocolysis does not reduce the rate of preterm birth.³¹⁰⁻³¹² Meta-analyses of the relevant data found no evidence of prolongation of pregnancy or decline in the frequency of preterm birth.^{309,313} Outpatient monitoring of uterine contractions and associated care did not improve the rate of delivery before 37 weeks, birth weight, or gestational age at delivery.^{314,315}

The duration of hospitalization for preterm labor is influenced by the dilation, effacement and sonographic length of the cervix, ease of tocolysis, gestational age, obstetric history, distance from hospital, and the availability of home and family supportive care. Risk factors that may complicate or increase the risk of recurrent preterm labor, such as a positive genital culture for chlamydia or gonorrhea, urinary tract infection, and anemia, should be addressed before the woman is discharged from hospital care. Social issues such as homelessness, availability of child care, or protection from an abusive partner are important determinants of a patient's ability to comply with medical care and must also be considered before the patient is released from the hospital.

Prevention of Preterm Birth

Great persistence will be required to address the health consequences of preterm birth, because the public significantly underestimates the

magnitude of the problem.³¹⁶ Primary prevention of the morbidity and mortality of preterm birth is an increasingly compelling strategy as the limitations of tertiary care are recognized. Secondary care for women at risk is a strategy limited to removal rather than avoidance of risk.

Until the multiple pathways that contribute to preterm parturition are better understood, attempts during pregnancy (secondary and tertiary prevention) to prevent preterm birth must accommodate the possibility that prolongation of pregnancy intended to promote maturation might in some cases allow continued exposure to a suboptimal or even hazardous intrauterine environment. Indeed, preterm birth is not a health outcome but instead a surrogate end point for optimal fetal, infant, and lifelong health.^{9,317} Indicated preterm birth, by definition, is undertaken to improve maternal and/or fetal and neonatal health, in contrast to presumed fetal benefit for continuing the pregnancy in spontaneous preterm parturition. However, the distinction between indicated and spontaneous preterm birth may be artificial, because factors leading to labor and membrane rupture are understood to include intrauterine inflammation related to microbial infection, uterine vascular compromise, and/or decidual hemorrhage, all of which may contribute to neonatal and infant morbidity as much if not more than fetal immaturity does. Strategies to prevent preterm birth undertaken before conception are not complicated by such concerns.

Prematurity Prevention in Routine Prenatal Care

More than 50% of preterm births occur in pregnancies without obvious risk.^{135,318} Prevention of these preterm births might be addressed by incorporating preventive measures into routine prenatal care or by screening apparently low-risk women for specific risk factors, or both. Most North American studies have focused on the content of prenatal care for women with evident risk of preterm birth, but prematurity prevention as part of routine prenatal care has received less attention.³¹⁹ European prenatal care, in contrast, emphasizes primary prevention of risk during pregnancy for all pregnant women, including social and financial support for low-risk women.³²⁰ This approach was associated with reduced rates of preterm birth in France in an observational report.^{321,322} Efforts to apply the European approach in the United States that emphasized identification and care of women with risk did not reduce the preterm birth rate in randomized trials.^{323,324}

Access to Prenatal Care

Early entry into care is associated with low rates of preterm birth, but the relationship is probably based on the high rate of preterm birth among women who receive no prenatal care rather than the content of care received. Early access to prenatal care did not influence the rate of preterm birth among women enrolled in the First- And Second-Trimester Evaluation of Risk (FASTER) study of prenatal diagnostic techniques in the first and second trimesters.³²⁵ Rates of preterm birth remained notably high among African-American women despite early entry into prenatal care in this study.

Nutritional Supplements for All Pregnant Women

Protein and calorie supplementation during pregnancy was not beneficial for preventing preterm birth when evaluated in controlled trials.³²⁶ Calcium supplementation did not reduce the rate of preeclampsia or that of preterm birth in a randomized trial involving 4589 healthy, nulliparous women.³²⁷ In this study, rates of birth before 37 and 34 weeks were not different, nor was the incidence of pPROM. A review of 10 trials including 14,751 women found no effect of calcium supple-

mentation on the risk of preterm birth (RR, 0.81; CI, 0.64 to 1.03), even though preeclampsia was less frequent in calcium-treated subjects (RR, 0.48; CI, 0.33 to 0.69; 12 trials, 15,206 women).³²⁸

The rates of spontaneous preterm birth before 37, 34, and 28 weeks' gestation were also not improved by supplemental vitamin C and vitamin E given to prevent preeclampsia in a randomized trial conducted in 1877 healthy women.³²⁹ In another trial, supplemental docosahexaenoic acid given to 291 women in the third trimester did not reduce the rate of preterm birth.³³⁰ Prophylaxis of preterm birth with supplemental Ω -3 polyunsaturated fatty acids in women with a history of preterm delivery is discussed later.

Smoking Cessation

Smoking cessation programs are more likely to be well received in pregnancy.³³¹ A brief (<15 minutes) counseling session with a trained provider offering pregnancy-specific counseling was found to reduce smoking rates in pregnant women.³³² The reduction was modest but clinically significant (RR, 1.7; CI, 1.3 to 2.2). Persistent attention to smoking reduction and cessation in prenatal visits is emphasized in most programs. Smoking cessation in pregnancy may be more successful when specific funding for this service is available.³³² One program reported successful results in 3569 indigent women who received care coordination, nutritional counseling, or psychosocial counseling to address specific risks including smoking and inadequate weight gain.³³³ Women who stopped smoking had fewer LBW infants than women who continued to smoke (8.5% versus 13.7%). The rate of LBW was lower in women who achieved adequate weight gain than in those who did not (6.7% versus 17.2%). A Cochrane Review concluded that smoking cessation programs in pregnancy reduce the rate of preterm birth (RR, 0.84; CI, 0.72 to 0.98).³³⁴

Periodontal Care

The risk of preterm birth rises with increased severity of periodontal disease and when periodontal disease progresses in pregnancy,¹²⁴ but the basis for the association is uncertain. It most likely results from shared variations in the inflammatory response to microorganisms in the oral and genital tracts.^{128,129} Periodontal care has been advocated as an intervention to reduce preterm birth, but recent randomized trials did not find lower rates of preterm birth in women treated for periodontal disease.^{127,335,336}

Screening Low-Risk Women to Reduce Risk ASYMPTOMATIC BACTERIURIA

Screening and treatment for asymptomatic bacteriuria prevents pyelonephritis³³⁷ and has been reported to reduce the rate of preterm birth, but the optimal screening and treatment protocols to prevent preterm birth have not been studied recently.^{123,338}

GENITAL INFECTIONS

Because genital tract colonization and infection have been consistently associated with risk of preterm birth, screening and treatment for organisms including *U. urealyticum*,³³⁹ GBS,³⁴⁰ and *T. vaginalis*.^{118,341} have been studied; however, no beneficial effect on the incidence of preterm birth was demonstrated, even when the targeted organism was eradicated. Indeed, screening and treatment of trichomonas may increase the risk of preterm birth.^{118,341}

Routine screening of all pregnant women for BV, with treatment intended to reduce preterm birth, has been extensively studied with mixed results.^{111,115,342-351} BV carriage has been associated with a positive screening test for fetal fibronectin.^{121,352} Although a secondary analysis suggested that antibiotic treatment might reduce the rate of preterm

birth in women with BV who also have a positive fibronectin screen,³⁵³ the rate of preterm birth was not reduced by antibiotic treatment of women with a positive fetal fibronectin result who were treated with antibiotics in a randomized trial.³⁵⁴ Therefore, despite the consistent linkage of maternal BV to risk of preterm birth and the ability of antimicrobial therapy to eradicate BV, screening and treatment for BV does not reliably reduce the occurrence of preterm birth in low-risk women^{111,351} and is not recommended in these patients.^{217,355}

Screening to Assess Risk of Preterm Birth SCORING SYSTEMS

Systems to identify women without apparent risk who will deliver preterm begin with individual characteristics such as low pre-pregnancy weight (BMI <19.6 kg/m²), African-American ethnicity, social risk, depression, and genitourinary colonization as noted earlier, each with a modest relative risk of 1.5- to 2-fold. Risk scoring systems combining these factors have been devised but have a sensitivity of about 25%, even when a history of preterm birth is included.²³ Improved sensitivity has been sought by adding markers of the parturitional process, including biochemical markers in maternal serum (α -fetoprotein, alkaline phosphatase, corticotropin-releasing hormone, relaxin) or in cervical fluid (fetal fibronectin, granulocyte colony-stimulating factor, interleukins) or biophysical markers such as cervical change determined by digital or ultrasound measurement, or combinations of these.^{135,352,356-359} Although studies of these markers have helped to define the parturitional process, they are insufficiently sensitive for clinical use.

FETAL FIBRONECTIN

Fetal fibronectin, a glycoprotein thought to act as an adherent at the maternal-fetal interface, is uncommonly present in cervicovaginal secretions in the late second and early third trimesters.^{352,360} Asymptomatic women with a positive test for fetal fibronectin have an increased risk of preterm birth before 35 weeks, and particularly within 2 weeks after a positive test.^{352,361} This association is believed to be related to disruption of the maternal-fetal decidual interface by inflammation. Although the sensitivity of the fibronectin test for spontaneous birth before 35 weeks approximates 25%, the sensitivity of the test at 22 to 24 weeks for births before 28 weeks was 65% in one study.¹³⁵ For this reason, a placebo-controlled trial of metronidazole and erythromycin was conducted in women with a positive test for fetal fibronectin at 21 to 26 weeks' gestation.³⁵⁴ Preterm birth rates before 37, 35, and 32 weeks were unaffected by antibiotic treatment, with ORs of 1.17 (CI, 0.80 to 1.70), 0.92 (CI, 0.54 to 1.56), and 1.94 (CI, 0.83 to 4.52), respectively. No other interventions for women with a positive fetal fibronectin test have been evaluated in controlled trials. Screening of low-risk women with fetal fibronectin testing is not recommended.²¹⁷

CERVICAL EXAMINATION

Changes in the cervix may precede overt uterine activation and therefore may be used to identify women in whom the parturitional process has begun. Evaluation of the cervix by digital or ultrasound assessment has been shown to identify women with increased risk for preterm birth,^{190-193,213} but, because preterm cervical ripening occurs over a period of weeks, the sensitivity to predict imminent preterm birth is modest (25% to 30% for digital examination and 35% to 40% for endovaginal sonography). Interventions undertaken to reduce the risk of preterm birth in response to evidence of cervical effacement have, in the absence of contractions, targeted presumed cervical insufficiency, but cerclage for short cervix in women without a previous early birth is apparently ineffective.^{362,363} A placebo-controlled, ran-

domized trial conducted in women with sonographic evidence of short cervix (≤ 15 mm) found that cerclage had no effect on the rate of preterm birth.³⁶² However, in another trial that enrolled similar women, treatment with vaginal progesterone significantly reduced the frequency of births before 34 weeks, compared with placebo.³⁶⁴ These studies have not yet been confirmed by others but represent clear progress. The apparent success of medical over surgical treatment for short cervix suggests that the causes of preterm cervical ripening are more likely biochemical than biophysical.

COMBINED TESTING

The combination of digital examination, fetal fibronectin testing, and cervical sonography in nulliparous and low-risk multiparous women was assessed in a secondary analysis of data from the Preterm Prediction Study.³⁶⁵ The sensitivity of cervical sonography was 39% for birth before 35 weeks in these low-risk, asymptomatic women. Sensitivities for the more widely available and less costly tests, digital examination and fibronectin, were less than 25%. The combination of serum markers for preterm birth with cervicovaginal fetal fibronectin and ultrasound measurement of cervical length showed improved sensitivity and positive predictive value³⁵⁶ but, in the absence of an intervention, has no clinical application.

Prevention of Preterm Birth in Women with Clinical Risk Factors

Indicated Preterm Birth

Strategies to prevent indicated preterm births target women with medical disorders and women with risk factors for preeclampsia, such as nulliparity, twin gestation, diabetes, chronic hypertension, and a history of preeclampsia or growth restriction. Numerous trials of various agents (low-dose aspirin,^{366,367} antioxidant vitamins C and E,³⁶⁸ and fish oil^{369,370}) have been conducted to test their effects on the rates of preeclampsia, fetal growth restriction, and preterm birth. Cochrane Reviews of these interventions³⁷¹ have found only modest benefit for antiplatelet drugs, chiefly low-dose aspirin, namely

- An 8% reduction in the risk of preterm birth from a review of 29 trials that enrolled a total of 31,151 women (RR, 0.92; CI, 0.88 to 0.97)
- A 10% reduction in small-for-gestational-age infants in a review of 36 trials that enrolled 23,638 women (RR, 0.90; CI, 0.83 to 0.98)
- A 14% reduction in fetal or neonatal deaths in a review of 40 trials that enrolled 33,098 women (RR, 0.86; CI, 0.76 to 0.98)

Although a Cochrane Review found a significant reduction in preeclampsia in women treated with supplemental calcium, there was no effect on the rate of preterm birth (RR, 0.81; CI, 0.64 to 1.03; 10 trials, 14,751 women) or on the rate of perinatal death (RR, 0.89; CI, 0.73 to 1.09; 10 trials, 15,141 babies).³²⁸ A similar review of the use of antioxidants to prevent preeclampsia found a slight decrease in preeclampsia but no evidence of a corresponding reduction in the risk of preterm birth.³⁷²

Spontaneous Preterm Birth

Secondary interventions to reduce spontaneous preterm birth have been studied in women with a history of spontaneous preterm birth alone,¹³⁹ in women with a prior preterm birth who also have a current pregnancy risk factor or marker (e.g., BV, short cervix),³⁷³⁻³⁷⁵ and in

women with no prior history who have a major clinical risk factor in the current pregnancy (e.g., multiple gestation,³⁸⁷ short cervix).³⁶⁴

Without a clear understanding of pathophysiology, these trials have been designed to answer clinical questions such as whether a given intervention can reduce the rate of preterm birth in women with historical or current risk factors. Interventions have been selected for study because of their presumed participation in a putative causal pathway. Women enrolled are selected for study because they are easily identified by a history of preterm birth or an inexpensive screening test without necessarily knowing whether they possess the risk factor addressed by the intervention being studied. Therefore, an unknown fraction of subjects in these trials receive an intervention that has no opportunity to exert a beneficial effect, leaving the interpretation of the results open to debate.^{377,378} Furthermore, although an effective intervention may interrupt a causal pathway (e.g., an antibiotic may eliminate a genital microorganism), the ultimate clinical outcome may be determined as much by host and environmental factors as by the treatment tested.¹³¹ Finally, the timing of an intervention may determine its clinical efficacy, as may be the case for antibiotic trials.³⁷⁹

Analysis from both primary hypothesis-testing and secondary hypothesis-generating studies of variable size and quality have been reported. Interventions tested include reduced maternal activity, nutritional supplements, augmented prenatal care and surveillance, antibiotic prophylaxis, progesterational supplements, and cervical cerclage.

MODIFICATION OF MATERNAL ACTIVITY

Restriction of physical activity, including bed rest, limited work, and reduced sexual activity, are frequently recommended to reduce the likelihood of preterm birth in pregnancies at risk of indicated and spontaneous birth, despite the absence of benefit in the literature.³⁸⁰ Yost and colleagues found no relationship between coitus and risk of recurrent preterm birth,⁹² but limitation of sexual and physical activity has not been tested since recent advances in understanding the pathophysiology of preterm parturition. Neither bed rest nor coital abstinence has, for example, been studied in women with short cervix or in the outpatient setting.

NUTRITIONAL SUPPLEMENTS

The preterm birth rate is low in populations with a high dietary intake of Ω -3 polyunsaturated fatty acids (PUFA), which reduce levels of proinflammatory cytokines. Dietary supplementation with PUFAs has been associated with reduced production of inflammatory mediators thought to participate in inflammation-driven parturition. A randomized trial of Ω -3 supplements conducted in women at risk for preterm birth found a 50% decrease in preterm births,³⁶⁹ and a subsequent randomized trial of supplemental fish oil also reported a significant reduction in recurrent preterm birth (RR, 0.54; CI, 0.30 to 0.98).³⁷⁰ However, a randomized, placebo-controlled trial of supplemental Ω -3 PUFAs in 852 women with a prior preterm birth found no effect of Ω -3 supplementation on birth or spontaneous birth before 37 or 35 weeks (RR, 0.91; CI, 0.77 to 1.07). The treatment groups did not differ when stratified by fish intake (RR, 0.92; CI, 0.78 to 1.08). In this study, all participants in both arms were treated with 17 α -hydroxyprogesterone caproate (17P).³⁸¹ In a secondary analysis of data from this study, women enrolled in the trial whose diet included fish once or more per month had a significantly reduced rate of spontaneous preterm birth compared to women who consumed fish less often than once per month (RR, 0.62; CI, 0.45 to 0.86), regardless of their study assignment—a hypothesis that will need to be tested in future studies (Table 29-5).

TABLE 29-5 EFFECTS OF OMEGA-3 POLYUNSATURATED FATTY ACID (PUFA) SUPPLEMENTATION AND CONSUMPTION OF FISH ON PRETERM BIRTH

	PUFA (n = 434)	Placebo (n = 418)	P (PUFA vs Placebo)	Fish ≥1 Meal/Month	Fish <1 Meal/Month	P (Fish Intake)

ENHANCED CARE FOR WOMEN WITH RISK

Although perhaps helpful in adolescents,^{382,383} enhanced prenatal care including social support, home visits, and education has not been an effective strategy to decrease preterm births.³⁸⁴⁻³⁸⁸ Reports suggesting that frequent provider-initiated contact and daily uterine contraction assessment for women with a prior preterm birth might reduce recurrence risk were overturned by a large, controlled trial that found no reduction in preterm birth for these measures and, in fact, reported an excess of care without benefit.³¹⁵ A Cochrane analysis similarly found no benefit for enhanced prenatal care in women with increased risk.³⁸⁹

ANTIBIOTIC TREATMENT

Although screening and treatment of low-risk women for genital tract organisms to reduce preterm birth is not effective, antibiotic treatment for women with a prior preterm birth who also have BV remains controversial. This strategy was suggested by secondary analyses of data in two trials, one that enrolled women at risk for preterm birth,³⁷³ in which benefit was found only in women with BV, and another that enrolled women with BV,³⁴³ in which benefit was limited to women with a prior preterm birth. Other trials of treatment for BV-positive women have produced conflicting results, perhaps because of variations in the timing, dosage, and antibiotic employed.³⁹⁰⁻³⁹² Arguments favoring antibiotic screening and treatment of at-risk women were summarized by Lamont,³⁷⁹ who argued that clindamycin should be used before 20 weeks' gestation to treat women with a prior preterm birth who have BV. Others have emphasized the increased rate of preterm birth in women treated with metronidazole^{118,354,392} and the generally negative results of a recent Cochrane Review of 15 trials involving 5888 women.¹¹¹ The reviewers concluded that, although antimicrobial treatment can eradicate BV in pregnancy, it does not reduce the risk of preterm birth or pPROM before 37 weeks for all women or for women with a prior preterm birth. However, they did note evidence that treatment before 20 weeks of gestation may reduce the risk of preterm birth.

One potential reason for the failure of antibiotics to reduce preterm birth is that they may not effectively prevent or treat chorioamnionitis.

Placental histology studies from two antibiotic trials found no difference in histologic chorioamnionitis between women randomized to receive antibiotics versus placebo.^{393,394} Another likely explanation is that host factors including diet, smoking, and genetic variants in inflammatory response influence the risk of infection-related preterm birth, regardless of antibiotic treatment.^{131,395}

The data produced by these trials suggest that the contribution to preterm birth of microorganisms colonizing and infecting the genital tract varies significantly among women, probably because of genetic and behavioral influences that must be further elucidated before antimicrobial agents can be used effectively and safely to prevent preterm birth. The appropriate role for antimicrobial therapy to reduce the risk of preterm birth cannot be determined until questions about the roles of concurrent exposures (e.g., smoking), host factors (e.g., genetic polymorphisms), and selection and timing of treatment are answered.^{131,377,395}

PROGESTATIONAL AGENTS

Progesterone supplementation for women at risk for preterm birth has been investigated based on several plausible mechanisms of action, including reduced gap junction formation and oxytocin antagonism leading to relaxation of smooth muscle, maintenance of cervical integrity, and anti-inflammatory effects.³⁹⁶ Small studies performed in women with recurrent miscarriage and preterm birth were reviewed by Keirse, who found no support for the view that 17P protects against miscarriage but suggested that it does reduce the occurrence of preterm birth.³⁹⁷ This observation prompted two randomized trials of progestational agents in women with risk factors for preterm birth.^{139,398} In a trial that enrolled 142 women with a history of preterm birth or other risk factors to receive placebo or 100 mg progesterone suppositories daily beginning at 24 weeks of gestation, the rate of preterm birth before 37 weeks was 28.5% in the placebo arm and 13.5% in the progesterone arm.³⁹⁸ In the second study, weekly intramuscular injection of 250 mg of 17P was compared with placebo in a randomized trial that enrolled 459 women with a prior spontaneous preterm birth.¹³⁹ Women treated with 17P were significantly less likely to deliver before 37, 35, and 32 weeks (Table 29-6).

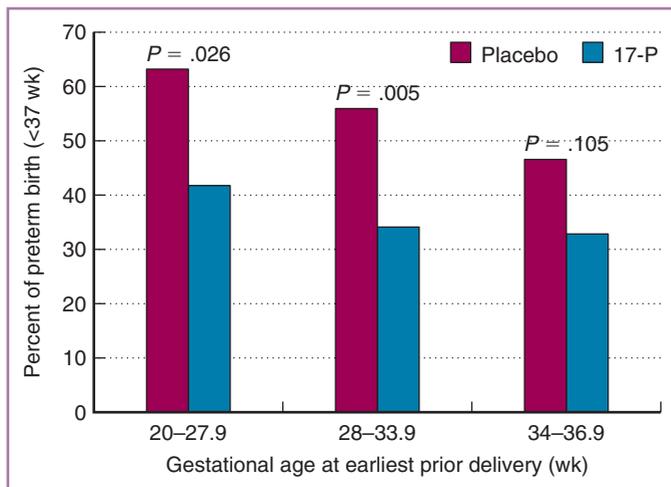

FIGURE 29-21 Effect of 17 α -hydroxyprogesterone caproate (17-P) in women with a prior spontaneous preterm birth, by gestational age at the prior delivery. (From Spong CY, Meis PJ, Thom EA, et al: Progesterone for prevention of recurrent preterm birth: Impact of gestational age at previous delivery. *Am J Obstet Gynecol* 193:1127-1131, 2005.)

Secondary analyses of this study revealed a stronger beneficial effect for women whose qualifying preterm birth was before 34 weeks³⁹⁹ (Fig. 29-21) and for women with more than one prior preterm birth.⁴⁰⁰ The rate of preterm birth before 37 weeks in the placebo group was deemed by some to be higher than expected,⁴⁰¹ but, as noted previously, the recurrence rate was not surprising given the demographics and obstetric history of the women enrolled: 59% of subjects in both groups were African-American, the mean gestational age of the qualifying preterm birth was 31 weeks in both groups, and 32% of women enrolled had more than one prior preterm birth—all factors that increase the risk of recurrence beyond the usual twofold risk associated with a prior preterm birth. The groups differed in the mean number of previous preterm deliveries (1.6 in the placebo group versus 1.4 in the 17P group; $P = .007$), a difference that might have influenced the recurrence rate of 55%.

Meta-analyses of these studies combined with data from earlier trials concluded that the risk of recurrent preterm birth was reduced by 40% to 55% (RR, 0.58; CI, 0.48 to 0.70⁴⁰² and RR, 0.45; CI, 0.25 to 0.80⁴⁰³). However, these trials were not sufficiently powered to detect effects on neonatal or infant outcomes.^{402,404}

Subsequent trials have enrolled women with short cervix (<15 mm) regardless of other historical or current risk,³⁶⁴ women with twins,³⁷⁶ and women with prior preterm birth.¹⁴⁰ In a randomized trial that enrolled women with short cervix, those who received vaginal progesterone had a significantly reduced rate of preterm birth before 34 weeks (19%), compared with women who received placebo (41%).³⁶⁴ However, in another randomized trial conducted in 600 women with twin pregnancies, 17P had no effect on the rate of preterm birth.³⁷⁶ A third study tested the effect of progesterone vaginal gel on the preterm birth rate in 659 women with a prior preterm birth, specifically taking care not to enroll women who were likely to receive a cerclage.¹⁴⁰ A cervical length measurement was obtained at entry to characterize the a priori risk of women enrolled; the mean cervical length at 18 to 20 weeks was 37 mm, indicating a population with a modest risk of preterm birth (studies indicate that cervical length is superior to obstetric history to predict recurrent PTB).

Progesterone did not decrease the frequency of preterm birth at or before 32 weeks, the primary outcome in this study. A secondary analysis of data from this trial suggested that the benefit of progesterone prophylaxis might be limited to women with short cervical length,⁴⁰⁵ consistent with another study that enrolled women with short cervix.³⁶⁴

The optimal clinical protocols for progesterone have not been developed. Recent small studies have suggested that initiation of prophylaxis after 20 weeks may be beneficial,⁴⁰⁶ that discontinuation of prophylaxis may increase the risk of preterm birth,⁴⁰⁷ and that treatment after an episode of preterm labor for women with short cervix might be helpful.⁴⁰⁸ None of these studies have been large enough to influence current practice, but they do support further investigation to define the appropriate role for this treatment.

The beneficial effect of supplemental progesterone compounds is not universally observed in women with a prior preterm birth, indicating that some pathways to recurrent preterm birth are not affected by this therapy. The absence of effect in twin pregnancy,³⁷⁶ coupled with reductions in preterm births among women with historical risk^{139,398} and short cervix,³⁶⁴ suggests that the effect may be related to modulation of inflammation or cervical ripening more than an effect on uterine contractility.

The safety of progesterone supplementation is supported by a review of outcomes of pregnancies treated before 1990,⁴⁰⁹ by a review of animal studies,⁴¹⁰ and, more recently, by a thorough neurodevelopmental evaluation of children at 4 years of age born in women treated in the NICHD trial.⁴¹¹ Data in the studies cited here do not show increased rates of fetal growth restriction or stillbirth, but, because prolongation of pregnancy due to progesterone prophylaxis may arise from its anti-inflammatory actions, potential risks related to that action must be a concern.⁴¹²

The potential benefit of wide clinical use of progesterone supplementation awaits further study. Although the rate of preterm birth may not decline appreciably if treatment is limited to those with a prior preterm birth,⁴¹³ the savings generated by treating only those women have been estimated at more than \$2 billion annually in the United States alone.^{414,415}

CERVICAL CERCLAGE

A short cervical length in midpregnancy is associated with an increased risk of early delivery¹⁹⁰⁻¹⁹² and is linked particularly to recurrent preterm birth.^{135,196} Cervical length is inversely related to risk of preterm birth, the risk rising as the cervical length decreases. The finding of a short cervix, variably defined as a measurement lower than the 10th or the 3rd percentile (25 or 15 mm, respectively, in the second trimester), may indicate the early onset of parturition in response to biochemical influences of paracrine, endocrine, or inflammatory origin; the biophysical effects of uterine stretch or contractions; or insufficient cervical strength. Because these congenital, biochemical, and biophysical factors may occur in any individual, alone or in combination, to produce a short cervix, the value of any intervention in response to a short cervix has been difficult to determine. Cerclage has been performed in this setting to correct a presumed structural deficiency, but the results have been inconsistent.

The ability of cervical cerclage to prolong pregnancy has been studied in observational and randomized trials,^{362,363,374,375,416-429} from which the following conclusions emerge:

- Cervical cerclage in women with a short cervix (<15 mm) who do not have a prior preterm birth does not reduce the rate of spontaneous preterm birth.^{362,363}

- Although cerclage may benefit women with short cervix who have a prior preterm birth, the evidence is not conclusive. Selection of the appropriate candidates for cerclage is uncertain.^{363,374,375,417-423}
- Prophylactic cerclage for women with a history of preterm birth who are without sonographic demonstration of short cervix in the current pregnancy is not justified by the current literature. There is evidence that these women can be monitored by serial sonographic examination of the cervix, followed by cerclage if the cervix shortens.^{416,421,422,430,431}

In a meta-analysis of data from four trials,³⁶³ women with a history of preterm birth who also had a short cervix (defined as <2.5 cm) in the current pregnancy were most likely to benefit from cerclage. In these patients, the risk of birth before 35 weeks was reduced with cerclage treatment (RR, 0.63; CI, 0.48 to 0.85). There was no benefit of cerclage treatment for women with a short cervix who did not have a prior preterm birth (RR, 0.84; CI, 0.60 to 1.17) in this analysis. The risk of preterm birth was actually increased in women with twins and short cervix who were treated with cerclage (RR, 2.15; CI, 1.15 to 4.01).

The efficacy of cerclage thus appears to vary according to the cause of the short cervix. In a study of women with prior preterm birth, the risk of recurrent preterm birth was decreased by cerclage treatment when the level of IL-8 in cervical secretions was low but increased in women treated with cerclage who had an elevated cervical IL-8.⁴³² These studies suggest that cerclage may reduce the risk of preterm birth in women with a prior preterm birth only when there is ultrasound demonstration of short cervix, and then only when preterm cervical effacement has occurred in the absence of inflammation. No clinical test for cervical inflammation is available. Until such a diagnosis can be made, prophylactic cerclage should be reserved for women who are believed to have anatomic insufficiency, rather than either early delivery history or sonographic findings alone.

Prematurity Prevention Before Pregnancy

Prevention of Risk among Women of Reproductive Age

Pre-conceptual interventions are attractive, because many risk factors are difficult to address successfully in pregnancy.⁶

PUBLIC EDUCATIONAL INTERVENTIONS

The public inaccurately perceives that the problems of preterm infants have been overcome by improved neonatal care.³¹⁶ Increased awareness of preterm birth as the leading cause of infant mortality offers an opportunity to raise public awareness of avoidable risk factors.² For example, greater public and professional knowledge of evidence suggesting that repeated uterine instrumentation may confer an increased risk of subsequent preterm birth might affect decision making about these procedures.^{158,159,162,165} Use of laminaria has been reported to reduce the risk of subsequent preterm birth in women undergoing second-trimester dilation and evacuation.⁴³³

Similarly, broader public knowledge of the increased risk of preterm birth in singleton gestations conceived with ART might, if coupled with information about the consequences of prematurity, influence fertility care.⁴³⁴⁻⁴³⁶ Such educational efforts could be modeled after successful efforts to reduce the prevalence of smoking.

PUBLIC AND PROFESSIONAL POLICIES

In contrast to public education strategies, policies adopted by government or medical bodies can have a more immediate effect. Policies adopted to reduce the risk of higher-order multiple gestation have been successful in Europe, Australia, and the United States. Rates of triplet and higher-order multiple pregnancies were rising rapidly in the United States until 1998, when voluntary adoption of limitations on the number of embryos transferred was promoted by professional groups. The rate of higher-order multiples then fell by 50% between 1996 and 2003.^{437,438}

Social policies to improve pregnancy outcomes have been adopted by many European countries.³²⁰ Minimum paid pregnancy leave of 14 weeks, time off for prenatal visits, exemption from night shifts, and protection from workplace hazards, including complete work leave if necessary, are among the strategies employed.

NUTRITIONAL SUPPLEMENTS

Women considering a pregnancy are routinely advised to initiate supplementation with prenatal vitamins before conception, chiefly to reduce risk of birth defects.⁴³⁹ A randomized, placebo-controlled trial of vitamin supplementation that enrolled women before conception and continued through the first 2 months of pregnancy found no effect of vitamins on the preterm birth rate.⁴⁴⁰

SMOKING

The attributable risk of cigarette smoking exceeds 25% for preterm birth⁴⁴¹ and approximates 5% for infant mortality.⁴⁴² An overall decrease in maternal smoking before conception might be expected to reduce preterm births, but preterm birth rate in the United States rose from 11.6% to 12.5% between 2000 and 2004, a time when smoking among women aged 18 to 44 years declined from 25.5% to 21.7%.¹⁶ Reduced prevalence of smoking would nevertheless have multiple health benefits for pregnant women and infants.

Pre-conceptual Care for Women with Risk

Pre-conceptual interventions to reduce risk of preterm birth typically target women with a previous preterm birth.⁴⁴³ The upper gestational age boundary for a preterm birth is commonly 37 weeks, and the risk of recurrence declines as the gestational age of the index preterm birth approaches 37 weeks.⁴ The lowest gestational age for which an increased risk of preterm birth is observed in subsequent pregnancies is optimal for clinical use and was determined to be 17 to 18 weeks for spontaneous preterm births in studies of data from the Preterm Prediction Study. Previous births before 17 weeks did not confer an increased risk of recurrent preterm delivery.^{4,138,443}

As noted earlier, the risk of recurrence is increased for both spontaneous and indicated preterm births.^{137,142,148} Risk increases as the gestational age of the previous preterm birth declines and as the number of preterm births increases.⁴ Careful review of records from prior pregnancies may be helpful to establish the gestational age of the index birth, estimate the recurrence risk, and identify risks amenable to intervention, including some that may require pre-conceptual intervention (e.g., correction of müllerian anomalies)⁴⁴⁴ and others that could determine care choices during pregnancy (e.g., prophylactic progesterone or cerclage). Pre-pregnancy medical risk factors have been identified in as many as 40% of preterm births,⁴⁴⁵ suggesting that women with these risks might benefit from pre-conceptual control of diabetes, seizures, asthma, or hypertension.

Internatal care for women with prior preterm birth has been proposed,⁴⁴⁶ but evidence that these steps can actually influence the preterm birth rate is lacking. A randomized trial of inter-conceptual

home visits and counseling by midwives did not reduce preterm birth and LBW in a study of 1579 women.⁴⁴⁷ Based on the hypothesis that pre-conceptional microbial colonization of the endometrium might increase the risk of preterm birth, a randomized, placebo-controlled trial of inter-conceptional antimicrobial treatment was performed in women with a prior early preterm birth.⁴⁴⁸ Study participants received metronidazole and azithromycin or placebo at 3-month intervals until their next pregnancy occurred. The rate of recurrent preterm birth was not influenced by antibiotic treatment. The proportion of women enrolled in this study whose qualifying preterm birth was related to infection is not known.³⁷⁷

Chapter 30

Cervical Insufficiency

Jay D. Iams, MD

Definitions of Cervical Competence and Insufficiency

The definition of cervical competence is functional: The task of the cervix is first to retain the conceptus until maturity and later to dilate sufficiently to allow delivery of the mature infant. The ability to perform these functions repeatedly in successive pregnancies is cervical *competence*. Cervical *insufficiency* describes a presumed physical weakness of cervical tissue that causes or contributes to the loss of an otherwise healthy pregnancy, usually in the second trimester. Anatomic, biochemical, and clinical evidence has consistently supported the belief that some percentage of second-trimester births are primarily or perhaps exclusively caused by congenital or acquired structural weakness of the cervix. However, the incidence, pathophysiology, clinical presentation, and management of the disorder have been difficult to distinguish from those of preterm cervical effacement and dilation caused by factors other than insufficient cervical strength. As described in Chapters 28 and 29, cervical strength or competence appears to be one of many continuous variables that influence the process of preterm parturition, including uterine volume, intrauterine microbial colonization, decidual hemorrhage, and genetic and environmental factors. The term *cervical insufficiency* is applied when participation by other variables is not clinically evident. Although this definition is conceptually straightforward, it is difficult to apply in practice because similar results from the history, symptoms, physical and sonographic examinations, and laboratory evaluation of women with cervical insufficiency are shared by many women with preterm parturition for whom cervical weakness is not the principal cause, and importantly, for whom cerclage is not likely to be beneficial. Indeed, an operational definition of cervical insufficiency is a pregnancy in which a cervical cerclage is likely to improve pregnancy outcome, but there are currently no definitive tests for the diagnosis.

The contribution of cervical insufficiency to spontaneous preterm parturition remains controversial. Studies described in Chapter 29 addressed the benefit of cervical cerclage for women with a prior spontaneous preterm birth and commonly omitted women thought to have “true” cervical insufficiency. Recognizing that the distinction between cervical insufficiency and early spontaneous preterm birth has become increasingly uncertain, this chapter focuses on pregnancy outcomes and treatment of women with structural abnormalities of the cervix.

The Cervix in Pregnancy

Anatomy

The uterine cervix and corpus are derived from fusion of the distal müllerian ducts and subsequent central atrophy.¹ The cervix is primarily fibrous tissue with some (10% to 15%) smooth muscle.² The cervicoisthmic zone of histologic transition from fibrous to muscular tissue may be narrow (1 to 2 mm) or relatively wide (5 to 10 mm).² The proportion of cervical smooth muscle ranges from 29% in the upper third to 6.4% in the lower third.³ The muscular uterine isthmus distends and elongates between the 12th and 20th weeks of gestation, consistent with ultrasound studies of the cervix and lower segment during the same period.⁴

Cervical Remodeling during Pregnancy

Biochemical Changes

The cervix changes soon after conception and continues to remodel throughout pregnancy and the puerperium. Cervical remodeling has been described as occurring in four phases: softening, ripening, dilation, and repair (Figure 30-1).⁵ Endocervical endothelial cells proliferate during pregnancy and supply cervical mucus and defensins to protect the upper tract from microorganisms. Collagen synthesis increases in early gestation, but collagen concentrations decline as the cervix ripens and the water content of the cervix increases before labor. Abnormalities of cervical remodeling may contribute to the clinical syndrome of cervical insufficiency.

Ultrasonographic Appearance of the Cervix in Normal Pregnancy

Understanding of cervical function in pregnancy has been enhanced by ultrasound images of the cervix over the course of pregnancy. Measurements of the cervix before pregnancy and in the first trimester of pregnancy do not correlate with pregnancy outcomes and are not useful to identify reduced function.⁶ Normative values of cervical length have been established in the second and third trimesters of pregnancy, as measured by transvaginal ultrasonography, and are normally distributed.^{4,7-12} The median and 10th percentiles of length before 20 weeks' gestation are approximately 40 and 30 mm, respectively.^{11,12} Between 22 and 32 weeks, the 10th, 50th, and 90th percentiles are 25, 35, and 45 mm, respectively. Parity does not influence cervical length.¹⁰

FIGURE 30-1 Stages of cervical function during pregnancy and the puerperium. Although the process occurs as a continuum, each stage is characterized by unique biochemical and cellular events. GAGs, glycosaminoglycans; HA, hyaluronan; IL-8, interleukin 8; iNOS, induced nitric oxide synthase. (From Word RA, Li, X-H, Hnat M, et al: Dynamics of cervical remodeling during pregnancy and parturition: Mechanisms and current concepts. *Semin Reprod Med* 25:69-79, 2007.)

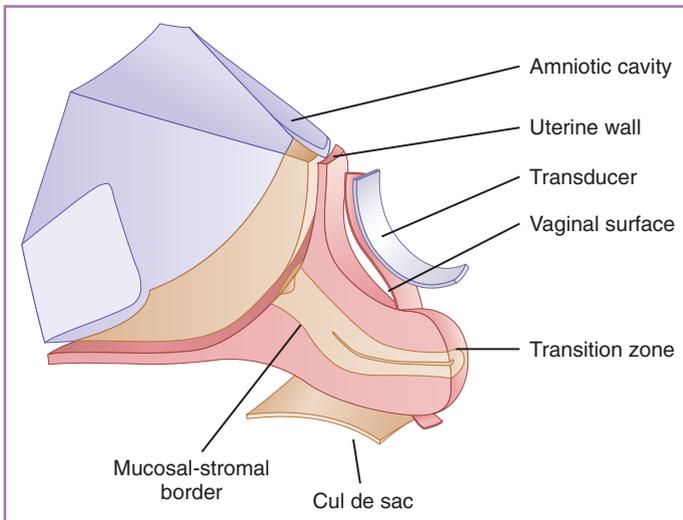

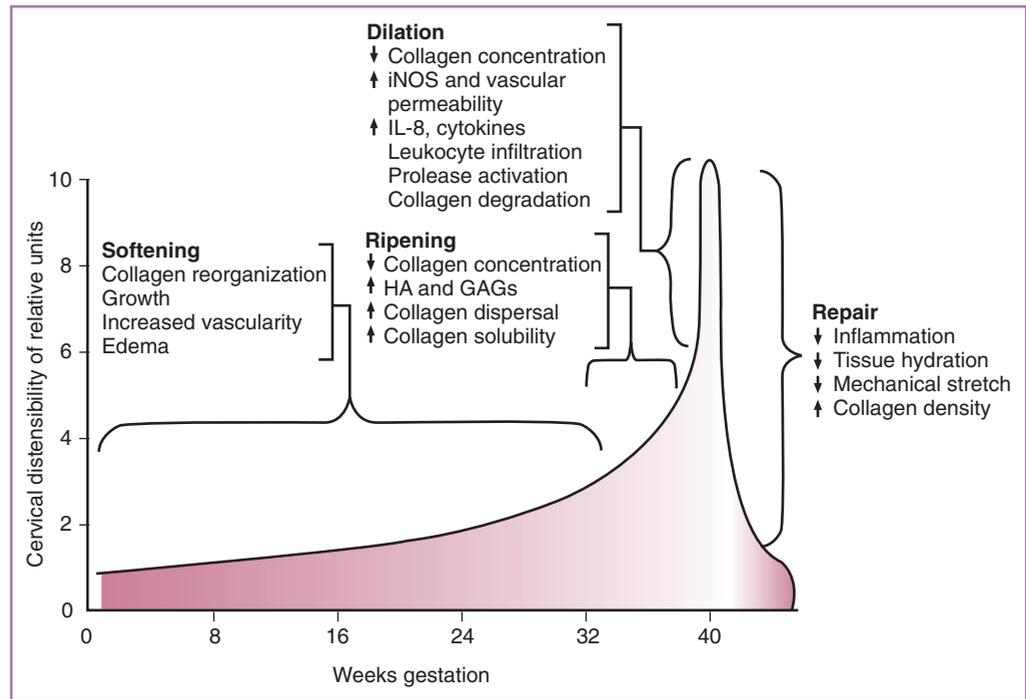

FIGURE 30-2 Schematic diagram of uterine and cervical structures imaged by endovaginal sonography. (Courtesy of Dr. Michael House, Tufts–New England Medical Center.)

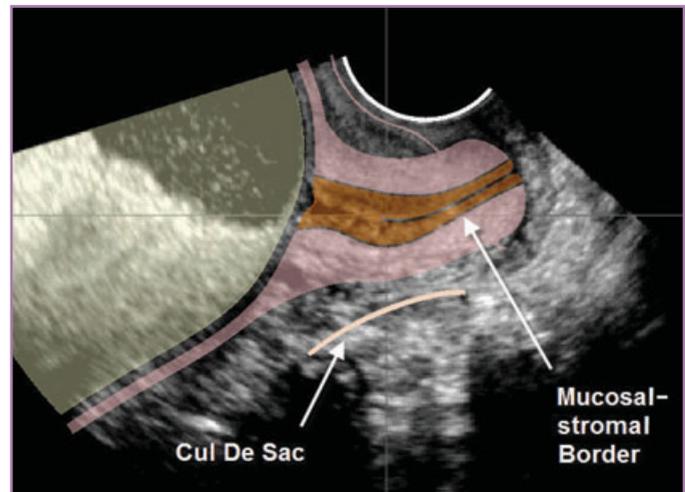

FIGURE 30-3 Cervix and cervical canal schematic superimposed on endovaginal ultrasound image. Arrows point to mucosal-stromal border and posterior vaginal cul de sac (pink line). (Courtesy of Dr. Michael House, Tufts–New England Medical Center.)

Measurements are obtained with an endovaginal transducer, as shown in Figures 30-2, 30-3, and 30-4.

Cervical effacement precedes decidual activation at term and for most preterm births by a period of several weeks (4 to 8 weeks or even longer). Effacement begins at the internal cervical os and proceeds caudad according to the T-Y-V-U sequence described by Ziliani and colleagues.⁹ The process of effacement usually proceeds incrementally, but it can occasionally be seen by real-time ultrasound to be dynamic; that is, the internal os is seen to open and close, giving the appearance of a funnel. Representative endovaginal ultrasound images that display

the progressive effacement seen in normal pregnancy are shown in Figures 30-5, 30-6, and 30-7.

The cervix begins to efface normally at about 32 to 34 weeks' gestation, in preparation for birth at term. These same changes often precede spontaneous deliveries in the second and third trimesters regardless of clinical presentation, often without uterine contractions. Therefore, a short or funneled cervix may be observed with ultrasound well in advance of delivery, regardless of gestational age, and regardless of the presumed mechanism—structural weakness, biochemically induced changes in the cervical stroma, or biophysical effects of uterine contractions.

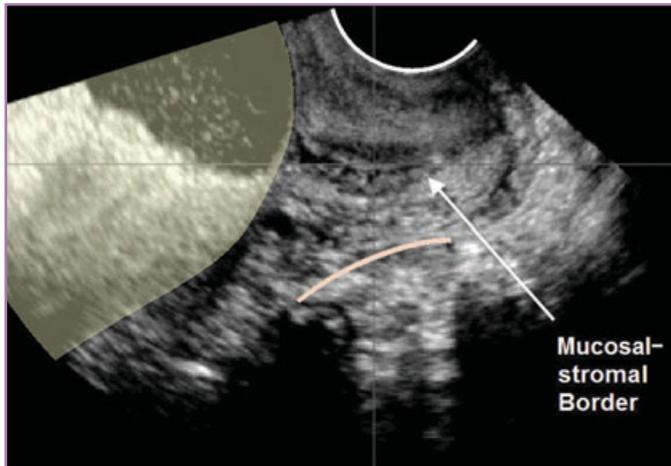

FIGURE 30-4 Endovaginal image of the cervix. Arrow points to mucosal-stromal border. Pink line indicates posterior vaginal cul de sac. (Courtesy of Dr. Michael House, Tufts–New England Medical Center.)

FIGURE 30-5 Endovaginal ultrasound image of a normal cervix at 24 weeks' gestation. The closed portion of the cervical canal is measured from the external os, identified as the most distal point at which anterior and posterior walls of the canal touch, to the internal os, identified as the most proximal point where the walls touch. The cervix in this image is measured in two segments because of the curved canal, a normal finding. The length is 40 mm, the 75th percentile. The internal os is closed, forming a “T” relationship to the canal.

Causes of Cervical Dysfunction

Congenital Causes

Collagen

Primary disorders of the cervicoisthmic junction may result from developmental abnormalities in the muscular isthmus and the upper cervix or from derangement of the cervical fibrous tissue resulting in decreased cervical resistance. Concentrations of smooth muscle relative to collagen fibers are higher in women with cervical insufficiency

FIGURE 30-6 Endovaginal ultrasound image of a cervix at 25 weeks' gestation, showing Y-shaped funneling at the internal os. The cervical length is 21.3 mm, approximately the 5th percentile.

FIGURE 30-7 Endovaginal ultrasound image of the cervix at 32 weeks' gestation, showing substantial effacement where the V shape has almost become a U. The cervix was 1 cm dilated by digital examination. The patient was an outpatient who was not in labor.

than in women who have no history of preterm birth.¹³ Cervical biopsy specimens obtained from normal women after parturition¹⁴ revealed a 12-fold decrease in mechanical strength, a 50% reduction in the concentrations of collagen and sulfated glycosaminoglycans, a 35% reduction in hyaluronic acid, an increase in collagen extractability, and a fivefold increase in collagenolytic activity compared with tissue obtained from normal nonpregnant women. In contrast, cervical biopsy specimens obtained in the second trimester from pregnant women with a history of cervical insufficiency revealed normal collagen concentrations but high collagen extractability and collagenolytic activity—higher than normal postpartum values.¹⁴ Significantly lower concentrations and increased extractability of hydroxyproline were observed in cervical tissue obtained from nonpregnant women with cervical insufficiency in their first pregnancy, compared with cervical tissue from normal parous controls.¹⁵

Alterations in the regulation of type I collagen expression may influence cervical ripening,¹⁶ and genetic disorders affecting collagen function (e.g., Ehlers-Danlos syndrome) have been associated with increased risk of preterm birth.¹⁷ Familial disorders of collagen are more prevalent than is usually recognized¹⁸ and may explain familial aggregation of cervical insufficiency. In a study of 121 women with,

and 165 women without, cervical insufficiency, more than 25% of the former group had a first-degree relative with the same diagnosis, a finding associated with polymorphisms in the genes for collagen type I α 1 and transforming growth factor- β .¹⁹ Familial collagen disorders may therefore contribute to cervical insufficiency.

Biologic Variation in Length

Cervical length, as measured by endovaginal ultrasound in the second trimester of pregnancy, is normally distributed.¹⁰⁻¹² The risk of preterm birth increases as the cervical length in the second trimester decreases (Fig. 30-8).

Individual variation in cervical function is suggested by a rising risk of spontaneous preterm birth before 35 weeks as cervical length declines, especially in the lower quartile of the bell-curve distribution.¹⁰⁻¹² Although this relationship may result from exogenous factors unrelated to inherent cervical strength, short cervical length has been specifically linked to repetitive preterm birth.^{20,21} Women with a short cervix during pregnancy are more likely to have a history of preterm birth.²¹ Moreover, the gestational age of a prior delivery has been related to cervical length in a subsequent pregnancy: The earlier the gestational age of the previous birth, the shorter the cervix in the current pregnancy.²⁰ Additional evidence of biologic variation in the cervical competence comes from studies that relate cervical length above the 50th percentile to a decreased risk of spontaneous preterm birth in women with twin and triplet pregnancies.²²⁻²⁵

Uterine Anomalies

Müllerian fusion anomalies may involve the cervix as well as the uterine cavity. Congenital structural uterine abnormalities have been associated with an increased incidence of reproductive loss for multiple reasons, including apparent cervical insufficiency. Case series describing pregnancy outcomes in women with uncorrected uterine anomalies indicate higher rates of preterm birth in women with bicornuate, didelphys, or arcuate uteri, compared to those with septate or subseptate uteri.²⁶⁻³⁴ Endovaginal sonography in women with uterine anomalies can reveal cervical duplication or altered uterine anatomy not visible on speculum examination or laparoscopy.

Teratogens: Diethylstilbestrol

Poor pregnancy outcome and structural genital tract abnormalities have been reported in women who were exposed to diethylstilbestrol (DES) in utero,³⁵ due at least in part to cervical insufficiency attributed to DES exposure.³⁶ The risk of second-trimester pregnancy loss in DES-exposed women compared with unexposed controls was increased fourfold to fivefold (6.3% to 7.1%, compared to 1.6% in controls).³⁵ Other possible causes for adverse pregnancy outcomes in DES progeny include upper genital tract abnormalities of uterine cavity shape (e.g., a T-shape) and intrauterine defects such as synechia and diverticulae.³⁷

Acquired Causes

Trauma

OBSTETRIC INJURY

Cervical injury may occur during labor or at the time of delivery. The cervix may be lacerated or stretched beyond tolerance, or it may

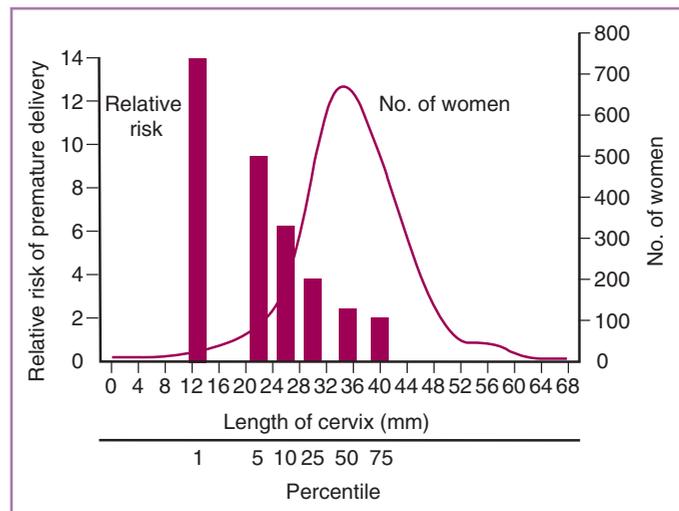

FIGURE 30-8 Distribution of subjects among percentiles for cervical length measured by transvaginal ultrasonography at 24 weeks of gestation (*solid line*) and relative risk of spontaneous preterm delivery before 35 weeks of gestation according to percentiles for cervical length (*bars*). The risks among women with values equal to or less than the 1st, 5th, 10th, 25th, 50th, and 75th percentiles are compared with the risk among women with values greater than the 75th percentile. (From Iams JD, Goldenberg RL, Meis PJ, et al: The length of the cervix and the risk of spontaneous preterm delivery. *N Engl J Med* 334:567, 1996.)

heal poorly. Women delivered by cesarean section after an arrested second stage of labor can present in the next pregnancy with cervical insufficiency.³⁸ The mechanism is not clear, but two hypotheses may explain this observation: (1) a prolonged second stage may injure the cervix directly by stretch and trauma, or (2) the low transverse uterine incision may heal poorly in this setting. Cervical injury might also occur during cesarean delivery should the incision extend vertically into the cervix. Poor healing is more common when cofactors such as obesity, smoking, hemorrhage, and infection are present.

DILATION AND CURETTAGE

Mechanical dilation of the cervix before gynecologic procedures or abortion has been blamed for cervical insufficiency,³⁹ but injury sufficient to alter cervical function is uncommon when performed by an experienced operator with the use of laminaria.⁴⁰⁻⁴² The risk of preterm birth after pregnancy termination is discussed in Chapter 29.

CERVICAL BIOPSY AND ABLATION OF NEOPLASIA

Diagnosis and treatment of intraepithelial neoplasia requiring cervical biopsy, laser ablation, loop electrosurgical excision procedure (LEEP), or cold knife conization are clearly linked to an increased risk of subsequent preterm birth (see Chapter 29).⁴³⁻⁴⁷ Whether the increase is related to an increased rate of cervical insufficiency, to other effects

FIGURE 30-9 Cervical polyp. Endovaginal ultrasound image of a cervix with a broad-based cervical polyp.

on cervical function, or to uterine microbial colonization is not known.

Biochemical Influences

Endocrine, paracrine and inflammatory stimuli can effect biochemical changes in cervical structure and function during pregnancy. Softening occurs normally in pregnancy⁵ and progresses to ripening, but these events may be prematurely triggered in women with preterm parturition, leading not only to increased risk of preterm labor and ruptured membranes but also to a clinical presentation consistent with cervical insufficiency.⁴⁸ The inflammatory cytokine interleukin 8 (IL-8) participates in cervical ripening as a neutrophil chemotactic factor.⁴⁹ Increased levels of IL-8 in cervical fluid are associated with increased risk of preterm birth and with failure of cerclage treatment in women with previous preterm birth and short cervix.⁵⁰ Weiner and coworkers demonstrated that proteomic markers in amniotic fluid associated with intrauterine inflammation or decidual hemorrhage predicted failure of rescue cerclage.⁵¹

INTRACERVICAL INFLAMMATION

Anecdotal evidence suggests that an inflamed cervical polyp or necrotic intracervical myoma can cause preterm cervical ripening that may resolve spontaneously or progress to preterm delivery (Fig. 30-9). These instances raise the possibility that other causes of intracervical inflammation, such as microbial infection, may contribute to preterm cervical effacement as well.

Diagnosis of Cervical Insufficiency

History

The diagnosis of cervical insufficiency has traditionally been made by an obstetric history of recurrent painless dilation of the cervix prior to preterm birth in the second trimester. This classic picture was once thought to be the only true presentation, distinct from other causes of early preterm delivery. However, asymptomatic effacement and dilation of the cervix may precede various clinical presentations.⁵² Evaluation to identify cervical insufficiency has in the past focused on exclusion of alternative explanations, such as preterm labor, ruptured membranes, discharge, or bleeding, that are now recognized as pre-

senting symptoms and signs of the preterm parturition syndrome (see Chapters 28 and 29), in which a complex interaction of factors can lead to preterm cervical ripening as early as 16 weeks' gestation, often with minimal symptoms. Prior obstetrical taxonomy assigned causation to the clinical presentation (e.g., preterm labor or preterm ruptured membranes *versus* cervical insufficiency) rather than to the underlying pathologic mechanisms that are now understood to be primarily biochemical.⁵³ For this reason, although a history of painful contractions against an uneffaced cervix argues against cervical insufficiency, presentation with cervical dilation and minimal symptoms is no longer accepted as unique to cervical insufficiency. Cervical insufficiency is characterized clinically more by *recurrent* midpregnancy delivery than by the absence of contractions or infection. A history of short labors, progressively earlier deliveries in successive pregnancies, advanced dilation at the time of first presentation, and prior cervical surgery or injury also suggest cervical insufficiency. Women ultimately diagnosed with cervical insufficiency often describe feelings of pelvic pressure, premenstrual symptoms, and increased vaginal discharge for several days before presentation, sometimes including an office or hospital visit at which the cervix was noted to be closed by digital examination.

Women with atypical obstetric histories that include births at term as well as second-trimester losses may also have cervical insufficiency. In some, the explanation may come from a cervical injury at the time of a prior term birth, or there may be an obvious nonrepetitive cause, but an undiagnosed uterine anomaly should also be considered. The duration of pregnancy in such cases may be determined by the uterine horn in which the pregnancy implants or by the placental implantation site on an incomplete uterine septum.

Physical Examination

Physical examination of the cervix in women who are not pregnant does not identify cervical insufficiency. Speculum examination may reveal cervical lacerations or the effects of previous cervical surgery, but correlation of findings with subsequent pregnancy outcome is poor. Substantial cervical tissue often lies above the lateral vaginal fornices, inaccessible to clinical examination, so that cervical performance in pregnancy is often normal in women with little or no cervix apparent at the vaginal apex.

Serial digital and speculum examinations have been employed to monitor patients with suspected cervical insufficiency, but effacement often precedes palpable or visible dilation of the canal. Initial findings on digital examination are progressive softening and thinning, followed by eventual dilation. Speculum examination first reveals a thin discharge and, with patience and fundal pressure or a Valsalva maneuver, membranes may be visible. Visible or even bulging membranes may be observed in women with no history of problems. Not surprisingly, a closed cervix does not exclude the diagnosis, because cervical effacement and dilation begin at the internal os. Digital examination is less reproducible than ultrasound examination of the cervix.⁵⁴⁻⁵⁷

Digital and speculum examination findings can supplement a diagnosis of cervical insufficiency based on maternal history, but they are not themselves definitive, because the same cervical status can result from causes other than structural weakness. Cervical dilation of 1 cm or more appears to be an optimal threshold for placement of cerclage.⁵⁸

Diagnostic Tests

There are no accepted tests or criteria to detect cervical insufficiency outside of pregnancy. Measurement of resistance to the passage of a

cervical dilator or Foley balloon and the hystero-graphic appearance of the cervix have been proposed but have not been helpful clinically.

Ultrasonography

The sonographic appearance of the cervix before conception and in early pregnancy does not offer any consistent evidence of subsequent insufficiency.

Ultrasound examination to detect incompetent cervix in pregnancy was first performed with transabdominal transducers.⁵⁹⁻⁶¹ The abdominal technique requires a full maternal bladder to visualize the cervix⁶² and thus introduces unpredictable measurement artifact.^{63,64} Transvaginal ultrasound examinations produce a more consistent and more accurate image of the cervix while avoiding the confounding effect of a full maternal bladder.⁶⁴⁻⁶⁶ Figures 30-3 through 30-7, 30-9, and 30-10 depict images generated by placing the endovaginal probe in the anterior vaginal fornix. The details of cervical measurement are important. The standard method employs endovaginal sonography and the “shortest best” technique of caliper placement, in which initial measurements are ignored until the same length is generated repeatedly with the least pressure applied to the cervix to obtain a good image of the endocervical canal.^{7,10-12,20,67} Alternative methods produce longer measurements that are not reproducible.⁶⁸

When these studies were first reported, cervical competence was viewed as comprising only two categories: competent or incompetent. The observation of funneling at the internal os in the absence of apparent uterine activity was believed to indicate cervical insufficiency, and ultrasound findings of funneling with a short residual cervix were proposed as diagnostic criteria, especially in women with a history of mid-trimester birth. Subsequent sonographic studies identified progressive cervical effacement that precedes uterine activation by several weeks in both normal and preterm parturition.^{7,10-12}

Cervical length is related to the risk of preterm birth.^{7,10-12,69,70} The absolute risk of preterm birth varies substantially by population, but an increasing risk of preterm birth as cervical length declines has been consistently reported. Although the risk is strongest for cervical length less than the 10th percentile, there is no threshold value below which a patient always or even usually presents with cervical insufficiency. In a study in which providers were unaware of the cervical ultrasound measurement, more than half of women whose cervical length was less than the 1st percentile (13 mm) at 22 to 24 weeks delivered after 35 weeks (see Fig. 30-8).¹⁰ The association between cervical length and preterm birth is strongest in women with a prior preterm birth and especially strong when the previous preterm birth occurred before 32 weeks.^{20,21,71}

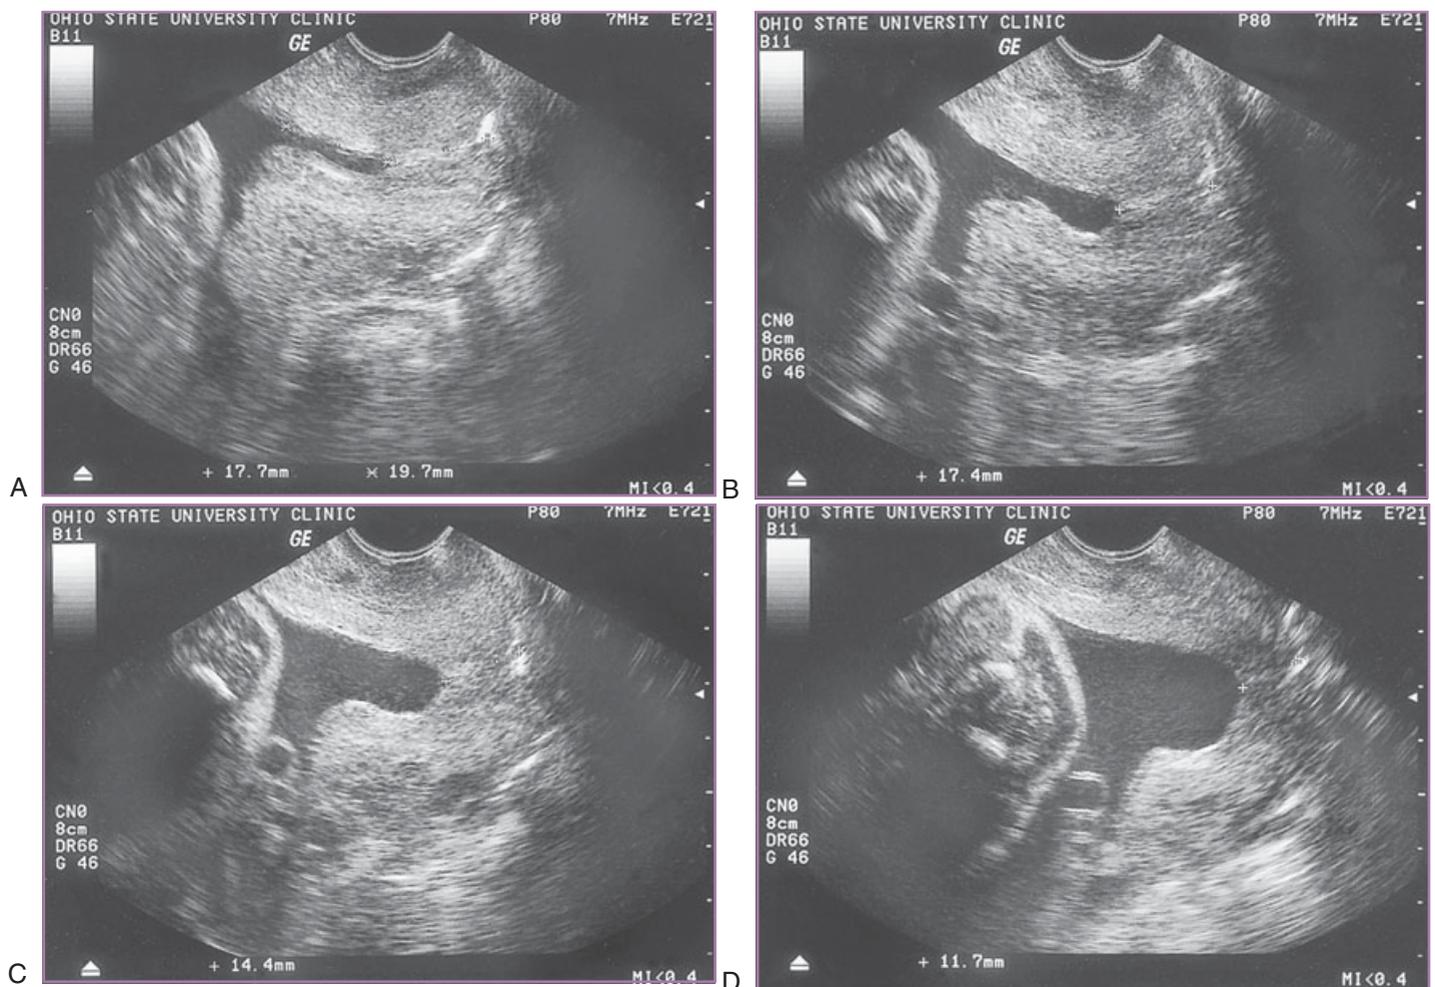

FIGURE 30-10 A sequence of four images obtained over a period of 90 seconds in a patient with a prior preterm birth. **A** through **D**, Progressive cervical change occurs in response to gentle suprapubic pressure. The cervical length measurement is 11.7 mm, the “shortest best” image of the sequence.

Attempts to use a percentile of cervical length, or a combination of length and other sonographic characteristics of the cervix, to distinguish cervical insufficiency from other causes of preterm cervical effacement have not been successful. Although abdominal pressure applied to the fundus or suprapubic area can aid the endovaginal ultrasound examination by revealing the internal os more clearly, funneling, whether spontaneous or in response to increased intra-abdominal pressure, does not define cervical insufficiency or add to the sensitivity or predictive value of cervical length to assess the risk of preterm birth.^{72,73} The rate of decrease in cervical length over time⁷⁴ and onset of effacement before 20 weeks^{71,72,75} are related to an increased risk of early preterm birth but also do not distinguish cervical insufficiency from other causes of preterm delivery.

Clinical Criteria

Attempts to assign a diagnosis of cervical insufficiency based on good response to cerclage therapy in a previous pregnancy have also faltered, first in anecdotes of successful outcomes in women who refused a recommended cerclage, as well as observational studies reporting successful pregnancy outcomes in upwards of 70% of untreated couples with a history of mid-trimester loss,^{76,77} and, more recently, in prospective studies of cervical length in women with prior early preterm birth. More than 60% of women with a history of early preterm birth maintain a cervical length greater than 25 mm without treatment and have correspondingly low rates of recurrent preterm birth.⁷⁸⁻⁸¹ A recently concluded study performed ultrasound surveillance of cervical length from 16 to 23 weeks in more than 1100 women with a prior preterm birth between 17 and 34 weeks; 70% of these women maintained a cervical length greater than 25 mm and therefore did not qualify for entry into the second phase of the study, a randomized trial of cerclage that will report results in 2009.⁸²

The American College of Obstetricians and Gynecologists was unable to identify any level I evidence for its 2003 practice bulletin on cervical insufficiency, in which it endorsed serial transvaginal ultrasound examinations between 16 and 20 weeks for women with historical risk factors for cervical insufficiency.⁸³ The American College of Radiology 2005 Expert Panel on Women's Imaging report on premature cervical dilation acknowledged the superior images obtained by transvaginal imaging of the cervix, recommended that the cervix be imaged transabdominally during all routine fetal ultrasound examinations in the second trimester, and suggested that women with a short or funneled cervix observed on abdominal ultrasound undergo transvaginal or translabial imaging of cervical length.⁸⁴ Diagnostic criteria for cervical insufficiency based on history, physical examination, and imaging studies must therefore be considered as uncertain. Emphasis should be placed on a history of prior cervical trauma, repeated mid-trimester loss, absence of painful contractions, advanced cervical dilation and effacement at presentation, and ultrasound findings of a cervical length of less than the 10th percentile before 24 weeks' gestation.

Treatment of Cervical Insufficiency

When cervical insufficiency was first described,^{85,86} surgical correction was proposed by placement of an encircling or cerclage suture or graft, applied before^{85,86} or during pregnancy, by either a transvaginal^{87,88} or a transabdominal approach.⁸⁹ The cerclage suture has been commonly placed electively between 11 and 15 weeks' gestation, or later in the

second trimester in response to physical or ultrasound evidence of cervical dilation. Evidence of benefit for cerclage in initial reports was descriptive.

In addition to cerclage, medical therapies including bed rest, pessaries, antibiotics, anti-inflammatory drugs, and progesterone supplementation have been proposed. As the definition, etiology, and clinical presentation of cervical insufficiency have evolved, the appropriate treatment for women with a history of recurrent midpregnancy deliveries has become increasingly uncertain.

Nonsurgical Treatment

Nonsurgical approaches to the management of cervical insufficiency have been attempted but have not gained widespread acceptance nor proved efficacious in a controlled trial.

Pessaries

Various types of vaginal pessaries have been used in an attempt to change the axis of the cervical canal and prevent alleged gravitational forces from causing cervical dilation and subsequent delivery. A 2000 review of pessaries concluded that there was insufficient evidence to exclude the possibility of benefit.⁹⁰ Subsequent observational studies suggested that pessaries may be superior to bed rest and equivalent to surgical cerclage in women with suspected cervical insufficiency.⁹¹⁻⁹³ There are no randomized trials that compare treatment with pessaries to cerclage.

Medications

Prostaglandin inhibitors have been employed as nonsurgical treatment for cervical insufficiency. A review of indomethacin in controlled trials found that indomethacin might be of benefit in women with short cervix when used before 24 weeks of gestation.⁹⁴ Progesterone treatment reduced the risk of preterm birth in asymptomatic women with short cervix (<15 mm),⁹⁵ but women with cervical insufficiency were not enrolled in this trial, which is discussed further in Chapter 29.

Surgical Treatment: Cervical Cerclage Procedures

Pre-conceptual Cerclage

Cerclage in the nonpregnant state may be considered if the cervix has a large traumatic defect. Pre-conceptual cerclage placement may complicate management of spontaneous first-trimester abortion or the second-trimester discovery of a serious fetal anomaly. Lash and Lash⁸⁶ described a transvaginal procedure to correct a structural defect within the cervix and later⁹⁶ reported improved fetal survival after the surgery, compared with prior pregnancies, but fertility was compromised.⁹⁷ An alternative procedure was described⁹⁸ in which a suture was placed at the level of the internal os after simpler procedures proved unsuccessful. The cervical mucosa was incised and dissected anteriorly and posteriorly to the level of the peritoneal reflection. A nonabsorbable suture was placed circumferentially at the level of the internal os; the uterosacral ligaments and a small amount of cervical tissue, both anteriorly and posteriorly, were included in the suture.

Transabdominal cerclage before conception has been reported in 19 women, all of whom did well.⁹⁹

Cerclage during Pregnancy

The two most commonly performed procedures during pregnancy were reported by Shirodkar⁸⁷ and McDonald.⁸⁸ If these procedures are

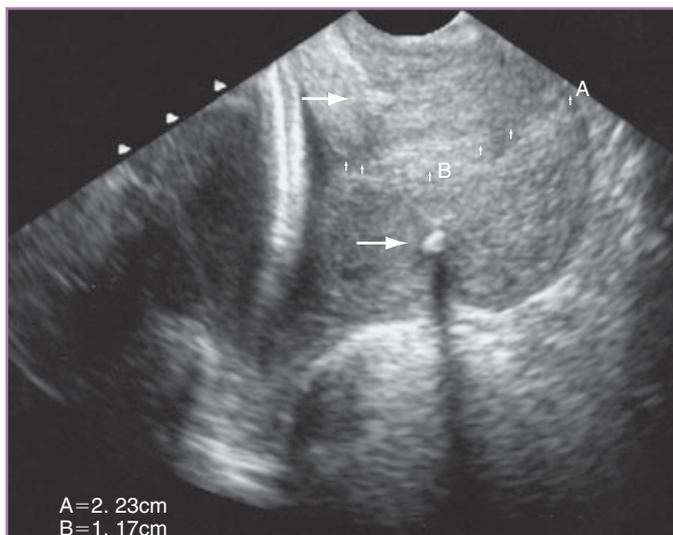

FIGURE 30-11 Transvaginal cerclage. Endovaginal ultrasound image of the cervix in a woman with a transvaginal Shirodkar cerclage. Arrows point to the 5-mm tape used for the procedure.

unsuccessful or are anatomically difficult, transabdominal cerclage (described later) or a transvaginal procedure using a technique similar to that described by Mann and colleagues⁹⁸ are reported to have a high success rate.¹⁰⁰

Intraoperative ultrasound may aid satisfactory placement of Shirodkar or McDonald cerclage sutures by helping the clinician to judge the site of the suture relative to the internal os and the maternal bladder and rectum (Fig. 30-11). Sonography is performed after the sutures are placed but before the knots are tied.¹⁰¹ This immediate feedback allows removal and replacement of sutures that are too low or that impinge on adjacent structures.

SHIRODKAR CERCLAGE

Shirodkar⁸⁷ used maternal fascia lata as the “suture” material and aneurysm needles to thread the fascia lata strip submucosally, after first incising the vaginal epithelium transversely both anteriorly and posteriorly and reflecting the vesicovaginal and rectovaginal fascia to the level of the internal os. The suture was tied anteriorly, and the anterior and posterior incisions were closed with absorbable material. Since the original report, many modifications have been suggested, including tying the knot posteriorly, leaving the ends of the knot exposed for easier removal, and, most commonly, replacing fascia lata with an inert suture or a 5-mm polyester band mounted on atraumatic needles. Instead of tunneling the suture submucosally, a long, curved Allis clamp may be inserted into the incisions anteriorly and posteriorly, with lateral traction applied on the submucosal tissue to place the cerclage next to the body of the cervix and medial to the uterine vessels. The knot is usually tied anteriorly and tagged to facilitate later removal. The Shirodkar suture may be anchored anteriorly and posteriorly, to avoid slippage or displacement, by including cervical tissue within the cerclage suture or by using a second nonabsorbable suture.

McDONALD CERCLAGE

McDonald⁸⁸ described a procedure that requires no submucosal dissection. A purse-string suture is begun anteriorly at the junction of the ectocervix and rugated vagina. Four to six bites of cervix are taken in a circumferential fashion, well into the body of the cervix, avoiding entry into the endocervical canal. Care must be taken to place the

suture high on the posterior aspect of the cervix, because this is the most likely site for suture displacement. The suture is tied anteriorly or posteriorly, and the ends are left long enough to facilitate removal at term or at the onset of labor. Variations include use of braided nylon, polyester, or a 5-mm tape. The cervix may be re-entered at the previous point of exit with successive bites to place the suture entirely submucosally, or it may be placed so that it encompasses the cervical serosa.

TRANSABDOMINAL CERVICOISTHMIC CERCLAGE

First described by Benson and Durfee,⁸⁹ the transabdominal approach to cerclage placement has become more common as experience has grown.^{81,102-107} The original criteria for selection of transabdominal cerclage included a congenitally short or amputated cervix, previously unsuccessful vaginal cerclage with cervical scarring, and cervical distortion or scarring that prevented the transvaginal approach. Transabdominal cerclage has also been recommended after one or more prior vaginal cerclage procedures have failed.^{106,108} An explanation for the reported success of the abdominal over the vaginal procedure may come from the novel work of House and Socrate, who created a biomechanical model based on three dimensional ultrasound and magnetic resonance images to study cervical function in pregnancy.¹⁰⁹ Their investigations indicate that the maximum load is born at the internal os,¹¹⁰ and therefore the cerclage suture is not load-bearing when placed at the midpoint of the cervix, as is often the case with vaginal cerclage.

Suggested timing for abdominal cerclage is between 10 and 14 weeks of gestation, so that uterine manipulation for visualization of both anterior and posterior leaves of the broad ligament can be accomplished easily; however, the procedure has been performed as late as 17 to 18 weeks’ gestation.

The operation described by Benson and Durfee⁸⁹ may be performed through a Pfannenstiel or vertical incision. The peritoneal reflections are divided transversely, and the bladder is advanced carefully to avoid wide lateral dissection that could injure the massive vascular plexus present during pregnancy. At the level of the uterine isthmus, the space between the ascending and descending branches of the uterine artery is identified and developed by blunt dissection, medial to the uterine arteries and veins and lateral to the connective tissue of the uterine isthmus. Upward traction on the uterine fundus by an assistant exposes the region of the internal os, and the vessels are placed on traction. After the tunnel has been developed in the vascular space bilaterally, the posterior leaf of the broad ligament is punctured bilaterally, and a 5-mm Mersilene tape is passed under direct vision to lie over the posterior peritoneum at the level of the insertions of the uterosacral ligaments. The Mersilene band is tied snugly anteriorly or posteriorly with a square knot, and the cut ends are sutured to the band with fine, nonabsorbable sutures. The peritoneum and abdomen are then closed in routine fashion.

Mahran¹⁰² advocated lateral retraction of the uterine vessels with the operator’s fingers while a synthetic 5-mm tape is placed around the cervix from anterior to posterior at the level of the isthmus. The suture is anchored in the cervical tissue both anteriorly and posteriorly (and laterally in the Mackenrodt ligament) and tied posteriorly. This technique minimizes the opportunity for injury to the dilated parametrial venous plexus.

Davis and colleagues¹⁰⁶ reported a retrospective comparison of transvaginal and transabdominal cerclage with the Mahran technique in women with grossly normal cervical anatomy who had a previous transvaginal cerclage with delivery before 33 weeks’ gestation. Both

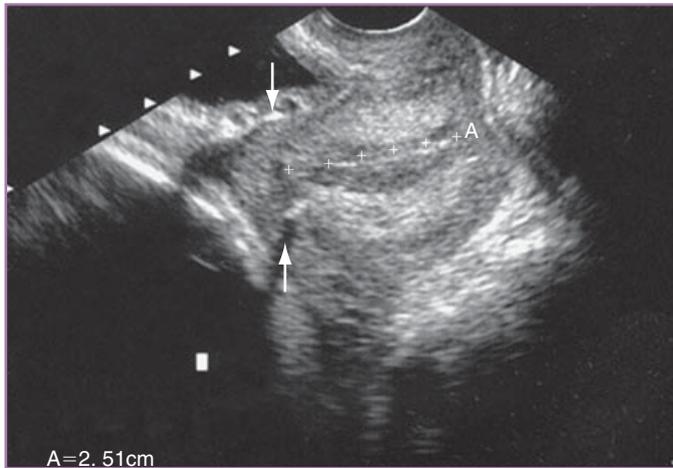

FIGURE 30-12 Transabdominal cerclage. Endovaginal ultrasound image of the cervix in a woman with a transabdominal cerclage. Arrows point to the 5-mm tape used for the procedure.

delivery before 35 and delivery before 33 weeks' gestation were less common (18% versus 42%; $P = .04$, and 10% versus 38%; $P = .01$, respectively) in the women treated with transabdominal cerclage ($n = 40$) than in those treated with transvaginal cerclage ($n = 24$). The principal difference was a marked reduction in the frequency of preterm ruptured membranes—8% versus 29%, respectively ($P = .03$). Figure 30-12 shows an endovaginal image of the cervix of a woman treated with a transabdominal cerclage. The cerclage is seen near the internal os at a level rarely achieved with a transvaginal procedure.

The transabdominal procedure requires laparotomy for cerclage placement and again for cesarean section. Transabdominal cerclage sutures have been placed laparoscopically¹¹¹ and with robotic assistance.¹¹² The suture may be removed by posterior colpotomy or laparoscopy to allow vaginal delivery, but more often it is left in place, with cesarean section planned before labor. A well-placed cerclage rarely causes symptoms between pregnancies if future childbearing is planned.

Efficacy of Cerclage

The majority of studies describing cerclage treatment are observational, without uniform criteria for diagnosis, choice of treatment, or outcomes. Variation in diagnostic criteria and absence of biomechanical studies have limited the evaluation of efficacy (see previous discussion of biomechanics and abdominal versus vaginal cerclage). Despite the prolonged controversy about the role of cerclage, no randomized trial comparing cerclage with bed rest or no therapy has been reported in women with the classic history. Randomized trials conducted in women with prior preterm birth have excluded those women who were thought to have “true” cervical insufficiency. Randomized trials performed before the advent of transvaginal sonography found little evidence of benefit for cerclage treatment of women with prior preterm birth. Two trials that enrolled women with low to moderate risk of preterm birth found no evidence that McDonald cerclage prolonged gestation or decreased perinatal mortality.^{113,114} A multicenter, randomized trial of cervical cerclage in 1292 women with second-trimester loss, preterm delivery, or previous cervical surgery reported fewer deliveries before 33 weeks (13% versus 17%; $P = .03$), fewer infants with birth weights of less than 1500 g (10% versus 13%; $P = .05$), and

fewer pregnancy losses including miscarriage, stillbirth, and neonatal death (9% versus 11%; $P = .06$) in women treated with cerclage, but no difference in the percentage of births between 33 and 36 weeks.¹¹⁵ This trial specifically excluded women thought to have true cervical insufficiency.

Studies of women with clinical risk factors for preterm birth who also had ultrasound documentation of a short cervix were expected to show benefit for cerclage, but descriptive series reported mixed results.^{69,72,116-118} The cervical length threshold for cerclage placement ranged from 15 to 30 mm in these studies.

Several randomized trials of cerclage have since been performed in women with risk factors for preterm birth and sonographic evidence of short cervix, again excluding women thought to have cervical insufficiency.^{79,119-122} Data from these trials have been combined and analyzed by the original authors into a useful report that suggests that cerclage may reduce the risk of recurrent preterm birth before 35 weeks (relative risk [RR], 0.61; 95% confidence interval [CI], 0.40 to 0.92) in women with a prior preterm birth whose cervical length in the current pregnancy is less than 25 mm, but it appears to provide no benefit for women with a short cervix who have not had a prior preterm birth (RR, 0.84; CI, 0.60 to 1.17).^{123,124}

Although these data support consideration of cerclage for women with a prior early preterm birth who have a cervical length of less than 25 mm in the current pregnancy, several recent lines of evidence may modify that conclusion. The first was noted previously: More than two thirds of women with a history of prior preterm birth who are monitored with serial cervical sonography in a subsequent pregnancy do not display a short (<25 mm) cervix and have a low likelihood of recurrent preterm birth without cerclage.^{79,80,81,125} Second, among the one third of women with a prior preterm birth who manifest a short cervix in a subsequent pregnancy, an “ultrasound-indicated” cerclage, placed only when the cervix has begun to shorten, is as effective as an early prophylactic cerclage in reducing the risk of recurrent preterm birth.^{78-80,126,127} Third, there is evidence that cerclage placement in some women may *increase* the risk of recurrent preterm birth. Sakai and associates⁵⁰ studied outcomes in 246 women with a prior preterm birth and a cervical length of 25 mm or less; 165 of these patients were treated with cerclage, and 81 were not, as determined by physician preference. Rates of preterm birth did not differ between these two groups; however, when the data were analyzed according to the level of IL-8 in cervical fluid at enrollment, a different conclusion emerged. Women who had an elevated level of cervical IL-8, indicating cervical inflammation, had *more* preterm births if treated with cerclage, whereas those with a normal level of IL-8 had improved outcomes after cerclage compared with expectant management. Because a clinical test for intracervical inflammation is not available, it is not possible to determine whether a cerclage placed in these circumstances might reduce or increase the risk of preterm birth. Finally, there is evidence from a randomized trial that medical treatment with progesterone for women with a very short cervix (<15 mm) may significantly reduce their risk of preterm birth before 34 weeks, from 44% to 19%.⁹⁵ The pathway by which progesterone influences the risk of preterm birth is uncertain, but an anti-inflammatory effect has been proposed. In women with a multiple gestation, cerclage for short cervix has been reported to carry an increased risk for preterm birth (RR, 2.15; CI, 1.15 to 4.01).^{123,128}

These reports could be interpreted as suggesting the superiority of one cerclage technique or surgeon over another, or of noncompliance with postoperative care. However, despite strongly voiced anecdotal reports to the contrary, there is no evidence that the Shirodrot technique is more efficacious than the McDonald procedure¹²⁹ or that

particular operative techniques are essential to good outcome. The more likely explanation for conflicting anecdotal and research results lies in (1) the increasing recognition that preterm cervical shortening is more often a medical than a surgical condition, (2) the inability to identify appropriate candidates for cerclage treatment, and (3) for the few who will benefit, the difficulty in placing a cerclage at the internal cervical os by the vaginal route. Taken together, current research results challenge the wisdom of prophylactic cerclage over selective ultrasound-indicated cerclage, as well as the role of cerclage versus medical treatment for women with a previous preterm birth. The Cochrane Library reviewers found insufficient evidence to support the use of cerclage for women with a prior second-trimester birth or for women with a short cervix.¹³⁰ Forthcoming results from a recently concluded trial may aid decisions about selection of candidates for cerclage.

At present, cerclage treatment may be recommended for women with an appropriate obstetric history who also manifest sonographic evidence of cervical change in the current pregnancy. Cerclage is not currently recommended for women with a short cervix who have no history of preterm birth or cervical surgery, nor for women with a prior preterm birth whose cervical length remains greater than the 10th percentile (25 mm). Although prophylactic placement of cerclage at 11 to 14 weeks' gestation may be appropriate in women with convincing histories or prior pregnancies successfully treated with cerclage, the uncertainty of diagnosis and the high likelihood of a good outcome for pregnancy managed with sonographic surveillance and selective cerclage argue against routine placement of prophylactic cerclage in women with a prior preterm birth.

Clinical Use of Cerclage

Contraindications to cerclage placement at any time during pregnancy include ruptured membranes, evidence of cervical or intrauterine infection, major congenital anomalies of the fetus, vaginal bleeding of undetermined cause, and active labor regardless of etiology.

After contraindications are excluded and the uncertainties regarding cerclage have been discussed with the patient, cerclage placement may be considered in the following situations.

History of Recurrent Mid-trimester Pregnancy Loss

A history of one or more early births between 16 and 30 weeks should generate a thorough review of all previous pregnancies and gynecologic procedures, including pregnancy terminations, cervical LEEP or conization, and cesarean section after a long second stage of labor. A history of cervical surgery followed by a mid-trimester birth requires consideration of cerclage. The index pregnancy should be reviewed to ascertain a history of pelvic pressure, premenstrual symptoms, or increased vaginal discharge in the days preceding the birth. Cervical dilation and effacement at clinical presentation that is out of proportion to clinical symptoms is suggestive, even if it is accompanied by mild uterine activity, ruptured membranes, or vaginal spotting. Presentation with a closed cervix followed by painful labor lasting several hours suggests a diagnosis other than cervical insufficiency. Ultrasound findings of a short or funneled cervix (<25 mm) support but do not establish the diagnosis. Pathology studies of the fetus, placenta, and membranes after a second-trimester birth commonly reveal inflammation, a finding that does not exclude cervical insufficiency but makes it less likely.

Depending on the strength of the history, the options of prophylactic cerclage or serial cervical ultrasound surveillance should be considered, with a preference for the latter as evidence of its safety has

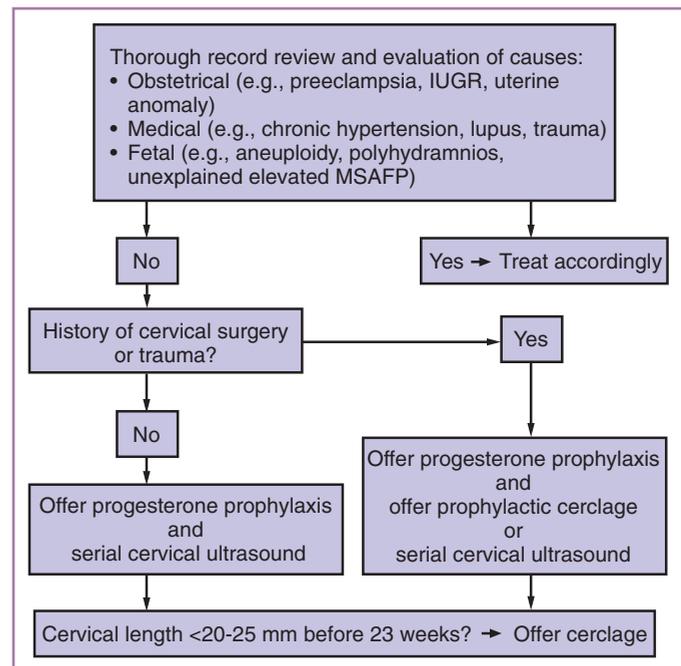

FIGURE 30-13 Care algorithm for women with a history of birth at 16 to 28 weeks. Algorithm of care for women with a prior second-trimester birth used in the Ohio State Prematurity Prevention Program. MSAFP, maternal serum α -fetoprotein.

accumulated. If prophylactic cerclage is chosen, concerns about exposure of the fetus to medication may be reduced by the use of ultrasound confirmation of fetal viability and conduction anesthesia. For women who choose prenatal diagnosis, serum screening or chorionic villus sampling, or both, may be performed before the cerclage, or an amniocentesis may be elected 2 or more weeks after the cerclage is placed. Prophylactic transabdominal cerclage is reserved for women with poor cervical anatomy who have had an unsuccessful transvaginal cerclage; it may be placed before or after conception.

If sonographic surveillance is chosen, sonography begins at 15 to 16 weeks of gestation, with cerclage placement offered if the cervical length falls to less than 20 to 25 mm before 23 to 24 weeks. The frequency of surveillance is governed by the gestational age at delivery in prior pregnancies and the cervical length, with visits scheduled no less often than every 2 weeks between 15 and 25 weeks' gestation. Women with this history whose cervical length is less than 30 mm before 20 weeks are monitored weekly in our clinic. Our experience is consistent with the literature in that more than 60% of women observed with sonography maintain a cervical length greater than 25 mm and do well without cerclage. Figure 30-13 summarizes the algorithm of care used at Ohio State University Hospital for women with one or more prior second-trimester preterm births.

History of Conization, Loop Electrosurgical Excision Procedure, Diethylstilbestrol Exposure, or Uterine Anomaly without a Prior Preterm Birth

Observation by ultrasound between 15 and 25 weeks is a common choice in this situation. In women with a history of conization, substantial cervical tissue is often visible on ultrasound that is not appreci-

ated by inspection or palpation. The cervical length may be surgically shorter than expected,⁴⁴ so observation of progressive effacement or funneling may be better than cervical length as an indicator of risk in these patients. Women with uterine anomalies may have unsuspected cervical duplication or abnormalities that are best found by obtaining coronal and transverse as well as sagittal views of the cervix on endovaginal ultrasound. There is no established protocol for surveillance frequency.

Incidental Ultrasound Observation of Short Cervix

This is an increasingly common scenario for which no evidence-based management exists. Many of these women are identified at the time of a second-trimester ultrasound to assess fetal anatomy. A thorough and confidential reproductive history should be obtained; if risk factors are found, they may be managed accordingly.

Women with incidental short cervix who are nulliparous, or multiparous with a benign obstetric history, are not candidates for cerclage. A randomized trial found no benefit for cerclage,¹²⁴ nor did an observational study.¹³¹ Moreover, the risk of preterm birth is increased by cerclage treatment in women with twin pregnancies who are found to have short cervix.^{123,128} There is preliminary evidence that treatment with progesterone might reduce the risk of preterm birth in women with an incidental observation of short cervix,⁹⁵ but additional studies are required before it can be recommended.

Presentation with Unanticipated Advanced Cervical Dilatation on Physical Examination in a Nulliparous or Parous Woman

Symptoms are typically mild or absent, except for pressure and increased discharge. A thorough and confidential history should be obtained, looking specifically for cervical stretch or injury related to delivery or gynecologic disorders, as described earlier. A uterine anomaly should be considered as well.

In contrast to women with ultrasound evidence of short cervix, women who present with advanced dilation detected by digital and speculum examination may benefit from emergent cerclage if no contraindications are present. An observational study of 225 asymptomatic women with cervical dilation of 1 cm or more found improved outcomes for women treated with cerclage compared with bed rest.⁵⁸ In a descriptive study of 46 women with bulging membranes, pregnancy outcomes in women treated with cerclage were superior, compared with outcomes in women who refused the procedure.¹³² Clinical application of these studies is described later.

Perioperative and Intraoperative Care

Perioperative care for prophylactic cerclage is minimal. In the absence of cervical dilation or effacement, the benefit of adjunctive medications is doubtful. The patient is ordinarily ready to go home after her anesthetic has worn off, with instructions to expect urinary hesitancy, mild abdominal cramping, labial and vaginal discomfort, and light spotting. Women undergoing cerclage after surveillance has revealed short cervix are often treated empirically with antibiotics, nonsteroidal anti-inflammatory drugs, and a period of observation before and after cerclage placement.

If cerclage is performed for a woman with membranes visible at the external os or in the vagina, the prognosis for neonatal survival decreases significantly; however, a cerclage may still be placed if infection and other contraindications can be excluded. A speculum exami-

FIGURE 30-14 Amniotic fluid “debris.” Endovaginal ultrasound image of cervix with a funnel and debris within the funnel.

nation should be performed to be certain that the membranes have not ruptured. The patient should be supine or in Trendelenburg position. Uterine activity should be monitored. Infection is a frequent complication; maternal temperature and white blood cell and differential counts should be determined and repeated as necessary to exclude infection.

Separation of the membranes from the decidua and the presence of “debris” or sludge within the amniotic fluid seen on endovaginal sonography suggest an increased chance of infection and are poor prognostic signs.^{51,133-135} Debris or sludge has been determined to be a biofilm, a mechanism employed by low-virulence microorganisms to resist host defenses.^{136,137} Amniocentesis to obtain amniotic fluid for aerobic and anaerobic culture, Gram staining, and glucose determination should be considered (Fig. 30-14).

If infection, abruption, and progressive cervical change can be ruled out, prophylactic antibiotics and tocolytics are sometimes employed empirically.^{119,121} Reports of candida amnionitis in women treated with antibiotics suggest that a limited duration of prophylaxis may be wise.¹³⁸

The McDonald cerclage is most commonly used if the cervix is well dilated, but the Shirodkar and the Wurm techniques have also been employed. (In the Wurm procedure, nonabsorbable mattress sutures are placed in the cervix from 12 to 6 o'clock and from 3 to 9 o'clock.) Placement of a cervical cerclage of any type under these circumstances is difficult at best. Bulging or prolapsed membranes are easily ruptured intraoperatively. The membranes should be inspected to identify separation or loss of the chorion from the intact amnion. If only the amnion remains, prolongation of pregnancy beyond a few days is unlikely, and consideration should be given to abandoning the procedure. Visible membranes may be replaced into the uterus with gauze on a ring forceps covered by either a condom or a finger cot¹³⁹ or with a 16F Foley catheter.¹⁴⁰ The cerclage may then be placed and tied with the catheter in place. The balloon is deflated, and the catheter is withdrawn. Transabdominal amniocentesis may temporarily reduce amniotic fluid volume and assist in spontaneous replacement of the membranes within the uterus.¹⁴¹ Filling of the maternal bladder with sufficient fluid to compress the lower uterine segment¹⁴² and placement of the cerclage suture with the patient in the knee-chest position¹⁴³ have also been reported.

Preoperative dilation of the cervix was the factor most strongly associated with complications and fetal survival in a review of 482 cerclage procedures.¹⁴⁴

Reported success rates after emergency cerclage—with success defined as reaching “viability”—rose from 10% in 1980¹⁴⁵ to 60% in 1995.¹⁴⁶ Aarts and coworkers summarized data from 13 reports that described 249 patients treated with emergency cerclage procedures performed at a median gestational age of 22.8 weeks. The mean prolongation of pregnancy was 8.1 weeks, and the mean neonatal survival rate was 64% (range, 22% to 100%).¹⁴⁶ Others have found similar results.^{147,148}

Often, the only alternative to emergency cerclage in patients with advanced dilation is hospital bed rest. Olatunbosun and associates¹⁴⁹ compared pregnancy outcomes in women treated with emergency cerclage versus bed rest in a nonrandomized study. All patients were enrolled between 20 and 27 weeks of gestation, and all had cervical dilation greater than 4 cm. The perinatal mortality rate did not differ, but the cerclage group spent fewer days in the hospital. There is no consensus about an upper gestational age limit for placement of a cerclage suture, but 24 weeks is commonly used. Prophylaxis against thromboembolism and a dietary and laxative regimen to produce a soft stool may reduce the risks of blood clot and constipation that accompany bed rest, but the emotional and musculoskeletal consequences of bed rest are more difficult to prevent.¹⁵⁰

Complications after Cerclage

Morbidity associated with cervical cerclage of all types includes complications related to the procedure itself (anesthetic risks, bleeding, maternal soft tissue injury, spontaneous suture displacement, preterm premature rupture of the membranes [pPROM], and infection) and those related to subsequent delivery (cervical lacerations and fistulas, increased incidence of cesarean section). Ruptured membranes are reported in 1% to 40% of women treated with cerclage. This risk increases with the degree of dilation and effacement and with the gestational age at placement.¹⁴⁴

Management of pPROM in a patient with a cerclage is controversial. The incidence of infectious complications and poor neonatal outcome was increased in one series when the cerclage was in situ after membrane rupture,¹⁵¹ but two other reports did not find an increased rate of infection or other neonatal or maternal morbidity with delayed removal.^{152,153} Deferred removal to prolong pregnancy may be acceptable if pPROM occurs early, but the benefit-to-risk ratio declines as gestational age increases.¹⁵⁴

Chorioamnionitis resulting from cervical cerclage placement has been reported with varying frequency, from 1%¹⁴⁵ to 6% to 8%.¹⁴⁴ Treadwell and colleagues¹⁴⁴ found that the rate of chorioamnionitis identified on aerobic cultures was significantly associated with cervical dilation (6.2% if the cervix was no more than 2 cm dilated, versus 41.7% if the cervix was >2 cm) and with the timing of the procedure (5.2% if elective versus 14.4% if emergent). The incidence of chorioamnionitis has been reported to be as much as 40% to 50% when anaerobic cultures and research laboratory techniques are used.¹⁵⁵

Remote sequelae of cervical cerclage procedures include uterine rupture, excessive bleeding with suture removal, cervical dystocia related to scarring at the cerclage site, and cervical lacerations and fistulas. The cervix may not dilate normally in response to labor after a cerclage has been in place, despite its removal at the appropriate time.^{145,156} Lindberg¹⁵⁷ reported uterine rupture when labor began

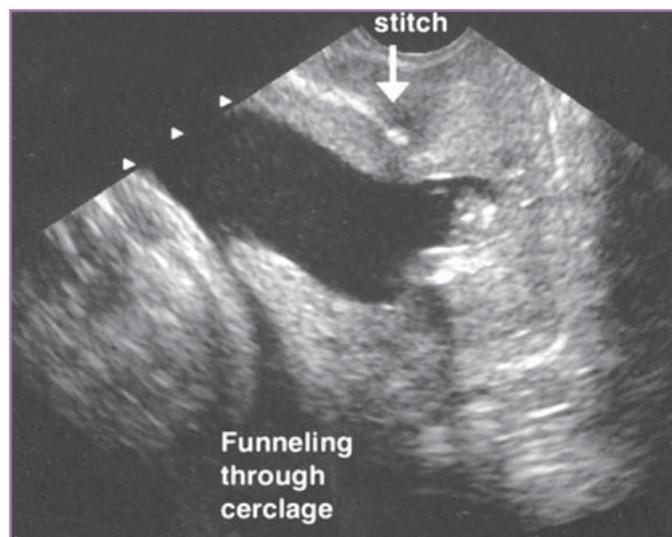

FIGURE 30-15 Protrusion of the membranes past the plane of the cerclage. Endovaginal ultrasound image of cervix with membranes funneled past the level of a McDonald cerclage suture. Arrow points to the cerclage suture in the anterior cervical lip.

before the suture could be removed, a particular concern for women with a prior vertical uterine incision.

Treadwell and coworkers¹⁴⁴ reported an overall incidence of cesarean delivery of 31.8% in 482 patients. Cesarean section for cervical dystocia was more common after Shirodkar than after McDonald cerclage in this series: 11.4% versus 2.6%, respectively ($P < .005$). Cervical lacerations at delivery thought to be related to cerclage have been reported.^{144,145} Treadwell and coworkers¹⁴⁴ observed cervical lacerations in 6.2% of patients, more commonly when the cerclage was placed after 18 weeks' gestation. Other maternal morbidity associated with cerclage placement includes vesicovaginal and urethrovaginal fistulas and ulceration of the trigone of the bladder from erosion of the knot of the cerclage.

Postoperative assessment of suture location as well as pregnancy management and outcome can be improved with ultrasonographic assessment of the cervix.^{158,159} Both the nylon and Ethibond sutures commonly used in the McDonald procedure (Fig. 30-15) and the 5-mm Mersilene tape used in the Shirodkar procedure (see Fig. 30-11) can be seen easily on transvaginal ultrasonography. The length of the cervix from the plane of the suture to both the internal and external os can be measured. Pregnancy outcomes are better when the membranes do not descend past the plane of the suture and when the cervix is seen to be closed above and below the sutures.^{158,159}

Placement of a second cerclage when the first appears to be failing, as indicated by protrusion of the membranes past the plane of the cerclage, can be considered if observed before 20 to 22 weeks' gestation. Patients in whom membrane protrusion is noted with ultrasound after 22 to 24 weeks' gestation are placed on bed rest, usually in the hospital if the membranes are seen to extend below the level of the cerclage on transvaginal sonography (see Fig. 30-15).

Removal can usually be accomplished in the office or clinic without anesthesia if good lighting is provided. Most women expect labor to begin immediately, but that is the exception. An interval of days between removal and the onset of labor does not mean that the diagnosis was incorrect but instead typifies the various etiologies of abnormal cervical competence.

Summary

The clinical syndrome of cervical insufficiency results in early, often recurrent preterm birth in the second trimester. Advanced cervical dilation and effacement with minimal uterine activity is the most typical presentation, but not an exclusive one. The syndrome is the result of the interaction of many factors that affect the strength of the cervix, including biologic variation, obstetric and gynecologic injuries, and inflammation-mediated changes. Diagnosis is difficult and should be based on both the obstetric history and ultrasound evidence of premature effacement. The most effective treatment has not been established. Treatment with cerclage is considered when both historical and ultrasound criteria are met.

Chapter 31

Premature Rupture of the Membranes

Brian M. Mercer, MD

Rupture of the fetal membranes is an integral part of the normal parturition process at term and is inevitable in the process of preterm birth. Spontaneous rupture of the membranes (SROM) at term and preterm can occur any time before or after the onset of contractions. SROM before the onset of contractions is referred to as premature rupture of the membranes (PROM). Membrane rupture at term usually occurs as a result of a physiologic process of progressive membrane weakening. Preterm PROM generally results from pathologic weakening of the fetal membranes, which has several causes. Although delivery after PROM may be required by the presence of advanced labor, intrauterine infection, vaginal bleeding due to placental abruption, or non-reassuring fetal status, the physician often needs to make the decision whether to actively pursue delivery or conservatively manage the pregnancy. Management of PROM hinges on knowledge of gestational age, the neonatal risks related to immediate delivery, and an understanding of the anticipated clinical course and relative risks of intrauterine infection, abruptio placentae, and fetal distress or death from umbilical cord accident or intrauterine infection with conservative management.

Physiology and Pathophysiology of Membrane Rupture

The fetal membranes consist of the amnion, which lines the amniotic cavity, and the thicker chorion, which adheres to the maternal decidua. Initially, the amnion and chorion are separate layers. The amniotic sac is visible on first trimester ultrasound scans until it fuses with the chorion by the end of the 14th week of gestation. Subsequently, the amnion and chorion are connected by a collagen-rich connective tissue layer, with the amnion represented by a single cuboidal epithelial amnion layer and subjacent compact and spongy connective tissue layers, and a thicker chorion consisting of reticular and trophoblastic layers. Together, the amnion and chorion form a stronger unit than either layer individually. Physiologic membrane remodeling occurs with advancing gestational age, reflecting changes in collagen content and type, changes in intercellular matrix, and progressive cellular apoptosis. These changes lead to structural weakening of the membranes, which is more evident in the region of the internal cervical os.¹⁻⁸

Membrane weakening can be stimulated by exposure to local matrix metalloproteinases (e.g., MMP-1, MMP-2, MMP-9), decreased levels of membrane tissue inhibitors of matrix metalloproteinases (e.g.,

TIMP-1, TIMP-3), and increased poly[ADP-ribose]polymerase (PARP) cleavage.^{6,9} Term or preterm uterine contractions can also lead to membrane rupture resulting from increased bursting pressure due to increased intra-amniotic pressure and from “strain hardening” with repeated uterine contractions. If the fetal membranes do not rupture before labor, the work to cause membrane rupture at the internal cervical os decreases with advancing cervical dilatation because of the lack of anchoring to the supportive decidua and enhanced ability to stretch with contractions.¹

Preterm membrane rupture can arise through a number of pathways that ultimately result in accelerated membrane weakening. Bacterial collagenases and proteases can directly cause fetal membrane tissue weakening.¹⁰ An increase in local host cytokines or an imbalance in the interaction between MMPs and TIMPs in response to microbial colonization can have similar effects.¹¹ There is specific evidence linking urogenital tract infection and colonization with preterm PROM. Amniotic fluid cultures after PROM are frequently positive (25% to 35%),¹²⁻¹⁹ and histologic evaluation in the setting of preterm birth frequently has demonstrated acute inflammation and bacterial contamination along the choriodecidual interface.²⁰ Although these findings may reflect ascending infection after PROM, it is likely that ascending colonization and infection are directly involved in the pathogenesis of preterm PROM in many cases. Genital tract pathogens that have been associated with PROM include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*, and group B β -hemolytic streptococcus.²⁰⁻²⁶ Although group B streptococcus (GBS) bacteriuria has been associated with preterm PROM and low-birth-weight infants²⁷ and an association between cervical colonization and preterm PROM is possible,²⁸ it does not appear that vaginal GBS carriage is associated with preterm PROM.^{29,30} Although there is a well-established association between bacterial vaginosis and preterm birth, including that related to preterm PROM,^{31,32} it remains unclear whether bacterial vaginosis merely identifies women with a predisposition to abnormal genital tract colonization and inflammation, facilitates ascent of other bacteria to the upper genital tract, or is directly pathogenic and causative of membrane rupture. Physical effects related to preterm contractions and prolapsing membranes with premature cervical dilatation can predispose the fetal membranes to rupture, as can the increased intrauterine pressure seen with polyhydramnios.^{4,33} It is likely that certain connective tissue disorders (e.g., Ehlers-Danlos syndrome) can result in intrinsic weakening of the membranes. Clinical associations with preterm PROM include low socioeconomic status, lean maternal body mass (<19.8 kg/m²), nutritional deficiencies (e.g., copper, ascorbic acid), and prior cervical conization. During pregnancy, maternal cigarette smoking, cervical cerclage, second- and

third-trimester bleeding, pulmonary disease, prior episodes of preterm labor or contractions, and uterine overdistention with polyhydramnios or multiple gestations have been linked to preterm PROM.^{4,33-45}

Although one or more risk factors may lead to membrane rupture, the ultimate clinical cause of PROM is often not evident at delivery. In some cases, factors leading to membrane rupture are subacute or chronic in nature. Women with a prior preterm birth have increased risk for preterm birth due to PROM in subsequent pregnancies, especially if the prior preterm delivery resulted from PROM.⁴⁶ Asymptomatic women with a short cervical length (<25 mm) remote from delivery are also at increased risk for subsequent preterm birth due to preterm labor or PROM. Some women may have polymorphisms for inflammatory proteins that alter their inflammatory response and increase the risk for preterm birth.^{47,48}

Prediction and Prevention

Because PROM at term usually is part of the normal parturition process, the focus of efforts has been on the prediction and prevention of preterm birth caused by PROM. Prevention of preterm PROM would be particularly appealing because labor and intrauterine infection or other complications necessitating delivery often ensue soon after membrane rupture occurs. The optimal way to prevent complications from preterm PROM is to prevent its occurrence. Potentially modifiable risk factors for preterm PROM include cigarette smoking, poor nutrition, urinary tract and sexually transmitted infections, acute pulmonary diseases, and severe polyhydramnios.

Other than treatment of infections, it is unknown whether correction of these factors can avert this complication. Although most other risk factors are fixed in that they cannot be removed or remedied in a particular woman, knowledge of risk can help to counsel women about suspicious symptoms and the importance of timely evaluation if preterm PROM occurs. Broad-based preventive strategies such as progesterone supplementation can be considered for those at risk due to less specific risk factors such as a history of spontaneous preterm birth^{49,50} (see Chapter 29). Although one study suggested that vitamin C supplementation had value in preventing preterm PROM (7.6% versus 24.5%; $P = .02$), studies in which vitamin C was given alone or with other supplements to women without prior preterm birth as a risk factor indicate a trend toward *increased* preterm birth with such treatments (relative risk [RR] = 1.38; 95% confidence interval [CI], 1.04 to 1.82).^{51,52} Vitamin C supplementation to prevent preterm birth due to PROM thus cannot be recommended until there is solid evidence of benefit.

Perhaps the strongest risk factor for preterm PROM is a history of prematurity or PROM.⁵³ Those with an early preterm birth have the highest risk for a recurrence. A history of preterm birth after PROM confers a 3.3-fold increased risk for recurrent preterm birth due to the same cause (13.5% versus 4.1%; $P < .01$) and a 13.5-fold higher risk of subsequent delivery before 28 weeks (1.8% versus 0.13%; $P < .01$). Because prior obstetric outcome has such a strong influence on subsequent pregnancy outcomes, it is useful to evaluate nulliparas separately from those with prior deliveries. When assessed at 22 to 24 weeks' gestation, medical complications (e.g., pulmonary disease in pregnancy), work during pregnancy, low maternal body mass index (<19.8 kg/m²), and bacterial vaginosis are associated with preterm birth due to PROM.⁴⁶ Identification of a cervical length shorter than 25 mm on transvaginal ultrasound also confers an increased risk of subsequent PROM in nulliparas and multiparas. In this study, nulliparas with a short cervix and a positive cervicovaginal fibronectin screen-

ing result at 22 to 24 weeks had a one-in-six chance (16.7%) of delivering a preterm infant because of PROM, and the combination of a prior preterm birth due to PROM, a short cervical length, and a positive fetal fibronectin screening result increased the risk of delivery at less than 35 weeks because of preterm PROM by 10.9-fold (25% versus 2.3%).⁴⁶

Unfortunately, despite knowledge of a broad range of potential risk factors for preterm birth, we are able to predict only a small fraction of women destined to deliver preterm, and most preterm births due to preterm labor or PROM occur in women considered to be at low risk for these events. Ancillary tests such as fetal fibronectin screening or transvaginal cervical sonography should be incorporated into routine practice only after effective interventions to prevent PROM have been identified for those with an abnormal test result. Because most cases of preterm PROM cannot be predicted or prevented, clinical efforts continue to be focused on evaluation and treatment of women who present with symptoms of preterm PROM.

Clinical Course

PROM affects approximately 8% of pregnancies at term, and 95% of these women will deliver within 28 hours of membrane rupture.⁵⁴ Preterm PROM is also associated with brief latency from membrane rupture to delivery; delivery within 1 week is the most common outcome after preterm PROM at any gestational age. On average, latency increases with decreasing gestational age at membrane rupture. When PROM occurs before 34 weeks' gestation, 93% of women will deliver within 1 week, and 50% to 60% of those who are managed conservatively will deliver within 1 week.^{55,56} With PROM near the limit of viability, 60% to 70% deliver within 1 week, but 1 in 5 will have a latency of 4 or more weeks if they are managed conservatively.³⁵ Although the likelihood of spontaneous resealing of the membranes after preterm PROM is low (3% to 13%), the prognosis for those with PROM occurring after amniocentesis is much better, with 86% to 94% resealing spontaneously.^{44,57,58} In a study of women with PROM after second-trimester amniocentesis, leakage stopped in most cases with conservative management, although a normal fluid volume sometimes took time to re-accumulate (in a range of 8 to 51 days).⁵⁸

Complications after Premature Rupture of the Membranes

Maternal Complications

Chorioamnionitis complicates 9% of pregnancies with term PROM, a risk that increases to 24% with membrane rupture lasting longer than 24 hours.⁵⁹ The risk of intrauterine infection increases with the duration of membrane rupture and with declining gestational age.^{54,55,60-62} Conservative management of PROM provides the opportunity for subclinical deciduitis to progress to overt infection and for ascending infection to occur.^{20,54,55,62} Chorioamnionitis can complicate 13% to 60% of cases when PROM occurs remote from term. Endometritis occurs in 2% to 13% of cases.^{63,64} Placental abruption is diagnosed in 4% to 12% of pregnancies complicated by PROM and can occur before or after the onset of membrane rupture.^{34,65,66} Maternal sepsis (0.8%) leading to death (0.14%) is a uncommon complication of preterm PROM occurring near the limit of viability.⁶⁷

Fetal Complications

The risks to the fetus are primarily those related to intrauterine infection, umbilical cord compression, and placental abruption. Fetal heart rate patterns consistent with umbilical cord compression due to oligohydramnios are commonly seen after PROM.⁶⁸ Umbilical cord prolapse can occur after membrane rupture, particularly with fetal malpresentation, which is more common with preterm gestations. Fetal death occurs in 1% to 2% of cases of conservatively managed PROM.⁵⁶ The reported incidence of fetal death after PROM at 16 to 28 weeks ranges from 3.8% to 22%.^{36,69,70} This particularly high risk of fetal loss may reflect increased susceptibility to umbilical cord compression and hypoxia or intrauterine infection, but it may also reflect less aggressive obstetric interventions for fetal compromise before the limit of viability.

Neonatal Complications

Gestational age at delivery is the primary determinant of the frequency and severity of neonatal complications after PROM. Respiratory distress syndrome, necrotizing enterocolitis, intraventricular hemorrhage, and sepsis are the most common serious acute morbidities, and they are common with early preterm birth. Neonatal sepsis is twofold more common after preterm PROM than after preterm birth due to preterm labor. Neonatal infection can manifest as congenital pneumonia, sepsis, meningitis, and late-onset bacterial or fungal infection. Early preterm birth can lead to long-term complications, including chronic lung disease, visual or hearing difficulties, mental retardation, developmental and motor delay, and cerebral palsy. In general, these long-term morbidities are uncommon with delivery after about 32 weeks' gestation.^{71,72} Cerebral palsy and periventricular leukomalacia have been associated with amnionitis,⁷³ and increased amniotic fluid cytokines and fetal systemic inflammation have been associated with preterm PROM, periventricular leukomalacia, and cerebral palsy.⁷⁴⁻⁷⁶ This highlights the need for potential neonatal benefit from delayed delivery if conservative management is to be attempted because this delay offers the opportunity for intrauterine infection to develop. Alternatively, early gestational age at birth has been associated with neonatal white matter damage ($P < .001$) after controlling for other factors.⁷⁷ Despite the described associations between PROM, intrauterine infection or inflammation, and adverse neurologic outcomes, it has not been shown that immediate delivery after PROM can prevent these morbidities.

In the past, mid-trimester PROM, which encompasses membrane rupture occurring at about 16 to 26 weeks' gestation, was considered as a separate entity from preterm PROM because neonatal death usually could be anticipated with immediate delivery. With current survival rates of about 25% to 85% after delivery at 23 to 26 weeks' gestation, mid-trimester PROM is no longer a relevant clinical entity.^{71,72,78-80} Previably PROM occurring before the limit of viability (i.e., before 23 weeks' gestation) is a special circumstance that places the fetus in particular jeopardy. Immediate delivery will result in neonatal death. Conservative management may result in fetal or neonatal loss before viability, and if viability is reached, delivery is likely at an early gestational age, when the risks of long-term sequelae are highest. The neonatal survival rate after PROM occurring before 24 weeks has previously been reported to be approximately 30%, compared with 57% for rupture at 24 to 26 weeks' gestation.⁶⁷ In a review of 201 cases from 11 studies, the perinatal survival rate with conservative management of PROM before 23 weeks' gestation was 21%, but there was similar survival after PROM at less than 20 weeks.⁸¹ These

reported outcomes of previable PROM may be optimistic because most studies have been retrospective and have included only patients amenable to conservative management.

Fetal lung growth and development can be especially adversely affected when PROM occurs in the early phases of development.⁸²⁻⁸⁷ With PROM occurring during the late pseudoglandular or canalicular stage of pulmonary development, tracheobronchial collapse or loss of intrinsic factors within the tracheobronchial fluid, or both, may lead to failure of the terminal bronchioles and alveoli to develop, with resultant failure of lung growth.⁸⁸⁻⁹¹ Pulmonary hypoplasia develops over weeks after membrane rupture occurs. It is most accurately diagnosed pathologically based on radial alveolar counts and lung weights.^{92,93} In surviving infants, pulmonary hypoplasia is suggested by a small chest circumference with severe respiratory distress or persistent pulmonary hypertension and radiographic findings such as small, well-aerated lungs with a bell-shaped chest and elevation of the diaphragm.^{83,88}

Overall, pulmonary hypoplasia becomes evident in 0% to 26.5% of infants (mean = 5.9%) delivering after PROM at 16 to 26 weeks' gestation. Early PROM before 20 weeks' gestation carries the highest potential for lethal pulmonary hypoplasia ($\approx 50\%$ with PROM before 19 weeks' gestation).^{83,86-88,94-96} With PROM at 15 to 16 weeks, an amniotic fluid index of 2 cm or less, and a latency of 28 days, the risk of pulmonary hypoplasia is estimated to be 74% to 82%.⁹⁷ Lethal pulmonary hypoplasia is uncommon with PROM after 24 to 26 weeks' gestation (0% to 1.4%) because there has been adequate alveolar development to support extrauterine life by this time.^{83,84,98} However, nonlethal pulmonary hypoplasia increases the likelihood of pulmonary barotrauma, including pneumothorax, pneumomediastinum, and the need for high ventilatory pressures because of poor pulmonary compliance.^{83,98,99} With prolonged oligohydramnios, restriction deformities can occur in up to 27% of fetuses.^{67,83,98-101}

Diagnosis

In more than 90% of cases, the diagnosis of PROM can be confirmed by clinical assessment, including the combination of history, clinical examination, and laboratory evaluation. Because optimal clinical care requires an accurate diagnosis, attention should be paid to confirming the diagnosis when a suspicious history or ultrasound finding of oligohydramnios is identified. Other potentially confounding findings such as urine leakage, increased vaginal discharge with cervical dilatation or membrane prolapse, cervical infection, passage of the mucous plug, and the presence of semen or vaginal douching should be considered.

A sterile speculum examination should be performed to provide confirmatory evidence of membrane rupture and to inspect for cervicitis and for umbilical cord or fetal prolapse, to assess cervical dilatation and effacement, and to obtain cultures, including endocervical *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, and anovaginal *Streptococcus agalactiae* (i.e., GBS), as appropriate. Initially, digital cervical examination should be avoided unless imminent delivery is anticipated because the needed information usually can be obtained with visualization of the cervix. Digital examination can shorten latency between membrane rupture and delivery, and some studies have shown it to introduce vaginal organisms into the cervical canal and to increase the risk of infection.¹⁰²⁻¹⁰⁷

The diagnosis of membrane rupture is confirmed by visualization of fluid passing from the cervical canal. If the diagnosis is not confirmed on initial inspection, the pH of the vaginal side walls or pooled

vaginal fluid can be evaluated using Nitrazine paper, which turns blue at a pH above 6.0 to 6.5. Amniotic fluid usually has a pH of 7.1 to 7.3, whereas normal vaginal secretions have a pH of about 4.5 to 6.0. Blood or semen contamination, alkaline antiseptics, and bacterial vaginosis can cause false-positive Nitrazine test results. If further clarification is needed, microscopic inspection can be performed for the presence of arborized crystals (i.e., ferning) (Fig. 31-1) in an air-dried sample collected from the vaginal side walls or pooled vaginal fluid. Ferning results from the interaction of amniotic fluid proteins and salts. Cervical mucus should be avoided during sampling because it can also yield a ferning pattern on microscopy. The fern test is unaffected by meconium and vaginal pH, but it can be falsely positive if there is heavy blood contamination.^{108,109} Prolonged leakage with minimal residual fluid can lead to false-negative clinical, Nitrazine, and ferning test results. Re-examination after prolonged recumbency or alternate measures can be considered if initial testing is negative. Assessment of cervicovaginal secretions for fetal fibronectin, prolactin, human chorionic gonadotropin (hCG), and other markers may assist in the diagnosis of PROM. However, these tests usually are not more helpful than the initial measures listed previously, because a positive test result may reflect decidual disruption rather than membrane rupture in some cases and a negative test result cannot exclude the diagnosis unequivocally.

If the diagnosis remains unclear after initial evaluation, documentation of oligohydramnios by ultrasound, in the absence of fetal urinary tract malformations or significant growth restriction, is suggestive of membrane rupture. Ultrasonographically guided amniocentesis with infusion of indigo carmine dye (1 mL of dye in 9 mL of sterile normal saline), followed by observation for passage of blue fluid from the vagina onto a perineal pad, can confirm or disprove the diagnosis of membrane rupture. Amniocentesis in the setting of oligohydramnios can be difficult, and particular attention should be paid to avoidance of the umbilical cord vessels, which can have the appearance of a thin, linear fluid space under this circumstance.

Some women with a history suspicious for membrane rupture but a negative speculum examination result and a normal amniotic fluid volume on ultrasound subsequently return with gross membrane rupture. This pattern may reflect initial transudation of a small amount

FIGURE 31-1 Ferning. A typical ferning appearance is seen after a swab from the posterior vaginal fornix was smeared on glass slide and the specimen allowed to air dry. The sample was obtained from a patient with premature rupture of the membranes. (Image courtesy of Thomas Garite, University of California at Irvine, Orange, California.)

of fluid across a weakened membrane or minimal leakage around a firmly applied presenting fetal part. Women with a suspicious history and initially negative testing should be encouraged to return for reevaluation if symptoms are persistent or recurrent.

Management of Premature Rupture of the Membranes

Management of PROM is based primarily on the estimated risks for fetal and neonatal complications with immediate delivery weighed against the potential risks and benefits of conservative management to extend the pregnancy after membrane rupture (Fig. 31-2). The risks of maternal morbidity should also be considered, especially under the circumstance of previable PROM.

Initial Evaluation

After the diagnosis of membrane rupture is confirmed, the duration of membrane rupture should be estimated to assist the pediatric caregivers with subsequent management decisions. Gestational age is established based on the combination of menstrual dates, clinical history, and ultrasound findings, as appropriate. Fetal presentation is assessed, and the patient is evaluated for labor, clinical findings of intrauterine infection, and significant vaginal bleeding. Fetal well-being is assessed by continuous heart rate monitoring if the limit of viability has been reached. After preterm PROM, it is important to evaluate fetal growth and residual amniotic fluid volume by ultrasound, and the potential of fetal abnormalities that can lead to polyhydramnios should be considered. Although narrowing of the biparietal diameter (i.e., dolichocephaly) due to oligohydramnios or breech presentation can result in underestimation of gestational age and fetal weight, ultrasound usually is as reliable after PROM as it is with intact membranes.¹¹⁰ Tables using fetal head circumference rather than biparietal diameter can be consulted as needed. GBS carrier status should be ascertained if available from culture results within 6 weeks or there has been a positive urine culture in the current pregnancy, and the need for intrapartum prophylaxis should be determined. In the absence of available culture results, a risk factor–based approach should be used for prevention of vertical transmission.¹¹¹

If conservative management is planned, the patient should be cared for in a facility with the ability to provide emergent delivery for placental abruption, fetal malpresentation, or fetal distress. The facility should also have neonatal intensive care facilities and offer acute neonatal resuscitation, because conservative management usually is undertaken only if there is a significant risk of neonatal morbidity and mortality with immediate delivery. Prenatal maternal transfer should be undertaken early in the course of management if these resources are not available. Because of the potential for acute complications, outpatient management usually is not recommended when PROM occurs after the limit of viability.

Term Premature Rupture of the Membranes

There is no substantial fetal benefit to expectant management of pregnancy after membrane rupture at 37 weeks' gestation or later. Expectant management of PROM at term was practiced in the 1980s and early 1990s based on studies suggesting that immediate induction after term PROM might increase the risks of infection and cesarean delivery.¹¹²⁻¹¹⁵

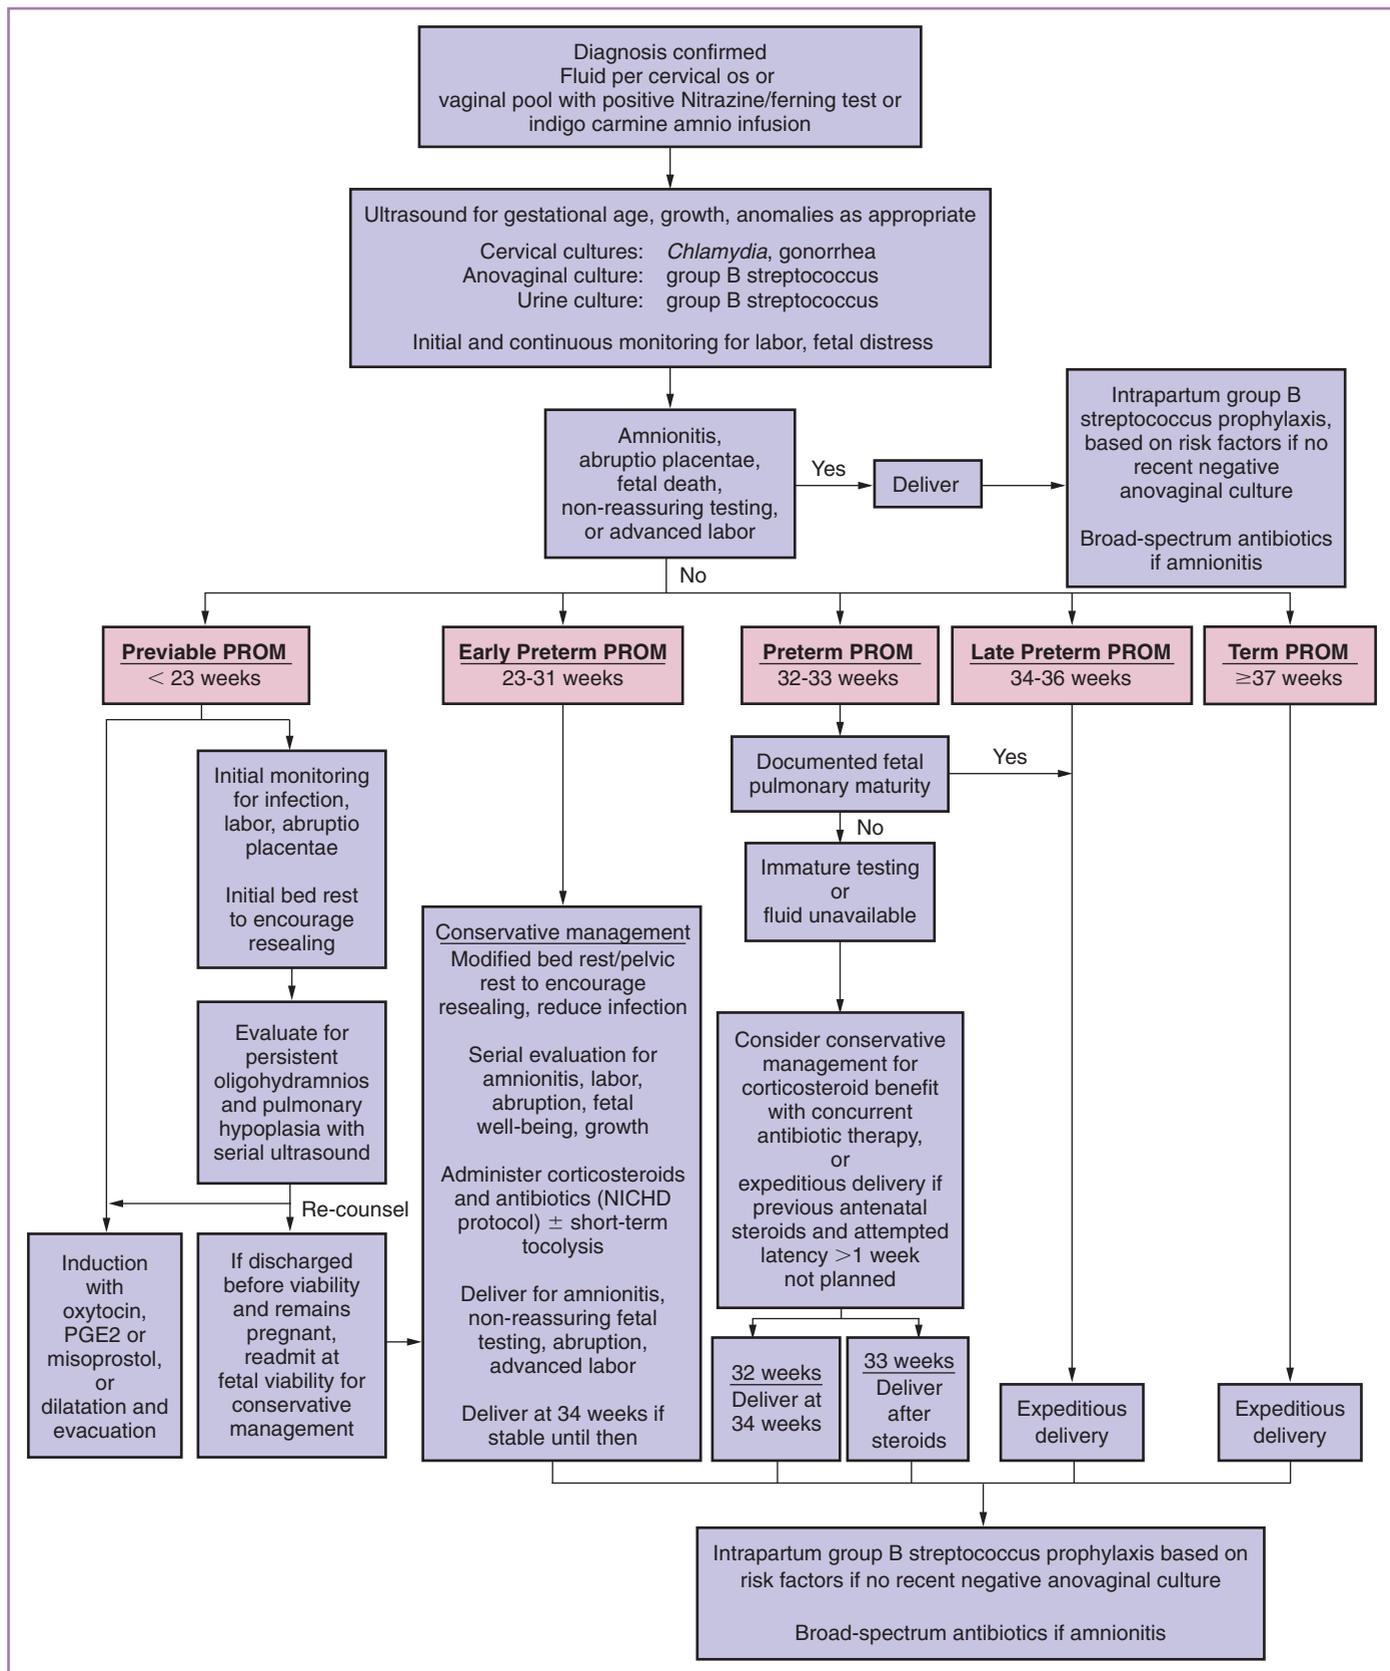

FIGURE 31-2 Algorithm for management of premature rupture of the membranes (PROM). The algorithm includes several alternatives for the approach to term and preterm PROM. NICHD, National Institute of Child Health and Human Development; PGE2, prostaglandin E₂. (Adapted from Mercer BM: Preterm premature rupture of the membranes. *Obstet Gynecol* 101:178-193, 2003.)

However, four large studies have since found that induction with oxytocin after term PROM does not increase the risks of maternal or neonatal infections, nor does it make cesarean delivery more likely.^{54,116-118} In the largest study, oxytocin induction after term PROM reduced the duration of membrane rupture (17.2 versus 33.3 hours; $P < .001$) and the frequencies of chorioamnionitis (4.0% versus 8.6%; $P < .001$) and postpartum febrile morbidity (1.9% versus 3.6%; $P = .008$), without increasing the risk of cesarean delivery (13.7% versus 14.1%) or neonatal infections (2.0% versus 2.8%).⁵⁴ Neonatal antibiotic therapy was less common with immediate induction (7.5% versus 13.7%; $P < .001$), likely because of a lower concern regarding the potential for neonatal infection with less frequent prolonged rupture of the membranes and less chorioamnionitis. Meta-analysis of studies comparing prostaglandin induction and conservative management in this setting has found shorter latency, decreased rates of chorioamnionitis, and less frequent neonatal intensive care unit (NICU) admissions with no increase in cesarean delivery rates with prostaglandin administration.¹¹⁹ Because oxytocin can more easily be discontinued, this choice is somewhat more appealing, given similar efficacy for labor induction.

In summary, available data indicate that women with PROM at term who are not in labor on arrival at the hospital should have labor induced, usually with an oxytocin infusion, to reduce the risk of maternal and neonatal complications. Caregivers should allow an adequate time for the latent phase of labor and minimize digital vaginal examinations until the active phase of labor.

Preterm Premature Rupture of the Membranes at 32 to 36 Weeks' Gestation

Although infants born at 34 to 36 weeks' gestation (i.e., late preterm birth) have a higher risk of complications than term infants, severe acute morbidities and mortality are uncommon, and antenatal corticosteroids for fetal maturation are not typically recommended in this gestational age range.^{71,120} Conservative management of PROM at 34 to 36 weeks prolongs pregnancy by only days, significantly increases the risk of chorioamnionitis (16% versus 2%; $P = .001$), and reduces umbilical cord pH (7.35 versus 7.25; $P = .009$), and it has not been shown to improve neonatal outcomes.^{121,122} For these reasons, women presenting with late preterm PROM at 34 to 36 weeks should be actively delivered.

With delivery at 32 to 33 weeks' gestation, gestational age-dependent neonatal morbidities, including respiratory distress syndrome, can occur, but the likelihood of survival is high, and chronic morbidities are uncommon. Amniotic fluid can be collected from the vaginal pool at initial sterile speculum examination or by amniocentesis if vaginal fluid is not available. Each of the TDx/TdXFLx FLM II assay (Abbott Laboratories, Abbott Park, IL), the lecithin-to-sphingomyelin ratio (L/S ratio), and the phosphatidylglycerol (PG) test can predict pulmonary maturity when performed on vaginal pool specimens.¹²³⁻¹²⁸ Modest reductions in the duration of neonatal hospital stay and hyperbilirubinemia with conservative management of PROM at 32 to 33 weeks' gestation have been reported.¹²² Alternatively, conservative management prolonged pregnancy only briefly (36 versus 14 hours; $P < .001$) in a randomized, controlled trial of conservative management versus immediate induction after PROM at 32 to 36 weeks' gestation. This limited benefit was offset by a 2.5-fold increased risk of chorioamnionitis (27.7% versus 10.9%; $P = .06$), increased neonatal sepsis workups (59.6% versus 28.3%; $P = .003$) and increased neonatal antibiotic treatment for suspected infection (78.7% versus 34.8%; $P < .001$).¹²⁹ The potential for occult umbilical cord compression during

conservative management of PROM is highlighted by the high incidence of recurrent variable decelerations found during intermittent monitoring (19.4%) among conservatively managed women. In this study, documented fetal pulmonary maturity was a requirement for enrollment, and neither group suffered any significant noninfectious neonatal morbidities. Specific attention to those enrolled at 32 to 33 weeks' gestation revealed similar trends regarding brief latency, increased amnionitis, suspected neonatal sepsis, and antibiotic treatment with conservative management.¹³⁰ Based on these findings, the woman with PROM and documented fetal pulmonary maturity at 32 to 33 weeks' gestation is at low risk for complications after immediate delivery and increased risk with conservative management. Amniotic fluid studies documenting pulmonary maturity in this gestational age range are useful to identify women who should be offered expeditious delivery.

If fetal pulmonary testing reveals an immature result or if amniotic fluid cannot be obtained for assessment, conservative management with antenatal corticosteroid administration for fetal maturation is an appropriate choice. Concurrent antibiotic treatment should be given to reduce the risk of intrauterine infection during conservative management (discussed later). There are no data regarding optimal management after antenatal corticosteroid treatment is completed. However, because conservative management increases the risks of chorioamnionitis and prolonged hospitalization and because it is unlikely that conservative management for less than 1 week will result in further significant spontaneous fetal maturation, delivery should be considered if elective delivery is planned within 7 days after antenatal corticosteroid benefit has been achieved. If antenatal corticosteroids are not to be given to accelerate fetal pulmonary maturity after PROM at 32 to 33 weeks, consideration should be given to the potential benefits of expeditious delivery unless conservative management to extend latency for 1 or more weeks will be attempted. These decisions should take into consideration local population-based risks of infection and neonatal morbidities.

Preterm Premature Rupture of the Membranes at 23 to 31 Weeks' Gestation

Because delivery before 32 weeks' gestation is associated with a high risk for perinatal death, severe neonatal morbidities, and long-term sequelae, women with PROM between 23 and 31 weeks' gestation usually should be managed expectantly to prolong pregnancy unless there is evidence of intrauterine infection, suspected placental abruption, advanced labor, or a non-reassuring fetal heart rate pattern. Under certain additional circumstances, delivery may be appropriate despite an early gestational age at membrane rupture (e.g., fetal transverse lie and back up with coexisting advanced cervical dilatation, human immunodeficiency virus infection, primary herpes simplex virus infection).

In women with conservatively managed PROM remote from term, a low initial amniotic fluid volume (amniotic fluid index < 5.0 cm or maximum vertical fluid pocket < 2.0 cm) is associated with shorter latency to delivery and increased neonatal morbidity (including respiratory distress syndrome) but not with increased maternal or neonatal infection after PROM.¹³¹ Despite this, the predictive value of a low amniotic fluid volume for adverse outcomes is poor. A short cervical length on endovaginal ultrasound after preterm PROM has been associated with shorter latency to delivery.¹³²⁻¹³⁴ The latest study of cervical length in women with preterm PROM found that 83% of women delivered within 7 days if the initial cervical length was 1 to 10 mm, compared with 18% for a cervical length more than 30 mm, but only

41 women were evaluated.¹³² However, currently available studies of initial amniotic fluid volume and cervical length assessment in women with preterm PROM have insufficient power and consistency to guide management.

Conservative management includes initial prolonged continuous fetal heart rate and maternal contraction monitoring to assess fetal well-being and identify occult contractions and evidence of umbilical cord compression. If initial testing results are reassuring, the patient can be transferred to an inpatient unit or transferred to a facility capable of emergent delivery and acute neonatal resuscitation for modified bed rest. Because of the high risk of heart rate abnormalities due to umbilical cord compression (32% to 76%), fetal assessment should be performed at least daily for those with initially reassuring test results.^{68,135} Continuous monitoring may be appropriate for women with intermittent fetal heart rate decelerations but otherwise reassuring findings. Although the nonstress test and biophysical profile have the ability to confirm fetal well-being in the setting of preterm PROM, fetal heart rate monitoring can identify variable and late decelerations in addition to uterine activity. Biophysical profile testing may also be confounded by the presence of oligohydramnios but can be helpful if the nonstress test is equivocal, particularly remote from term when the fetal heart rate pattern is less likely to be reactive. A nonreactive result for a nonstress test and a biophysical profile score of 6 or less within 24 hours of delivery have been associated with perinatal infection.^{136,137} A nonreactive nonstress test subsequent to an initially reactive result should be considered suspicious.

Conservative management requires surveillance for the development of labor, abruptio placentae, and intrauterine infection. Chorioamnionitis confers increased risks of perinatal mortality and intraventricular hemorrhage, and it is diagnosed clinically by the presence of maternal fever above 38.0°C (100.4°F) with uterine tenderness or with maternal or fetal tachycardia in the absence of another evident source of infection.⁶³ After the diagnosis of chorioamnionitis is made, delivery should be pursued and broad-spectrum antibiotics should be initiated because treatment before delivery has been shown to decrease the incidence of neonatal sepsis.¹³⁸⁻¹⁴⁰ Although evaluation of the maternal white blood cell count can be helpful if clinical findings are equivocal, the counts can be artificially elevated within 5 to 7 days of antenatal corticosteroid administration. If the diagnosis of chorioamnionitis is suspected but additional confirmation is needed, amniocentesis may yield helpful results.^{15,141,142} A glucose concentration below 16 to 20 mg/dL (sensitivity and specificity of 80% to 90% for a positive culture) and a Gram stain positive for bacteria (sensitivity of 36% to 80% and specificity of 80% to 97% for a positive culture) support the presence of intrauterine infection. The presence of leukocytes alone in amniotic fluid after PROM is not well correlated with intrauterine infection. Although a positive amniotic fluid culture supports clinical suspicion of chorioamnionitis (sensitivity of 65% to 85% and specificity of 85%), these results are not likely to be available before the diagnosis is clarified.¹⁷ One study suggested that determination of glucose levels from vaginally collected amniotic fluid may be a simple and noninvasive method for identification of intra-amniotic infection.¹⁴³ In this promising study, a vaginal pool glucose value below 5 mg/dL had a 74.2% accuracy rate for identifying women with a positive amniotic fluid culture. Although research has found elevated amniotic fluid interleukin levels to be associated with early delivery and perinatal infectious morbidity,¹⁴¹ such testing is not available in most clinical laboratories.

Antenatal Corticosteroids

Respiratory distress syndrome is the most common acute morbidity after conservatively managed preterm PROM.¹⁴⁴ Antenatal corticoste-

roid administration after preterm PROM has been extensively studied, generating several meta-analyses.¹⁴⁵⁻¹⁴⁷ Although early reviews produced conflicting conclusions about the utility of antenatal corticosteroid treatment after PROM, a later meta-analysis concluded that antenatal glucocorticoids significantly reduce the risks of respiratory distress syndrome (20% versus 35.4%), intraventricular hemorrhage (7.5% versus 15.9%), and necrotizing enterocolitis (0.8% versus 4.6%), without increasing the risks of maternal (9.2% versus 5.1%) or neonatal (7.0% versus 6.6%) infections in women with preterm PROM.¹⁴⁷ Multivariate analysis of prospective observational trials suggested a benefit of antenatal corticosteroid use regardless of membrane rupture.¹⁴⁸ Three studies in which prophylactic antibiotics were given concurrent to antenatal corticosteroids found treatment to reduce respiratory distress syndrome (18.4% versus 43.6%; $P = .03$) perinatal mortality (1.3% versus 8.3%; $P = .05$), and composite morbidities (29.3% versus 48.6%; $P < .05$), with no increase in perinatal infections.¹⁴⁹⁻¹⁵¹

The National Institutes of Health Consensus Development Panel recommended a single course of antenatal corticosteroids for women with PROM before 30 to 32 weeks' gestation in the absence of intra-amniotic infection.¹⁵² Data regarding repeated weekly courses of antenatal corticosteroids after preterm PROM are conflicting. In a retrospective study that controlled for gestational age and other factors, two or more courses of antenatal corticosteroids were associated with increased early neonatal sepsis (15.3% versus 2% for a single course or 1.5% for no courses; $P < .001$).¹⁵³ In another retrospective analysis of repeated antenatal corticosteroids, there was no reduction in respiratory distress syndrome, but intraventricular hemorrhage and amniotitis were less common, and there was a trend toward less sepsis.¹⁵⁴ Respiratory distress syndrome was less common in another retrospective review of repeated courses of antenatal corticosteroids (34.9% versus 45.2%) without an increase in neonatal sepsis (9.9% versus 6.2%).¹⁵⁵

Based on current evidence that antenatal corticosteroids are effective for induction of fetal pulmonary maturity without increasing the risk of infection and that most women will remain pregnant for the 24 to 48 hours needed to achieve corticosteroid benefit after PROM, a single course of antenatal corticosteroids should be considered when PROM occurs before 32 weeks' gestation and for women with documented pulmonary immaturity at 32 to 33 weeks' gestation. Betamethasone (two doses of 12 mg IM, given 24 hours apart) or dexamethasone (four doses of 6 mg IM, given 12 hours apart) is considered appropriate. Repeated weekly antenatal corticosteroids are not recommended after preterm PROM. The benefits and risks of a single rescue course remote from initial corticosteroid administration remain to be determined.

Adjunctive Antibiotics

Antibiotic therapy is given during conservative management of preterm PROM to treat or prevent ascending decidual infection to prolong pregnancy and to reduce gestational age-dependent morbidity while limiting the risk of neonatal infection. More than two dozen randomized clinical trials have been summarized in several meta-analyses.^{56,156,157} In the latest one, antibiotic treatment after preterm PROM significantly reduced chorioamnionitis (relative risk [RR] = 0.57); delivery within 48 hours (RR = 0.71) and within 7 days (RR = 0.80); and reduced infant morbidities, including neonatal infection (RR = 0.68); and major cerebral abnormalities on ultrasound before discharge (RR = 0.82) compared with placebo therapy.¹⁵⁷ The need for surfactant administration (RR = 0.83) and oxygen therapy (RR = 0.88) was also reduced. Antibiotics did not influence the risk of necrotizing

enterocolitis (RR = 1.14; CI, 0.66 to 1.97). Oral amoxicillin-clavulanic acid treatment was associated with increased necrotizing enterocolitis (RR = 4.60; 95% CI, 1.98 to 10.72) in this analysis, but oral erythromycin therapy was not (RR = 1.00; CI, 0.56 to 1.80).¹⁵⁷ The study that dominated this meta-analysis included women with PROM up to 36 weeks' gestation and included a population at low risk for necrotizing enterocolitis overall (i.e., 0.5% among controls), and it was the only one of 10 studies that found a significant increase in necrotizing enterocolitis with antibiotic therapy.¹⁵⁸ The meta-analysis found treatment with "all penicillins" (excluding amoxicillin-clavulanic acid) versus placebo to be associated with fewer births within 48 hours and 7 days of PROM, less overall maternal infection and chorioamnionitis, less neonatal infection, fewer positive neonatal blood cultures, and fewer major intracranial cerebral ultrasound abnormalities. Because of the increased risk of neonatal necrotizing enterocolitis with amoxicillin-clavulanate, the study authors recommended erythromycin as a better choice, even though benefits were limited to reduction in delivery at 48 hours, fewer positive neonatal blood cultures, and a reduced need for oxygen therapy.

In a clinical trial with adequate power to evaluate antibiotic therapy during conservative management of women with preterm PROM before 32 weeks' gestation, the National Institutes of Child Health and Human Development Maternal Fetal Medicine Units (NICHD-MFMU) Research Network assigned women with PROM to initial aggressive intravenous therapy for 48 hours (2 g of ampicillin IV every 6 hours and 250 mg of erythromycin IV every 6 hours) followed by oral therapy for 5 days (250 mg of amoxicillin PO every 8 hours and 333 mg of enteric-coated erythromycin base PO every 8 hours) to provide limited-duration, broad-spectrum antimicrobial coverage before delivery.^{144,159} GBS screening was performed. GBS carriers were treated with ampicillin for 1 week and again in labor, and they were analyzed separately. Antibiotic treatment increased the likelihood of continued pregnancy after 7 days of treatment by twofold. Benefit persisted for 3 weeks after randomization despite discontinuation of antibiotics at 7 days. Babies born to women treated with ampicillin plus erythromycin had a reduced incidence of one or more major infant morbidities (53% versus 44% rate of composite morbidity, including death, respiratory distress syndrome, early sepsis, severe intraventricular hemorrhage, and severe necrotizing enterocolitis; $P < .05$). Antibiotic therapy also significantly reduced individual gestational age-dependent morbidities, including respiratory distress syndrome (40.5% versus 48.7%), patent ductus arteriosus (11.7% versus 20.2%), chronic lung disease (bronchopulmonary dysplasia: 20.5% versus 13.0%), and stage 3 or 4 necrotizing enterocolitis (2.3% versus 5.8%), with P values of 0.05 or less for each. Chorioamnionitis was reduced with the study's antibiotics (23% versus 32.5%; $P = .01$), and neonatal sepsis (8.4% versus 15.6%; $P = .009$) and pneumonia (2.9% versus 7.0%; $P = .04$) were reduced for those who were not GBS carriers. The antibiotic study group had less neonatal GBS sepsis (0% versus 1.5%; $P = .03$). Two other studies have attempted to determine whether antibiotic therapy of shorter duration could provide similar benefit, but the studies lacked size and power to demonstrate equivalent effectiveness.^{160,161}

In summary, broad-spectrum antibiotic (ampicillin-amoxicillin plus erythromycin) therapy for women with preterm PROM before 32 weeks' gestation prolongs pregnancy sufficiently to reduce neonatal gestational age-dependent morbidities and reduce the frequencies of maternal and neonatal infections.¹⁴⁴ An alternative conclusion from the latest meta-analysis is that penicillins other than amoxicillin-clavulanic acid are an acceptable treatment for preterm PROM and that the benefits of erythromycin are limited to brief pregnancy pro-

longation, less need for oxygen therapy, and fewer positive neonatal blood cultures.¹⁵⁷ This is not inconsistent with the NICHD-MFMU approach. Up to a 7-day course of parenteral and oral therapy using ampicillin-amoxicillin and erythromycin is recommended for women undergoing conservative management of preterm PROM remote from term. Shortages in intravenous and oral antibiotics have led to the need for alternative antibiotic choices. Oral ampicillin, erythromycin, and azithromycin are likely appropriate alternatives if needed.

Adjunctive antibiotic administration to prolong latency must be distinguished from intrapartum prophylaxis to prevent vertical transmission of GBS from mother to baby.¹¹¹ Known GBS carriers and those who deliver before carrier status can be determined should receive intrapartum prophylaxis to prevent vertical transmission, regardless of prior antibiotic treatments. Women with a diagnosis of chorioamnionitis should receive broad-spectrum intrapartum antibiotic therapy.

Tocolysis

Evidence from prospective studies of tocolysis after PROM is similar to that from studies of tocolysis for preterm labor with intact membranes.¹⁶²⁻¹⁶⁷ After preterm PROM, prophylactic tocolysis with β -agonists before the onset of contractions can prolong pregnancy briefly. Therapeutic tocolysis administered only after contractions occur has not been shown to be effective in prolonging latency. In a retrospective comparison of aggressive tocolysis with limited treatment for contractions only during the first 48 hours, aggressive therapy was not associated with longer latency (3.8 versus 4.5 days; $P = .16$).¹⁶⁷ A report from the Collaborative Study on Antenatal Steroids suggested tocolytic use after PROM was associated with subsequent neonatal respiratory distress syndrome, but the biologic mechanism for this association is unclear.¹⁶⁸

Overall, the available prospective studies have not found tocolytic treatment after PROM to increase or prevent neonatal morbidities after PROM. Tocolytic therapy has not been studied when antenatal corticosteroids and antibiotics were administered concurrently, and it remains plausible that prophylactic tocolysis could delay delivery long enough to allow antibiotic suppression of subclinical decidual infection and for corticosteroid effects on the fetus. Pending further study in this area, tocolytic therapy should not be considered an expected practice after preterm PROM, but it may be appropriate in pregnancies at high risk for neonatal complications with early preterm birth.

Cervical Cerclage

Preterm PROM complicates about one fourth of pregnancies with a cervical cerclage and one half of pregnancies requiring an emergent cerclage.^{43,169,170} Because no prospective studies have been performed regarding management of preterm PROM with a cerclage in situ, recommendations reflect the data available from retrospective cohorts. The risk of adverse perinatal outcomes does not appear to be different when PROM occurs with a cerclage or without one, provided the cerclage is removed on admission after PROM.¹⁷¹⁻¹⁷²

Several small studies comparing pregnancies of preterm PROM in which the cerclage was retained or removed have yielded consistent patterns.¹⁷³⁻¹⁷⁵ No study has found cerclage retention after PROM to reduce the frequency or severity of infant morbidities after preterm PROM, and each has demonstrated statistically insignificant trends toward increased maternal infectious morbidity with only brief pregnancy prolongation. One study found increased infant mortality and mortality due to sepsis with cerclage retention after PROM.¹⁷³ One study that compared different practices at two institutions found longer latencies with cerclage retention, but this finding could reflect

population or practice differences at these institutions rather than the effect of cerclage retention.¹⁷⁴

Because cerclage retention after PROM has not been shown to improve perinatal outcomes and there are potential risks related to leaving the cerclage in situ, removal is recommended when PROM occurs, particularly if the indication for initial cerclage placement was not strong. While deferred removal might enhance pregnancy prolongation for corticosteroid administration, the risks and benefits of this approach have not been determined.

Maternal Herpes Simplex Virus Infection

Neonatal herpes simplex infection most commonly results from direct maternal-fetal transmission at delivery, but hematogenous transmission can occur to the fetus in utero in some cases. Neonatal infection rates after primary and secondary maternal infections occur in 34% to 80% and 1% to 5% of cases, respectively,^{176,177} and infection can result in mortality rates of 50% to 60% and serious sequelae in up to 50% of survivors.^{178,179}

Based on two case series including a total of 35 women with an active maternal genital herpesvirus infection, it has been generally accepted that increasing latency after membrane rupture of more than 4 to 6 hours increases risk of neonatal infection and that cesarean delivery should be performed expeditiously to prevent fetal infection in this setting.¹⁸⁰⁻¹⁸² However, a case series of women with conservatively managed PROM before 32 weeks' gestation coincident to active recurrent herpes simplex virus lesions suggests that conservative management may be considered.¹⁸³ Antenatal corticosteroids and antibiotics were not administered, and antiviral therapy was inconsistent in this series. Cesarean delivery was performed for women with active lesions at the time of delivery. After latencies ranging from 1 to 35 days, none of the 26 infants developed neonatal herpes infection (CI, 0% to 10.4%).

Based on these data, conservative management of PROM complicated by recurrent maternal herpes simplex virus infection may be appropriate if membrane rupture occurs remote from term and the potential for mortality or serious sequelae with delivery is considered to be high. Antiviral therapy (e.g., acyclovir) during conservative management can reduce viral shedding and the frequency of recurrence.

Previaible Premature Rupture of the Membranes before 23 Weeks' Gestation

Although the cause is often not apparent, clinical antecedents can be helpful in determining the likely outcomes in some cases of previable PROM. Membrane rupture after amniocentesis is associated with cessation of leakage and subsequent successful pregnancy outcomes in most cases. Alternatively, previable PROM in a pregnancy complicated by persistent second-trimester bleeding, oligohydramnios, or an elevated level of maternal serum α -fetoprotein more likely reflects an abnormality of placentation, which carries a poor prognosis.

The patient with previable PROM and no other indication for immediate delivery should be counseled regarding the risks and benefits of expectant management, including a realistic appraisal of potential fetal and neonatal outcomes according to the available information for gestational age-appropriate outcomes.^{71,72,184} In addition to the maternal risks of conservative management previously delineated, muscle wasting, bone demineralization, and deep venous thrombosis can also occur with prolonged bed rest, and there are significant financial and social implications of prolonged hospitalization. Prediction of

specific neonatal outcomes after previable PROM is extremely difficult because it is not possible to predict extended latency, the ultimate gestational age at delivery, or the degree of neonatal pulmonary hypoplasia at the time of initial presentation with PROM.

For women who decide that the risks of conservative management exceed the potential benefits, delivery can usually be accomplished with vaginal prostaglandin E₂, oral or vaginal prostaglandin E₁ (i.e., misoprostol), with a high-dose oxytocin infusion, or by dilatation and evacuation. The optimal approach depends on the patient's characteristics (e.g., gestational age, evident amnionitis, prior cesarean delivery) and preference, the available facilities, and the physician's experience with these techniques.

Data to guide the management for women who choose conservative management of previable PROM are lacking. There is no consensus about the advantages of inpatient versus outpatient management. Initial inpatient evaluation may include strict bed and pelvic rest to enhance the opportunity for resealing and for early identification of infection and placental abruption. Women who are discharged should be advised to abstain from intercourse and limit physical activity. They should return immediately in case of fever, abdominal pains, suspicious vaginal discharge, or any vaginal bleeding. Hospitalization for the duration of amniotic fluid leakage may be appropriate in some circumstances. Discharged patients are typically readmitted to hospital after the limit of viability has been reached to allow early intervention for infection, placental abruption, labor, and non-reassuring fetal heart rate patterns. Administration of antenatal corticosteroids for fetal maturation at this time is appropriate.

After an initial ultrasound assessment, repeated evaluation can be performed every 1 to 2 weeks to determine whether there is re-accumulation of amniotic fluid and to evaluate lung growth. Persistent, severe oligohydramnios after PROM before 20 weeks is the strongest predictor of subsequent lethal pulmonary hypoplasia. Serial fetal biometric evaluation (e.g., lung length, chest circumference), ratios to adjust for overall fetal size (thoracic to abdominal circumference, thoracic circumference to femur length) and Doppler studies of fetal pulmonary artery and ductus arteriosus waveform modulation with fetal breathing movements can demonstrate whether fetal pulmonary growth has occurred over time. These results have a high predictive value for neonatal mortality due to pulmonary hypoplasia.^{88,96,185-190} If pulmonary hypoplasia becomes evident before the limit of viability or there is persistent, severe oligohydramnios, the patient may choose to reconsider her decision regarding ongoing expectant management.

Treatments to seal the membrane defect or restore normal amniotic fluid volume include transabdominal amnioinfusion and membrane sealing with fibrin, platelet, cryoprecipitate, or gel-foam plugs. These methods are described in a review.¹⁹¹ The maternal risks and fetal benefits of these interventions have not been adequately evaluated, and there are inadequate data to recommend that any of these approaches be incorporated into routine clinical practice.

Summary

When term or preterm PROM occurs, there is the potential for significant perinatal morbidity and mortality, which can be reduced by considered and timely obstetric interventions. Expedient delivery of the patient with term and late preterm PROM can reduce the risk of perinatal infections without increasing the likelihood of operative delivery. Conservative management of PROM remote from term can reduce infectious and gestational age-dependent morbidities. Regardless of management approach, infants delivered after early preterm or previ-

able PROM are at high risk for perinatal complications, many of which cannot be avoided with current technologies and management algorithms. Attention to early diagnosis and management of complications that occur after PROM can lead to good perinatal outcomes in many cases.

Chapter 32

Post-term Pregnancy

Jamie L. Resnik, MD, and Robert Resnik, MD

In 1902, Ballantyne¹ described the problem of the post-term pregnancy for the first time in modern obstetric terms. Although the language used to describe the entity in early 20th-century Scotland was different from that of today, Ballantyne's words clearly reflected the thinking of his time: "The postmature infant . . . has stayed too long in intrauterine surroundings; he has remained so long in utero that his difficulty is to be born with safety to himself and his mother. The problem of the . . . postmature infant is intranatal."

During the ensuing years, the issue of post-term pregnancy, its risks, and its management generated great interest and controversy. An abundance of older as well as more recent data have firmly established that the fetal risk associated with a prolonged pregnancy is real, albeit small. Consequently, the pregnancy that continues beyond 42 weeks requires careful surveillance.

Definition and Incidence

By definition, a term gestation is one that is completed in 37 to 42 weeks. Pregnancy is considered prolonged, or post-term, when it exceeds 294 days from the last menstrual period (LMP), or 42 weeks. The frequency of this occurrence has been reported to range from 4% to 14%, with only 2% to 7% of pregnancies completing 43 weeks. The chances that parturition will occur precisely at 280 days after the first day of the LMP (40 weeks) is only 5%.

One of the major problems in delineating the extent of risk beyond term is the limited reliability of the LMP as a basis for accurately predicting gestational age. Traditionally, and until the 1990s, most epidemiologic studies pertaining to fetal and neonatal risks of delayed parturition were based on the LMP. Since that time, the use of ultrasound, particularly in the first trimester, has led to much greater precision in pregnancy dating, and data confirm that the LMP is a much less reliable predictor of true gestational age. For example, as early as 1988, Boyd and colleagues² showed that the incidence of post-term gestation fell from 7.5% when based on menstrual dating to 2.6% when early ultrasound examination was used. In a subsequent study by Gardosi and colleagues,³ the post-term delivery rate among women dated by LMP was 9.5% but decreased to 1.5% if ultrasound dating was used. In their study, 71.5% of "post-term" inductions as dated by LMP were not post-term according to ultrasound studies. This finding is consistent with the observations of Taipale and Hiilesmaa,⁴ who performed ultrasound examinations at 8 to 16 weeks' gestation in 17,221 women. When ultrasound biometric criteria rather than the LMP were used to determine gestational age, the number of post-term pregnancies fell from 10.3% to 2.7%. Although a second-trimester

screening examination performed between 17 and 22 weeks' gestation was reported in one recent study to be more accurate in predicting the delivery date than a first-trimester screen,⁵ most reports have tended to agree with the findings of Bennett and associates.⁶ These authors randomly assigned women to either a first-trimester ($n = 104$) or a second-trimester ($n = 92$) ultrasound examination; 5 of the women in the first group underwent labor induction for a post-term gestation, compared with 12 of those in the second group. In any case, it is clear that use of the LMP alone tends to substantially overestimate the number of post-term gestations and that the widespread use of first-trimester ultrasound examinations, now used for noninvasive genetic screening, will have a great impact on the diagnosis and subsequent management of this entity.

Pathogenesis

Knowledge of the mechanism of parturition is increasing rapidly, and the current understanding of the pertinent molecular, biochemical, and physiologic findings are reviewed in Chapter 5. It is clear that the normal timing of parturition requires the integration and synchrony of numerous factors, including the fetal hypothalamic-pituitary-adrenal axis, the placenta and its membranes, and the myometrium and cervix. Although it is not known specifically why some pregnancies are abnormally prolonged, clues exist from interesting observations of aberrant timing of labor in humans and other species. For example, it has long been known that fetal pituitary defects in Holstein cattle may lead to failure of normal delivery timing.⁷ In humans, congenital primary fetal adrenal hypoplasia and placental sulfatase deficiency leading to low estrogen production may result in delayed onset of labor and failure of normal cervical ripening.^{8,9}

Whether the primary defect in delayed parturition involves aberrations in fetal endocrine signaling or abnormalities in the setting of the "placental clock" (as was suggested by McLean and colleagues¹⁰), or whether the myometrial contractile and cervical softening mechanisms are at fault, it is clear from the abundant data currently available that the timing of parturition is determined by complex interactions at the maternal-fetal interface.

Risk Factors

Primiparity has long been known to be more frequently associated with post-term gestation than multiparity. However, there also appears to be an increased frequency of recurrence among women who have

had a previous post-term pregnancy. One large cohort study from Denmark has demonstrated that women who delivered post-term in their first pregnancy had an almost threefold increase in the incidence of subsequent post-term pregnancy, compared with those whose first delivery was at term.¹¹ These findings were recently confirmed by Kistka and coworkers¹² in a study of 368,633 births in Missouri, in which mothers with an initial post-term birth were at increased risk for a subsequent post-term pregnancy (relative risk [RR], 1.88; 95% confidence interval [CI], 1.79 to 1.97). These findings also suggest the possibility of a genetic predisposition, inasmuch as the risk of recurrent post-term pregnancy in the Danish study was not observed if the first and second children had different fathers.

Perinatal Risks

Morbidity and Mortality

Almost all reports up to the present time, even those with inherent limitations imposed by inaccuracies in gestational age determination, suggest an increase in perinatal morbidity and mortality when pregnancy goes beyond 42 weeks' gestation. One of the earliest and most frequently cited studies was provided by the National Birthday Trust of Britain in 1958, which undertook a detailed examination of more than 17,000 births in the United Kingdom from March 3 to March 9 of that year.¹³ Their data demonstrated that the perinatal mortality rate began to increase after 42 weeks' gestation, doubling by about 43 weeks, and was four to six times higher at 44 weeks than at term. A more recent study showed that the risks begin to accelerate between 41 and 42 weeks and rise more sharply after that point (Fig. 32-1).¹⁴ Numerous other reports have confirmed this increase in risk.¹⁵⁻¹⁷ Alexander and associates¹⁸ retrospectively evaluated outcomes of more than 27,000 pregnancies with 41 or 42 weeks' gestation, compared with approximately 29,000 completed at 40 weeks' gestation. Length of labor, incidence of prolonged second-stage labor, forceps use, and cesarean delivery were all increased with the longer gestation period. It is not clear, however, whether the observed increase in complications was due to prolonged gestation, routine use of induction at 42 weeks, or both.

In a more recent Norwegian study, in which 17,493 pregnancies with confirmed dates by second-trimester ultrasound were analyzed, 1336 were found to be post-term. The post-term group had twice the perinatal mortality rate (CI, 0.9 to 4.6); the RR of having an Apgar score lower than 7 at 5 minutes was 2.0 (CI, 1.2 to 3.3), and the RR of requiring neonatal intensive care was 1.6 (CI, 1.3 to 2.0).¹⁹ Another prospective cohort study of 27,514 pregnancies from the same country demonstrated that maternal and fetal risks were lowest at 39 weeks' gestation, with increasing rates of maternal and neonatal complications, as well as operative deliveries, as pregnancy proceeded past term.²⁰ Similar findings were reported in a Danish population.²¹

Abnormal Fetal Growth

Since the report of Clifford²² and his description of the postmature-dysmature neonate with wasting of subcutaneous tissue, meconium staining, and peeling of skin, many have focused their attention on the problems of the undernourished post-term fetus. In fact, only 10% to 20% of true post-term fetuses exhibit any of the findings described by Clifford. *Macrosomia* is actually a far more common complication, because, under most circumstances, the fetus continues to grow in utero. Twice as many post-term fetuses weigh more than 4000 g, com-

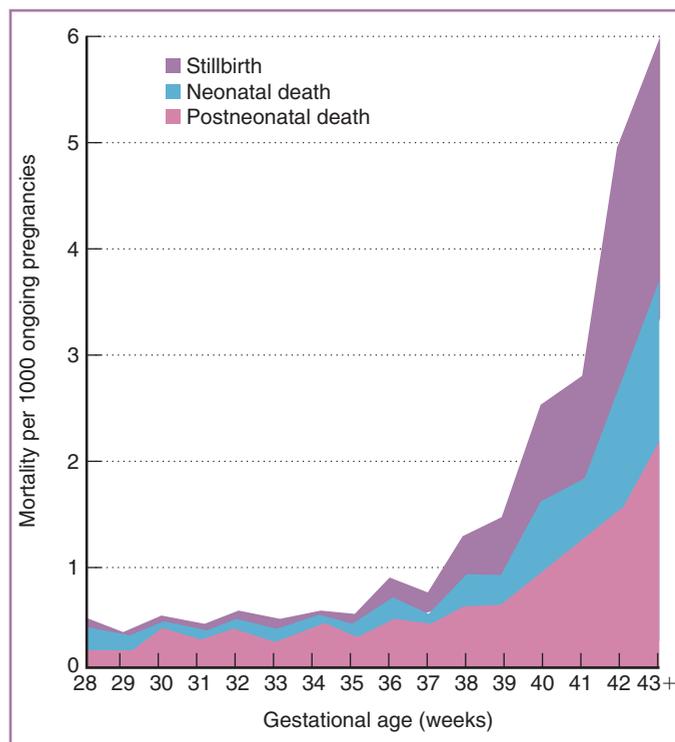

FIGURE 32-1 Perinatal mortality as a function of gestational age. The rates of stillbirth, neonatal, and postneonatal death increase with advancing gestational age beyond 41 weeks. The perinatal mortality is expressed per 1000 ongoing pregnancies. (From Hilder L, Costeloe K, Thilaganathan B: Prolonged pregnancy: Evaluating gestation-specific risks of fetal and infant mortality. *BJOG* 1998;105:169-173.)

pared with term infants,^{17,23} and birth injuries can occur as a result of difficult forceps deliveries and shoulder dystocia. Morbidity also includes cephalohematomas, fractures, and brachial plexus palsy.²⁴ Study of fetal growth characteristics in 7000 post-term infants confirmed a gradual shift toward higher birth weights and greater head circumference between 273 and 300 days of gestational age.²⁵ These findings were further reinforced by a study of 519 pregnancies extending beyond 41 weeks, in which 23% of the newborns weighed more than 4000 g and 4% weighed more than 4500 g.²⁶

Although the majority of post-term infants are appropriately grown or macrosomic, the risk of a small-for-gestational-age (SGA) infant is also increased in post-term pregnancy. In a population-based study of 510,029 singleton pregnancies from the Swedish Birth Registry, the rate of SGA infants increased from 2.2% in term infants to 3.8% in post-term infants.²⁷

Meconium Staining and Pulmonary Aspiration

Almost all studies of post-term gestation report a markedly higher incidence of meconium-stained amniotic fluid, compared with term pregnancies, and the greater risk of meconium aspiration syndrome in these infants is well recognized.¹⁷ Among those infants defined by ultrasound-estimated fetal growth curves to be appropriately sized for gestational age (AGA), those delivered post-term had a threefold higher incidence of meconium aspiration and twice the risk of an Apgar score of less than 4 at 5 minutes, compared with term AGA infants.²⁷ The

presence of oligohydramnios further complicates the risks of meconium staining because of the lack of fluid to dilute the meconium, which results in thicker, more tenacious material in the oropharynx and lower in the respiratory tract.

Fetal Evaluation and Management

When one considers the rapidly accelerating risk of fetal morbidity and mortality between 42 and 43 weeks' gestation and again between 43 and 44 weeks' gestation (see Fig. 32-1), it becomes apparent that no historically derived or laboratory-measured fetal age provides the precision required in the management of the post-term pregnancy. Traditional landmarks, such as LMP, uterine size, and first auscultation of fetal heart tones, can miscalculate gestational age by 2 weeks or more. Even sensitive sonographic determinations, such as crown-to-rump length in the first trimester, demonstrate a range of several days. In fact, in any given gestation, the actual fetal age is known only if the time of ovulation and conception have been studied, as in ovulation induction and in vitro fertilization. Therefore, a gravida thought to be at 41 to 42 weeks or further in gestation, in current practice, either is induced and delivered or undergoes meticulous antenatal monitoring.

Antenatal Fetal Monitoring

Despite the lack of randomized clinical trials, it is generally accepted that careful antepartum and intrapartum fetal monitoring can virtually eliminate fetal post-term mortality and reduce fetal morbidity.²⁸⁻³² However, a careful evidence-based literature analysis concluded that data were insufficient to determine whether routine antenatal surveillance before 41 weeks' gestation improves outcome or which type of monitoring and frequency are most appropriate.³³ Consequently, most obstetricians initiate antenatal testing at 41 weeks' gestation and repeat the testing twice weekly. This testing consists of either a biophysical profile (BPP) or a nonstress test and assessment of amniotic fluid volume.

In a study of 307 women whose pregnancies had proceeded beyond 294 days, a normal twice-weekly BPP that included normal amniotic fluid volume resulted in no perinatal mortalities, and morbidity was equivalent to that observed in a comparison group undergoing elective labor induction with a favorable cervix.³² Based on a cumulative experience with 19,221 high-risk pregnancies, the same investigative group recommended delivery if amniotic fluid volume decreases.³⁴

The technique used to assess *amniotic fluid volume* and its role in evaluation of the prolonged gestation remains controversial because of conflicting studies regarding which of the two tests of volume (amniotic fluid index [AFI] or single vertical pocket) is the better predictor of outcome and the possibility that the AFI may lead to too many unnecessary interventions. Oligohydramnios is thought to be a marker for fetal complications, including umbilical cord compression, hypoxemia, and meconium aspiration, as well as fetal heart rate abnormalities and risk of neonatal admission to an intensive care unit.³⁵⁻³⁷ Bchner and coworkers³⁶ observed an almost 24-fold increase in cesarean delivery for the indication of fetal distress when the maximum vertical amniotic fluid pocket depth was less than 3 cm. The incidence of meconium-stained amniotic fluid in the post-term gestation was 37% among those women with adequate amniotic fluid volume but increased to 71% if the amniotic fluid volume was decreased.³¹

However, a cohort study done in Sweden showed no correlation between an AFI of less than 5 cm and adverse outcome.³⁸ Similarly, Divon and associates,³⁹ in a longitudinal assessment of AFI in 139 women with post-term pregnancy, found an increased frequency of abnormal fetal heart rate tracings and meconium staining but no other significant adverse fetal outcome. Alfirevic and colleagues⁴⁰ compared both methods with respect to pregnancy intervention in post-term pregnancies and found more frequent abnormal AFIs than abnormal vertical pocket depths, leading to more inductions and fetal monitoring but no difference in perinatal outcome. Morris and colleagues⁴¹ conducted a prospective, double-blinded, cohort study to determine whether an AFI of less than 5 cm or a single vertical pocket of less than 2 cm was superior in predicting adverse perinatal events. They found the AFI to be significantly more associated with birth asphyxia and meconium aspiration, but with poor sensitivity. More recently, Zhang and associates,⁴² using data from the Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) study, compared a large population of women screened by ultrasound to control subjects and observed that women with isolated oligohydramnios had no greater adverse perinatal events or impaired growth. Another study comparing the two techniques showed that the single vertical pocket method used for antepartum surveillance led to less frequent diagnosis and intervention for oligohydramnios, but without any difference in adverse perinatal outcomes.⁴³

Given these disparate findings, it is not difficult to understand why there is no consensus as to the reliability or superiority of either technique for identification of the fetus at risk in prolonged pregnancy. Therefore, it is reasonable to conclude that an AFI of less than 5 cm, particularly if it has been falling sharply over a short time interval, or the absence of a single identifiable vertical pocket of greater than 2 cm, indicates that delivery is warranted. Conversely, it is also reasonable to consider that the finding of a normal amniotic fluid volume implies little fetal risk.

There does not appear to be any value in monitoring Doppler flow velocity in fetal vessels, inasmuch as there is no correlation between the findings and outcome.⁴⁴ Zimmerman and associates⁴⁵ demonstrated that the sensitivity of umbilical artery velocimetry for predicting poor outcome was 7%.

Fetal Monitoring versus Induction of Labor

Even though antenatal monitoring can virtually eliminate perinatal mortality in the post-term gestation, some morbidity—including meconium staining, increased cesarean delivery for a diagnosis of fetal distress, and macrosomia with its associated complications—still exists. Although the frequency of morbid events is very low, the continuing concern has been addressed by an alternative approach—that of cervical ripening followed by induction at 41 or 42 weeks' gestation.

Comparison of these two management approaches in several randomized controlled trials has yielded generally similar results. Hannah and coauthors⁴⁶ studied 3407 women with uncomplicated pregnancies at 41 or more weeks' duration, who were randomly assigned to either elective induction after cervical ripening with prostaglandin E₂ (PGE₂) gel or serial antenatal monitoring (fetal kicks, nonstress test, amniotic fluid). In the monitored group, labor was induced only if there was evidence of compromised fetal status. The authors observed a lower rate of cesarean delivery for a diagnosis of fetal distress in the induction group but no significant difference between the two groups in fetal mortality or morbidity. The same investigators subsequently

reported that routine induction was more cost-effective than serial antenatal monitoring.⁴⁷ The Maternal-Fetal Medicine Network prospectively evaluated 440 patients, comparing induction with serial monitoring.⁴⁸ They observed no fetal deaths in either group, and rates of neonatal morbidity and cesarean delivery were similar. A more recent study from Norway, in which 254 women at 41 weeks' gestation were randomly assigned to an induction or expectant management group, found no differences in neonatal outcomes or mode of delivery.⁴⁹

These combined trials have led to the conclusion that neither approach has a substantive advantage over the other. A small advantage to the induction approach was suggested by the recent Cochrane Review of 19 studies, which determined that a policy of labor induction at 41 weeks resulted in fewer fetal deaths, although the differences and absolute risk were extremely small (1 in 2986 versus 9 in 2953; odds ratio, 0.3; CI, 0.9 to 0.99). There was no significant difference in the cesarean section rate.⁵⁰

Nevertheless, in terms of physician preferences in the United States, induction at 41 weeks has become the mode of practice and the debate moot. A recent survey of 1000 randomly selected members of the American College of Obstetricians and Gynecologists revealed that 73% routinely induce low-risk women at 41 weeks. For women who decline induction, approximately 65% of physicians initiate antenatal testing twice weekly at 41 weeks.⁵¹ It is clear that medical induction rates have increased sharply in the United States. Between 1980 and 1996, the rate of induction doubled (from 12.9% to 25.8%), the most common indication being that of the post-term pregnancy.⁵²

Management Summary

It seems appropriate to recommend the following steps to evaluate and manage the post-term gestation:

1. Although there is insufficient evidence because of the low-risk nature of either approach, current obstetric practice dictates that labor induction be offered between 41 and 42 weeks' gestation in the presence of a favorable cervix.
2. If the cervix is unfavorable, alternate approaches include either cervical ripening followed by induction of labor or twice-weekly fetal monitoring. Delivery should be accomplished promptly if there is evidence of fetal compromise.
3. It is prudent to use the BPP, or some modification of the BPP, to determine antenatal fetal condition.

Methods of Labor Induction

The issue of labor induction and cervical ripening agents is addressed in detail in Chapter 36 and is summarized briefly here.

Because normal labor depends on efficient myometrial contractions acting on a compliant cervix to efface and dilate it, methods of labor induction must take into account both components of the uterus. If the cervix is already soft, effaced, and partially dilated, intravenous infusion of oxytocin may be sufficient to stimulate contractions. Conventional practice requires amniotomy to be performed as a first step, because this procedure maximizes the effectiveness of oxytocin. If the cervix is unripe, oxytocin will not cause it to ripen, and amniotomy is inappropriate. Although labor contractions can be stimulated by oxytocin, such a result is futile, because many hours of such contractions are required to produce any sort of change in the cervix, and the ensuing prolonged labor can lead to an increase in obstetric morbidity,

including a significant risk of postpartum hemorrhage and an increased risk of cesarean delivery.

The Bishop score,⁵³ or some suitable modification of it, can be used as a guide to select the most appropriate induction technique. This is especially true in primigravid women. If the Bishop score is lower than 5, amniotomy and oxytocin infusion are associated with an unacceptably high incidence of unsuccessful inductions as well as fetal and maternal complications.⁵⁴ In these circumstances, cervical ripening should be undertaken before uterine contractions are provoked. Given the rapidly increasing use of transvaginal ultrasound (TVUS) to assess cervical length and dilatation and its usefulness in the diagnosis of preterm labor, it is not unreasonable to apply this technology to cervical assessment in post-term pregnancy. One study of 240 women, comparing TVUS with digital cervical examination using receiver operating characteristic (ROC) curves, demonstrated that a cervical length of 28 mm was a better predictor of induction success (vaginal delivery within 24 hours) than the Bishop score.⁵⁵ However, conflicting findings were reported by Chandra and associates.⁵⁶

The most frequently used current cervical ripening techniques include chemical agents such as PGE₂ (dinoprostone, trade names Prepidil and Cervidil Rx), administered vaginally or intracervically, and misoprostol (Cytotec Rx), administered vaginally or orally. Both appear to be effective in improving the Bishop score and to result in shorter labor times and possibly fewer failed inductions. Misoprostol, in doses of 25 µg given vaginally every 4 hours, appears to be slightly more effective than dinoprostone but is associated with a higher frequency of uterine tachysystole. A recent review of randomized trials performed between 1987 and 2005 compared the two agents and confirmed that misoprostol was superior to dinoprostone at any dose and route of administration in terms of achieving vaginal delivery within 24 hours. There was no difference in the rate of cesarean delivery.⁵⁷ This study confirmed an earlier Cochrane database review which concluded that the use of vaginal misoprostol is more effective than conventional methods of cervical ripening and labor induction. Compared with placebo, oxytocin, or intracervical or vaginal PGE₂, misoprostol resulted in increased cervical ripening, decreased use of oxytocin, and increased rates of vaginal delivery. However, misoprostol also caused an increased rate of uterine hyperstimulation.⁵⁸

Vaginal inserts such as balloon catheters also have their advocates for cervical ripening. A systematic review concluded that these mechanical dilators do not compare favorably with chemical inducing agents in terms of delivery success rates but are associated with less uterine hypercontractility.⁵⁹

Developmental Effects of Post-term Gestation

Studies on the development of children from prolonged pregnancies are difficult to evaluate because investigators have not separated neonates asphyxiated in utero and growth-restricted (dysmature) post-term neonates from otherwise normally born neonates. A study of neonatal behavior among 106 dysmature infants revealed an increased number of illnesses and sleep disorders as well as diminished social competence during the first year of life (Vineland Social Maturity Scale). Also, and not unexpectedly, the incidence of fetal distress was high, and those babies who were asphyxiated in utero had a higher incidence of abnormal neurologic signs in the neonatal period.⁶⁰ All infants had signs of desquamation of skin and wasting of subcutaneous tissue, however, and the group of children studied was not compared

with any post-term children who did not have these physical findings at birth.

Field and coworkers⁶¹ studied a group of 40 dysmature offspring, all of whom had parchment-like skin and long, thin bodies. At birth, their Brazelton interaction and motor scores were lower than in term controls, and at 4 months they scored lower on the Denver Developmental Scale. By 8 months, the Bayley motor scores of the post-term subjects were equivalent to those of control infants, but their mental scores were slightly lower. This study differed in at least one significant way from that of Lovell⁶⁰: The Apgar scores at 5 minutes in the two groups were identical, thus partially correcting for in utero asphyxia.

In a large retrospective review, Zwerdling²³ observed that post-term infants weighing less than 2500 g had a neonatal mortality rate seven times that of post-term infants as a whole. This finding confirmed the additional risk of the dysmature growth pattern in some post-term infants. The increased mortality rate was observed up to 2 years of age, but at 5 years the data on growth and intelligence in Zwerdling's study population revealed no differences between prolonged-gestation and normal-gestation children. These findings were confirmed in a prospective study in which 129 children born of prolonged pregnancy were compared with 184 term controls.⁶² At 1 year and again at 2 years of age, there were no differences between the two groups with respect to intelligence scores, physical milestones, or intercurrent illnesses.

One recent cohort study from Denmark linked hospital records of 277,435 pregnancies delivering at term or beyond to cases of childhood epilepsy. The researchers found a slight increase in the incidence of epilepsy as a function of gestational age at or after 43 weeks, but only among those infants delivered by cesarean section or other operative delivery.⁶³ The risk was not observed after 1 year of life. Whether this finding reflects a problem unique to advanced gestational age or complications that required expedient delivery is unclear.

Chapter 33

Embryonic and Fetal Demise

Michael J. Paidas, MD, and Nazli Hossain, MBBS

Miscarriage is the most common complication of pregnancy.¹ It is estimated that up to one half of women will have at least one miscarriage.²⁻⁴ Several factors contribute to inconsistencies in the definition, evaluation, and management of this pregnancy complication. One rational approach to the topic is to consider pregnancy loss according to gestational age intervals and to consider whether pregnancy loss is an isolated or recurrent phenomenon. Although approximately 15% of clinically recognized pregnancies end in miscarriage, if pregnancy loss from the period of conception is considered, more than 50% of pregnancies are lost.^{1,5,6} One percent of couples may have two or more consecutive losses before the third trimester.⁷

Embryonic Losses

Peri-implantation Loss

The earliest pregnancy losses occur in the peri-implantation period. Implantation begins approximately 7 days after ovulation, which is between days 19 and 24 of the preceding menstrual cycle.⁸ Implantation has been divided into three stages.⁹ The initial stage is blastocyst apposition to the endometrial epithelium. Progesterone-dependent organelles, called pinopodes, appear on the surface of the endometrial epithelium on day 19 to 21 of the menstrual cycle, and they interdigitate with the blastocyst's outer syncytiotrophoblast to mediate initial linkage.¹⁰ The second step in the implantation process is blastocyst adhesion, which is mediated by mucin 1. A subset of women with recurrent miscarriage has reduced levels of mucin-related secretory products.¹¹

The third stage of implantation is trophoblast invasion into the uterine endometrium and vasculature and formation of the maternal fetal interface, which is mediated by several decidual-derived paracrine growth and angiogenic factors and by leukocyte-derived cytokines.¹² Theoretically, genetic abnormalities in blastocyst or endometrial cell adhesion or in paracrine signaling may lead to peri-implantational loss. Postimplantation events are characterized by increased expression of decidualized endometrial T_H2 cytokines (i.e., interleukin 4 [IL-4], IL-5, and IL-10) and reduced levels of T_H1 cytokines (i.e., IL-2, interferon γ [IFN- γ], as well as tumor necrosis factor α [TNF- α]).¹³ Several immune factors have been implicated in pregnancy loss. Pregnancy should not be characterized as a state of immune suppression, but rather as a state of carefully orchestrated inflammation.¹⁴ Indeed, overexpression of the anti-inflammatory T_H2 phenotype has been found in women with recurrent pregnancy loss.¹⁵ Immune cells such as macrophages and uterine natural killer (uNK) cells may play a crucial role in normal implantation by producing angiogenic and growth factors

or cytokines required for blastocyst growth and differentiation and by clearing apoptotic endometrial cells to allow for expansion of the growing embryo and extraembryonic structures.

Trophoblast expresses the nonimmunogenic human leukocyte antigen G (HLA-G), which has been postulated to offer protection against lysis by uNK cells.¹⁶ However, HLA-G protein is not unique to pregnancy; it has been identified in unfertilized oocytes.¹⁷ Although several investigators have reported that the presence of soluble HLA-G molecules in human embryo culture supernatants after in vitro fertilization or intracytoplasmic sperm injection correlates with successful pregnancy outcome,^{18,19} others have disputed this finding.^{20,21} HLA-G may play a role in early pregnancy, but HLA-G-negative embryos can implant.²² It is unlikely that HLA-G polymorphisms represent a bona fide cause of early pregnancy loss.

Genetic Abnormalities Causing Embryonic Loss

Aneuploidy is the most common cause of embryonic loss before 10 weeks' gestation. At least one half of all miscarriages are caused by cytogenetic abnormalities. Collectively, the most common error is trisomy, followed by polyploidy and monosomy X.^{2,3,23} In a study of chromosomal abnormalities involving first-trimester loss in 96 women, Strom and colleagues²⁴ found that 83% of karyotypes were abnormal. Pauli and coworkers²⁵ found the relative distribution of chromosomal abnormalities causing pregnancy loss to be 23% each for monosomy X (45X) and trisomy 21, 21% for trisomy 18, and 8% for trisomy 13.

Aneuploidies are usually the result of errors occurring in the first meiotic oocyte division. The cause of recurrent aneuploid loss in the setting of advanced maternal age is not completely understood. One theory is that continuous exposure to physiological oxidative stress in cycling women leads to progressively poorer oocyte quality. Animal models have demonstrated that excess oxidative stress leads to premature ovarian failure.²⁶ Another theory holds that there is a progressive maternal age-dependent depletion of oocytes available at the stage of maturation needed to complete normal meiosis.²⁷ Consistent with this theory, women with at least one trisomic fetus enter menopause at an earlier age compared with women without a similar history.²⁸ Maternal age-associated shortening of oocyte telomeres has also been suggested as a cause of accelerated embryo fragmentation and apoptosis.²⁹ Moreover, shortened telomeres can lead to abnormal chiasma formation and nondisjunction, providing a potential explanation of the maternal age-associated embryonic aneuploidy.³⁰

Because advanced maternal age is associated with an increased risk of aneuploid offspring, one stochastic approach argues that to

increase the chance of euploid live births, superovulation with in vitro fertilization and preimplantation diagnosis should be performed for the common trisomies found in abortus materials. This would theoretically increase the number of available euploid embryos. However, it has been argued that the bulk of these excess oocytes would have been selected out by natural processes. Moreover, several studies have suggested that this approach does not increase live birth rates.³¹⁻³³

Low maternal folate levels have been found in women with miscarriage due to aneuploidy (odds ratio [OR] = 1.95; 95% confidence interval [CI], 1.09 to 3.48) but not when the fetal karyotype is normal (OR = 1.11; 95% CI, 0.55 to 2.24).³⁴ Folate deficiency may also have a role in meiotic nondisjunction. A meta-analysis suggested that fasting hyperhomocysteinemia is modestly associated with recurrent pregnancy loss (<16 weeks).³⁵ Folate supplementation can eliminate this potential mechanism. Because of the potential collateral benefits of folate in reducing the occurrence of fetal neural tube defects and its lack of toxicity, we recommend treating patients with unexplained early losses with folate (4 mg/day) beginning in the preconception period.

In addition to the advanced maternal age-associated risk of aneuploid pregnancy loss, other genetic, age-independent factors can predispose to recurrent miscarriage. Approximately 10% of patients with recurrent miscarriage may harbor such a factor.³⁶ Specific conditions include chromosomal fragility,^{37,38} mosaicism, and deletions and large pericentric and paracentric chromosomal inversions.^{39,40} A balanced reciprocal translocation or robertsonian translocation in one partner occurs in 4% of couples with recurrent miscarriage.⁴¹ Carriers of the former are phenotypically normal, but 50% to 70% of their gametes and embryos are unbalanced because of abnormal segregation at meiosis.⁴² Ironically, couples with a structural chromosomal abnormality who conceive spontaneously have a higher rate of live births (50% to 65%) than those conceiving after in vitro fertilization with preimplantation genetic screening, which is associated with a 29% live birth rate per oocyte retrieval and 38% per embryo transfer.⁴³

Embryonic deaths may also be associated with single-gene mutation. Results of these mutations include glycogen storage diseases and hemoglobinopathies.⁴⁴ There are also X-linked disorders, which result in death of male fetuses only. These disorders include incontinentia pigmenti and Rett syndrome. The risk of recurrence of Rett syndrome is higher for male fetuses.

Endocrine Disorders Causing Embryonic Loss

Progesterone is required for successful implantation and maintenance of pregnancy. It plays a critical role in endometrial hemostasis and architectural integrity.⁴⁵ Progesterone's endometrial effects are mediated by its specific receptor isoforms, A and B, which are structurally identical, except for an additional 165 amino acids in the B isoform. Each isoform is functionally distinct, mediating its physiologic effects without much overlap. Progesterone plays a critical role in regulating migration and proliferation of immune and inflammatory cell populations located in the endometrium.⁴⁶ Progesterone may act as an immune suppressant, blocking T_H1 activity and inducing release of T_H2 cytokines (i.e., IL-4 and IL-10).⁴⁷ Defective corpus luteum function, or a luteal phase defect, has been implicated in early pregnancy loss for several decades.⁴⁸

Removal of the corpus luteum before 8 weeks' gestation has led to spontaneous abortion.⁴⁹ This observation provides the rationale for exogenous progesterone therapy if the corpus luteum is removed early

in pregnancy. Conversely, progesterone receptor antagonists given within the first 7 weeks of pregnancy induce abortion.⁵⁰ A luteal phase defect is defined as a lag of more than 2 days from the histologic development of the endometrium compared with the day of the menstrual cycle.^{51,52} Because out-of-phase endometria can be found in up to 30% of the isolated menstrual cycles of fertile women, the diagnosis of luteal phase defect should be made only if it can be demonstrated in two consecutive cycles.⁵³

Many causes have been suggested for the luteal phase defect. They include diminished production of progesterone by the corpus luteum, lower follicle-stimulating hormone (FSH) levels in the follicular phase, abnormal patterns of luteinizing hormone (LH) secretion, decreased ovulatory levels of FSH and LH, and decreased endometrial response to secreted progesterone.⁵³ Other potential mechanisms include decreased gonadotropin-releasing hormone secretion, inadequate ovarian steroidogenesis, and endometrial receptor defects.⁵³ Clinical trials have provided mixed results concerning the significance of luteal phase defects and the efficacy of treatment. Daly and colleagues⁵⁴ evaluated 33 infertile women with documented luteal phase defects, and 14 women who had biopsy-proven correction of the luteal phase defect did not have miscarriages. However, among the 16 women without correction, there were only four pregnancies that ended in abortion.⁵⁴ Balasch and colleagues⁵⁵ reported the results of 1492 biopsies in 1055 women. Fifteen of 20 pregnancies in women with an in-phase biopsy result went to term, but so did four of six pregnancies in women with an out-of-phase biopsy result. Moreover, term pregnancy rates were similar in women treated and those untreated for luteal phase defects.⁵⁵

Serum progesterone levels are less invasive and less costly than endometrial biopsy, which is considered to be the gold standard for the diagnosis of luteal phase defect. Progesterone levels of 10 to 12 ng/mL determined 1 week before menses have been used as a marker for luteal phase defects. Unfortunately, progesterone levels do not correlate with endometrial histology.⁵⁶ The diagnostic criteria and proposed treatment for this putative disorder require validation.⁵⁷

Thyroid dysfunction resulting in overt hypothyroidism or hyperthyroidism has been implicated in pregnancy loss. However, subclinical hypothyroidism probably is not a cause of early pregnancy loss.⁵⁸ Some investigators have shown that antithyroid antibodies and milder forms of thyroid disease have been associated with miscarriage.^{59,60} One prospective study investigating the presence of antithyroid antibodies in patients with recurrent abortion found that 19% of affected women demonstrated anti-thyroglobulin or thyroid microsomal antibodies.⁶¹ Pratt and colleagues⁶² first reported that euthyroid women with first-trimester pregnancy losses had an increased incidence of antithyroid antibodies. However, they subsequently reported that an increase in nonspecific, multiorgan antibodies was responsible for the apparent increase in antithyroid antibodies.⁶³ Moreover, clinical outcomes were not significantly different among patients with or without these antibodies. Routine screening of patients with early pregnancy loss for antithyroid antibodies is not recommended, nor are therapies available.

Polycystic ovarian syndrome (PCOS) has been implicated in early pregnancy loss for several decades. Patients with recurrent pregnancy loss have a higher prevalence of polycystic ovaries (40%) compared with 23% of unselected women.⁶⁴ One randomized, placebo-controlled trial failed to demonstrate that suppression of LH secretion increased live birth rates.⁶⁵ Patients with PCOS and insulin resistance have elevated levels of plasminogen activator inhibitor 1 (PAI-1), reflecting impaired fibrinolysis.^{66,67} Elevated levels of PAI-1 may impede trophoblast invasion mediated by urokinase-type plasminogen activator. Homozygosity for the 4G/4G PAI-1 polymorphism, a mutation associ-

ated with mild hypofibrinolysis, has been found in higher frequency in patients with PCOS and pregnancy loss than in women with normal-appearing ovaries.⁶⁸

Analysis of follicular fluid from patients with PCOS demonstrates elevated levels of glucose, insulin-like growth factor 1 (IGF-1), and androgens, which can be embryotoxic. Metformin, an insulin-sensitizing agent, has been offered as a targeted therapy to reverse the pathologic endocrine changes associated with PCOS. Although a small, retrospective study demonstrated that treatment of patients with PCOS with metformin reduced the risk for miscarriage,⁶⁹ a large, prospective study failed to confirm these results.⁷⁰

Prolactin is a key hormone involved in ovulatory and endometrial development. Elevated prolactin levels have been implicated in pregnancy loss, and treatment with bromocriptine, which suppresses pituitary prolactin secretion, has been associated with improved pregnancy rates.⁷¹

Mixed Embryonic and Fetal Losses

Immunologic Causes

Analysis of the transcriptome of chromosomally normal chorionic villi from patients with recurrent pregnancy loss has demonstrated aberrant expression of several groups of immunologically relevant genes.⁷² Embryonic and unexplained fetal deaths have been associated with complement activation. The median plasma concentration of C5a was higher in patients with fetal death than in normal pregnant women (median of 16 ng/mL [range, 4.5 to 402.5] versus median of 11.6 ng/mL [range, 1.2 to 87.1]; $P < .001$).⁷³

Unexplained fetal death in the absence of evidence of infection also has been linked to memory T cells. Blackwell and associates⁷⁴ conducted a study to determine whether unexplained fetal death was associated with a change in the proportion of naive-like and memory-like T cells in the maternal blood, as determined by the CD45 isoforms on the surface of CD4⁺ lymphocytes. Patients with intrauterine fetal death had a higher percentage of CD45RO⁺CD4⁺ T lymphocytes than normal pregnant women (median of 57.7% [range, 35.4 to 78.6] for fetal death versus median of 49.9% [range, 19.1 to 86.8] for normal pregnancy; $P = .004$).⁷⁴

Natural killer (NK) cells are involved in direct killing of virus-infected cells, cytokine production, and immune surveillance.⁷⁵ Excessive NK cell activity has been implicated in pregnancy loss, presumably by damaging the implanting blastocyst or interfering with normal placentation.⁷⁶ The process is likely mediated by the interaction between surface NK receptors and major histocompatibility class I molecules, including human leukocyte antigens C, E, and G expressed on the surface of the invading trophoblast.⁷⁷⁻⁷⁹ The existence of discrete populations of peripheral blood and uNK cells has contributed to confusion regarding the role of NK cells and pregnancy loss. Approximately 90% of peripheral NK cells express low levels of CD56 but do express CD16. These CD56(dim) cells are more cytotoxic and express members of the killer immunoglobulin-like receptor (KIR) family. In contrast, D56(bright) cells have low cytotoxicity and do not express KIRs. In the uterus, 90% of the NK cells are CD56(bright)CD16⁻. There is evidence that uNK cells may modulate the cellular growth, differentiation, and regeneration of the uterine mucosa⁸⁰ and promote placental invasion.⁸¹ CD56(bright) cells express the high-affinity IL-2 receptor, higher levels of IFN- γ and TNF- α ,

granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-10, and IL-13.⁸²

Microarray data comparing peripheral NK and uNK cells have demonstrated that several genes are preferentially overexpressed in the uNK cells, suggesting the unique role of these cells.⁸³ Other gene array data reveal that several cytokines are very abundant in the endometrium: monocyte chemotactic protein 3, eotaxin, fractalkine, macrophage inflammatory protein 1 β , 6Ckine, IL-8, hemophiltrate CC chemokine 1 and 4, and macrophage-derived chemokine.⁸⁴ In early pregnancy, uNK cells represent 70% of the total leukocyte population. They are rarely seen by 20 weeks' gestation, and they are absent in term decidua.⁸⁵

Peripheral blood NK cell number and activity have been investigated in patients with pregnancy loss. Shakhar and associates⁸⁶ found that women with primary recurrent pregnancy loss had the highest levels of NK cell number and activity, whereas secondary aborters had intermediate levels, and control patients had the lowest levels, suggesting that NK cells are involved in pregnancy loss.⁸⁶ When patients with recurrent early pregnancy loss were examined prospectively during a subsequent pregnancy, pregnancies ending in loss (with normal fetal karyotype) were characterized by elevated NK cell percentage and activity.⁸⁷ Some investigators^{88,89} suggested that elevated peripheral NK cells are predictors of pregnancy loss, with levels of more than 18% associated with impending pregnancy loss.⁸⁹ This led to the empiric offering of immunophenotype profiling in such patients. However, decidual uNK cell numbers are not increased in spontaneous compared with induced abortion specimens.⁹⁰

Because of the clear differences between uNK and peripheral blood NK cells, the scientific basis for evaluating peripheral blood NK cells in patients with pregnancy loss is highly suspect. Moreover, there is growing evidence that increased decidual uNK cell activity is required for normal placentation,⁹¹ and that reduced decidual uNK cell activity may be associated with preeclampsia and intrauterine growth restriction.⁹² There is little evidence to support the assessment of peripheral NK cell activity in recurrent miscarriage patients.

Several studies of women with reproductive failure have been directed at suppressing NK cells with the use of steroids, intravenous immune globulin (IVIG), and TNF- α -blocking drugs. Morikawa and colleagues⁹³ evaluated the outcome of IVIG treatment in 18 pregnancies from 15 women with four or more consecutive, unexplained miscarriages. They found that 14 treated pregnancies resulted in live births and that 4 resulted in abortions with chromosomal abnormalities. Treatment also reduced preinfusion peripheral blood NK cell activity and NK cell number. However, meta-analysis of 19 such trials did not reveal any significant differences in live birth rates between treated and control groups.⁹⁴ The role of NK cells in pregnancy loss remains controversial, and treatments aimed at altering the NK cell status of women are highly investigational. Moreover, there is growing evidence against treatment to suppress decidual uNK cell activity with IVIG.

Absence of blocking antibodies has been offered as an explanation of maternally immunologically mediated pregnancy loss. These blocking antibodies were considered to be maternal antipaternal lymphocytotoxic antibodies. It was posited that excessive HLA sharing by prospective parents would lead to the absence of these antibodies. The proposed consequence was that placental antigens would be exposed to a more cytotoxic maternal immune response. Proposed treatments included infusion of male-partner or third-party leukocytes or extracts of placental trophoblast into the prospective mother to induce antibody production. However, meta-analyses fail to support such approaches.⁹⁵ In a double-blind, placebo-controlled, multicenter, randomized clinical trial in which 91 patients with recurrent miscarriage

were assigned to immunization with paternal mononuclear cells and 92 were assigned to sterile saline injections, higher numbers of viable pregnancies occurred in the placebo group (41 [48%] of 85 versus 31 [36%] of 86; OR = 0.60; 95% CI, 0.33 to 1.12). This therapy does not have merit.⁹⁶

Uterine Abnormalities

Müllerian fusion defects have been associated with fetal and neonatal losses because of preterm delivery, low birth weight, malpresentation, and abortion.^{97,98} There is contradictory evidence linking such defects with embryonic loss. Salim and associates⁹⁹ evaluated 509 women with or without a history of three or more consecutive, unexplained pregnancy losses before 14 weeks' gestation using three-dimensional ultrasound. They found major congenital anomalies in 23.8% of women with losses and 5.3% in controls.⁹⁹ However, in both groups, the most common anomalies were arcuate and subseptate uteri, which accounted for more than 90% of cases. The former anomaly does not appear to be associated with a higher rate of recurrent abortion and may represent a normal variant.¹⁰⁰ The prevalence of major anomalies was 6.9% among women with recurrent miscarriage, compared with 1.7% in controls.¹⁰⁰ Table 33-1 shows the relative distribution of the major anomalies and their associated miscarriage rates.¹⁰¹ Various theories have been promulgated to account for the association of uterine anomalies with recurrent miscarriage, including decreased vascularity in the septum, increased inflammation, and a reduction in sensitivity to steroid hormones.¹⁰¹ However, there is not substantial evidence to favor one putative cause over another. Moreover, there are no controlled, randomized clinical trials of pregnancy outcome after resection of the uterine septum, although reductions in recurrent loss have been reported in several large series.^{102,103} Traditional open metroplasty is rarely recommended for bicornuate or didelphys uteri because of the attendant risks of infertility and uterine rupture during pregnancy and because of the more favorable associated pregnancy outcomes.

Although myomas are quite common, they usually do not adversely impact pregnancy.¹⁰⁴ However, submucous myomas that distort the uterine cavity have been posited as causes of recurrent miscarriage and reduced *in vitro* fertilization success rates.¹⁰⁵ It is plausible that they cause pregnancy loss by a variety of mechanisms, including distorting the overlying endometrium, resulting in a poorly decidualized implantation site; compromising local endometrial blood supply; infarction resulting from rapid growth that outstrips the myomatous blood supply, leading to necrosis and so-called red degeneration that causes production of proinflammatory cytokines; and induction of fetal deformations when they encroach on the space occupied by the developing fetus, typically in the second or third trimester.¹⁰⁶ Hysteroscopic resection may improve fertility, live birth rates, and bleeding patterns.¹⁰⁷ A prospective study is being conducted to correlate the presence of sonographically identified myomas with pregnancy outcomes. Preliminary data on 1313 women have demonstrated that women with myomas had an increased rate of prior miscarriage (OR = 2.17).¹⁰⁸

Endometrial polyps have been posited as causes of recurrent miscarriage, and descriptive series suggest improvements in pregnancy outcomes after hysteroscopic resection.¹⁰⁹

Based on expert opinion, it seems reasonable to offer patients with recurrent miscarriage screening for uterine defects by sonohysterography. Subsequent magnetic resonance imaging (MRI) or concomitant use of three-dimensional ultrasound can enable differentiation of bicornuate from septate uteri. Operative hysteroscopy can then be employed for the treatment of submucous fibroids, polyps, and septa. However, these recommendations are not based on well-conducted, randomized clinical trials.

Approximately 15% to 30% of women with uterine synechiae (i.e., Asherman syndrome) have recurrent abortions.¹¹⁰ Lysis under direct hysteroscopic visualization should be offered to these patients. Postoperative management should include estrogen administration and insertion of an intrauterine device or inflated Foley bulb catheter.¹¹⁰

Fetal Loss

Fetal death has been defined by the World Health Organization (WHO) as death before complete expulsion or extraction from the mother of the product of conception, irrespective of duration of pregnancy.¹ It has been classified into three groups: early, occurring before 20 completed weeks' gestation; intermediate, occurring between 20 and 27 weeks; and late fetal death, occurring after more than 28 weeks' gestation.¹¹¹

Epidemiology of Second- and Third-Trimester Loss

The rate of stillbirth in United States is higher than the neonatal mortality rate. In 2003, the U.S. rate was 6.23 stillbirths per 1000 live births and fetal deaths after 20 weeks' gestation.¹¹² The rate of fetal loss at less than 27 weeks' gestation is 3.2 per 1000. It is estimated that approximately one half of the fetal deaths occur at less than 28 weeks' gestation and that only 20% of fetal deaths occur near term. The death rate is two to three times higher for black fetuses compared with white fetuses.¹¹³ An intermediate rate is observed for interracial couples, with a relative risk (RR) of 1.17 (95% CI, 1.10 to 1.26) found when the mother is white and the father is black.¹¹⁴

As expected, the fetal death rate is much higher for high-risk pregnancies than for low-risk pregnancies. Smulian and associates¹¹⁵ compared the fetal death rates for low-risk and high-risk groups. The fetal death rate for low-risk pregnancies was 1.6 per 1000 births. The fetal death rates per 1000 births for high-risk conditions (i.e., abortion, small for gestational age, gestational hypertensive disorders, chronic hypertension, and diabetes) were 61.4, 9.6, 3.5, 7.6, and 3.9, respectively.¹¹⁵

The rate of stillbirth is higher in resource-poor countries. A WHO study that included six developing countries found a stillbirth rate of

TABLE 33-1 MÜLLERIAN DUCT ANOMALIES AND THEIR ASSOCIATION WITH MISCARRIAGE

Müllerian Anomaly	Prevalence among Patients with Müllerian Anomalies	Risk of Spontaneous Loss at Less Than 20 Weeks
Septum	55%	65%
Unicornuate uterus	20%	51%
Uterus didelphys	5-7%	43%
Bicornuate uterus	10%	32%

12.5 per 1000 births at the gestational age of more than 28 weeks.¹¹⁶ Spontaneous preterm delivery and hypertensive disorders were the most common obstetric events leading to perinatal deaths (28.7% and 23.6%, respectively). Pregnancy loss also is associated with increased maternal morbidity, especially in low-income countries.¹¹⁷ Related problems include maternal infection, increased blood loss, and maternal death.

Advanced maternal age is an important factor contributing to fetal death. Medical disorders such as hypertension, diabetes mellitus, abruptio placentae, and multiple gestations are more commonly associated with advanced maternal age. Even after adjusting for these conditions, advanced maternal age continues to act as an independent risk factor for fetal demise. The risk of stillbirth is increased between 37 and 41 weeks' gestation. Reddy and colleagues¹¹⁸ studied a cohort of 5,458,735 singleton pregnancies without congenital anomalies and found that the relative risk of stillbirth was higher among women 40 years old or older compared with women between 35 and 39 years old (RR = 1.88 versus 1.32).¹¹⁸ A retrospective, cohort analysis¹¹⁹ of singleton births delivered between 1995 and 2000 used the U.S. linked birth and infant death data for women with ages ranging from 15 to 45 years. The relative risks for fetal death at 24 weeks or more and at 32 weeks or more among women between the ages of 35 and 39 years were 1.21 and 1.31, respectively, whereas the relative risks were 1.62 and 1.67, respectively, among women between the ages of 40 and 44 years.¹¹⁹ These findings have been confirmed in a number of other studies.^{120,121}

Hemoglobin concentration has been associated with a risk for stillbirth. In a Swedish population-based, matched case-control study, higher concentrations of hemoglobin in the first trimester were associated with an increased risk for stillbirth. Women with hemoglobin concentrations of 146 g/L or higher were at increased risk for stillbirth (OR = 1.8; 95% CI, 1.0 to 3.3).¹²²

Genetic Abnormalities Causing Second- and Third-Trimester Fetal Loss

Chromosomal abnormalities of the fetus are responsible for 6% to 12% of fetal death after 20 weeks' gestation.^{24,44,123} The proportion of chromosomal abnormalities is higher in fetuses with structural abnormalities. The most common type of abnormality is aneuploidy, and the most common aneuploidies are trisomies 21, 18, and 13. A genetic abnormality confined to the placenta in the presence of a normal fetal karyotype is associated with fetal death and severe growth retardation. This phenomenon is known as confined placental mosaicism (CPM). Increased maternal age is one of the etiologic factors for CPM; others include mitotic nondisjunction.⁴⁴

Infection Causing Second- and Third-Trimester Fetal Loss

Maternal infection may cause fetal death by several mechanisms. Systemic maternal infection may result in fetal death. It may take the form of maternal high-grade fever, respiratory distress, or other systemic reaction to the illness. In these cases, the fetus is not directly affected but presumably dies because of cardiovascular sequelae of the mother's systemic infection. Examples include fetal death associated with maternal influenza,^{77,124} chickenpox infections, and polio.¹²⁵ The placenta may be directly infected with the organism, resulting in placental insufficiency and causing fetal death, as occurs with malaria during pregnancy. The biologic basis for susceptibility to malaria in pregnancy was recently advanced by the discovery that erythrocytes infected with

Plasmodium falciparum accumulate in the placenta through adhesion to molecules such as chondroitin sulfate A.¹²⁶

The fetus may be directly infected through the membranes or placenta with the infectious organism, resulting in damaged fetal organs such as the lung, liver, brain, and heart. An example is infection with parvovirus. Maternal infections associated with fetal death include those caused by spirochetes, protozoa, viruses, and bacteria. Maternal-fetal infections are responsible for 10% to 25% of all fetal deaths. The earlier the gestational age at fetal death, the more likely infection is the etiologic agent. Copper and colleagues¹²⁷ found that 19% of fetal deaths were associated with infection at a gestational age less than 28 weeks, whereas only 2% were associated with infection in fetal death at term.

Maternal syphilis is an important cause of intrauterine fetal death, especially in countries with a high prevalence of syphilis. The prevalence of seropositivity in pregnancy is 0.2% to 4.5% in northern Europe and the United States. The rate of maternal syphilis has declined in the United States. From 1992 through 1998, 942 deaths, including 760 stillbirths, were reported among 14,627 cases of congenital syphilis, yielding a case-fatality ratio (i.e., stillborns and deaths/all cases) of 6.4%.¹²⁸ The seropositivity for African countries is between 3% and 18%.¹²⁹ Most deaths are observed in the second trimester. The organism can cross the placenta as early as 9 to 10 weeks' gestation.¹³⁰ Placental infection results in decreasing blood flow in the placenta, causing ischemic changes. Another spirochete responsible for fetal death is the tick-borne spirochete *Borrelia burgdorferi*, which is responsible for Lyme disease. The organism does cross the placenta, and there have been a few case reports of fetal death due to maternal infection.¹³¹

Other bacterial infections implicated in fetal death include those caused by *Ureaplasma urealyticum*, *Mycoplasma hominis*, group B streptococci, *Klebsiella*, *Escherichia coli*, and *Listeria monocytogenes*. These organisms may reach the fetus by ascending infections spreading from the lower genital tract and then into the decidua and chorion and occasionally into the amniotic fluid. Bacteria may also reach the fetus by hematogenous spread. Most fetal deaths due to bacterial infection occur between 24 and 27 weeks' gestation.¹³² Listeriosis in pregnancy, caused by a gram-positive rod, commonly occurs in the third trimester. In humans, this pathogen has the ability to cross the intestinal, placental, and blood-brain barriers, leading to maternal gastroenteritis, fetal infections, and meningoencephalitis, respectively.¹³³ Pregnant women may present with flulike illness, including fever, chills, and back pain. The diagnosis is usually based on a blood culture if other common causes of fever such as urinary tract infection and pharyngitis have been ruled out. *Listeria* infection during pregnancy may lead to fetal death, preterm labor, or in utero fetal infection. Affected newborns have multiple abscesses in skin and visceral organs, and they die soon after birth.

It is difficult to estimate the true burden of fetal demise caused by viral infections, mainly because of the difficulty in culturing the agent responsible for fetal death. The most common viral infection associated with nonimmune hydrops causing fetal death is parvovirus B19, which is responsible for 1% of fetal deaths in the United States.¹²⁷ Maternal infection before 20 weeks' gestation may cause hydrops by infecting fetal erythropoietic tissue or by directly affecting the fetal myocardium.¹³⁴ Infection with parvovirus elicits an immune response in the mother, resulting in subsequent protection against maternal and fetal infections. Close-contact exposure of nonimmune women results in maternal infection in about 25% of cases. Of these, about 30% will pass the infection to the fetus. Fetal hydrops or other sequelae occur in only 10% of those affected, and stillbirth occurs in about 1% of cases.¹³⁵

Viruses responsible for fetal death include enterovirus, echovirus, and coxsackievirus, all of which cross the placenta. This group of enteroviruses is associated with spontaneous abortions and stillbirths.^{136,137} In a study from Sweden, of 21 women who had stillbirths, 52% were positive for coxsackievirus B, whereas only 22% of controls were positive.¹³⁶

Cytomegalovirus (CMV), a herpes virus, infects 8000 infants each year in the United States.¹³⁸ About 10% of affected infants with congenital CMV infection have signs and symptoms at birth, whereas 90% remain asymptomatic but develop sequelae such as sensorineural hearing loss later in life. Maternal CMV infection can be primary or secondary. Lack of maternal immunity in cases of primary CMV infection results in more severe consequences. Symptomatic congenital CMV infection results from the mother becoming infected with CMV during or just before pregnancy. The risk for fetus is greater if the maternal infection occurs earlier in gestation.¹³⁹ The rate of congenital CMV infection diagnosis depends on maternal serology (i.e., anti-CMV IgM and low avidity anti-CMV IgG). Viral culture of amniotic fluid or polymerase chain reaction analysis after 20 weeks' gestation, ultrasound diagnosis of fetal abnormalities, and placental enlargement can identify disease and predict long-term sequelae.

Mother-child transmission of congenital CMV infection may be impeded by maternal administration of hyperimmune globulin (HIG) in women with primary CMV infection. Nigro and colleagues¹³⁹ have shown that monthly administration of HIG (100 U/kg) until delivery in women with primary infection starting at a gestational age less than 21 weeks significantly reduced the rate of congenital CMV infection compared with women who did not receive HIG (16% versus 56%; $P < .001$). The administration of HIG significantly ($P < .001$) increased CMV-specific IgG concentrations and avidity, decreased NK cells and HLA-DR⁺ cells, and had no adverse effects.¹³⁹

Placental Abruption Causing Second- and Third-Trimester Fetal Loss

Abruptio placentae is defined as decidual hemorrhage causing premature separation of normally implanted placenta. It complicates 1% of pregnancies. The incidence of abruption is highest between 24 and 28 weeks' gestation and decreases as the gestation advances. Risk factors include maternal substance abuse, hypertension, multiple pregnancy, hydramnios, infections, thrombophilia, and a history of abruption in a prior pregnancy. Inherited thrombophilia associated with placental abruption includes factor V Leiden (FVL) mutation, prothrombin gene mutation, and protein S deficiency.¹⁴⁰

Placental abruption may be associated with fetal death in cases of severe abruption (>50% separation of the placenta). The diagnosis of abruption is more often made on clinical grounds. Severe cases may be associated with disseminated intravascular coagulopathy (DIC). Only 10% of affected patients show significant coagulopathy. In the event of massive separation, coagulopathy is seen in 20% to 30% of cases. The risk of developing DIC in abruptio placentae depends on the degree of abruption, the time interval between placental abruption and delivery, and the prognosis of the fetus. In less severe abruption, it is assumed that silent placental infarcts cause consumption of coagulation factors such as factor VIII and the release of degradation products. Alternatively, in massive abruption, decidual tissue factor-activated coagulation factors enter into systemic circulation through the uterine veins and cause DIC. Abruptio placentae with fetal compromise has been associated with cardiovascular events in later life in a population-based study.¹⁴¹ The risk of recurrent stillbirth due to abruption is 9% to 15%.

Fetomaternal Hemorrhage Causing Second- and Third-Trimester Fetal Loss

Abruption can also cause fetomaternal hemorrhage (FMH). Other causes include external cephalic version and maternal trauma, which can lead to fetal death. FMH is responsible for 5% of stillbirths. A small amount of fetomaternal transfusion is of no major consequence, but large bleeds (>30 mL) are associated with clinical consequences that include unexpected anemia at birth.¹⁴²

The American College of Obstetricians and Gynecologists (ACOG) guidelines on stillbirths and neonatal deaths recommend immediate assessment for FMH. The clinical picture consists of decreased fetal movements, a sinusoidal pattern on cardiotocography, and ultrasound evidence of hydrops fetalis. The diagnostic tools include Kleihauer-Betke test, flow cytometry, and Doppler ultrasound of the middle cerebral artery to diagnose fetal anemia.^{143,144} The fetus can respond well to an acute blood loss of 40% of blood volume, but larger hemorrhages result in fetal death. Smaller bleeds over a prolonged time allow for cardiovascular adaptation. There is a role for intrauterine blood transfusion in these cases.¹⁴⁵ Anemia at birth is treated with postnatal transfusion. In a series of 48 fetuses described by Rubod and associates,¹⁴⁶ long-term follow-up of these newborns failed to reveal neurologic sequelae (0%; 95% CI, 0.0% to 11.6%).

Medical Conditions Causing Second- and Third-Trimester Fetal Loss

Overall, 10% of fetal deaths are attributed to maternal medical disorders such as preeclampsia, diabetes mellitus, thyroid disorders, systemic lupus erythematosus, intrahepatic cholestasis of pregnancy, and chronic renal diseases. The major contributors are preeclampsia (4% to 9%)^{147,148} and diabetes mellitus (2% to 5%). The risk of fetal demise due to hypertensive disorders is greater among African-American women than among white women.¹⁴⁹ Fetal death rates are also higher for women with severe preeclampsia, those with HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*), and women with chronic hypertension with superimposed preeclampsia.¹⁵⁰⁻¹⁵² The fetal mortality rate is also high for women with severe preeclampsia before 24 weeks' gestation.¹⁵³ The main reasons for fetal mortality in hypertensive disorders include prematurity, intrauterine growth restriction, and abruptio placentae. There has been a decline in fetal deaths from hypertensive disorders because of better medical and obstetric care. This is not true for the developing world, where maternal and fetal mortality rates are higher and hypertension is the second leading cause of maternal mortality.¹⁵⁴ Most fetal deaths linked to maternal hypertensive disorders occur before admission to the hospital.¹⁵⁵ In women having stillbirths due to hypertensive disorders, the risk of recurrence in the next pregnancy is about 14%. The risk of recurrent stillbirth due to hypertension is inversely proportional to the gestational age at the initial fetal death.

Type 1 and type 2 diabetes mellitus are associated with an increased risk of fetal demise. Overall fetal death rates for nondiabetic and diabetic patients were 4.0 and 5.9 per 1000 births, respectively, with an adjusted relative risk of 2.0 (95% CI, 1.8 to 2.2) in a report from the National Center for Health Statistics.¹⁵⁶ This study did not differentiate between gestational and pregestational diabetes. The reasons for fetal death in mothers with diabetes are postulated to be hyperglycemia, ketoacidosis, congenital anomalies, infections, and maternal obesity.¹⁵⁷ Fetal acidosis is the most likely reason for fetal death in the third trimester.¹⁵⁸ A comprehensive, multidisciplinary approach is the key to management of diabetic pregnancies. There is a role for antenatal fetal surveillance of

diabetic women. Doppler velocimetry of the maternal and fetal vasculature has been more useful in the surveillance of the fetuses of diabetic mothers than the biophysical profile.¹⁵⁹ The risk of cesarean delivery is also increased among diabetic mothers. Subclinical diabetes and thyroid disorders do not pose an increased risk for recurrent fetal loss.

There has been an increase in the prevalence of obesity in the United States; one in three women is obese.¹⁶⁰ Because obesity has been associated with an increased incidence of stillbirth, this epidemic may be driving higher loss rates even while other sources are being reduced. A meta-analysis of the literature found that the risk of stillbirth was almost twice as high among obese pregnant women as among lean pregnant women.¹⁶¹ It is not clear whether the relationship between obesity and stillbirth is direct or indirect. Obesity does lead to diabetes mellitus, hypertension, or undiagnosed impaired glucose tolerance, all of which may contribute to stillbirth. Other plausible mechanisms include hyperlipidemia, which leads to reduced prostacyclin secretion and enhanced peroxidase production, which results in platelet aggregation and vasoconstriction.¹⁶²

Multifetal Pregnancy Causing Fetal Loss

The risk of fetal death is increased in the multiple gestations; perinatal mortality is 8-fold to 10-fold higher.¹⁶³ The increased perinatal mortality rate is attributed to prematurity, preeclampsia, and abruption and to problems unique to multiple pregnancies, such as cord entanglement in monoamniotic twins and twin-twin transfusion syndrome (TTTS) in monochorionic and diamniotic twins. TTTS is seen in 10% to 15% of monochorionic twins because of a chronic imbalance between inter-fetal blood flow across vascular anastomoses. TTTS occurs between 15 and 26 weeks' gestation, and it can be diagnosed with ultrasound. The ultrasound features include hydramnios in the recipient twin (deepest vertical pocket of ≥ 8 cm before 20 weeks and ≥ 10 cm between 20 and 26 weeks) and oligohydramnios in the donor twin (deepest vertical pocket ≤ 2 cm). A combination of different markers can help to identify an at-risk monochorionic pregnancy with TTTS. They include increased nuchal translucency (>95 th percentile) on ultrasound in at least one fetus at 11 to 14 weeks' gestation, absence of arterio-arterial anastomosis on color Doppler, and velamentous cord insertion. The latter condition has been found in 60% of affected monochorionic twins.¹⁶⁴ The second twin is also at increased risk because of anoxia and premature placental separation during the second stage of labor.

Antiphospholipid Antibody Syndrome Causing Fetal Loss

Antiphospholipid syndrome is defined clinically by the presence of arterial or venous thrombosis, fetal death in the second or third tri-

mester, or thrombocytopenia, coupled with serologic findings such as anticardiolipin antibodies or lupus anticoagulant. The anticardiolipin antibodies are immunoglobulins directed against proteins bound to negatively charged (anionic) phospholipids. Such antibodies are thought to promote uteroplacental thrombosis and fetal death through multiple pathogenic mechanisms, such as interference with the prostacyclin-thromboxane balance and by affecting the adhesion molecules between trophoblast. Antiphospholipid antibodies can interfere with activation of protein C by disruption of the thrombomodulin-thrombin complex and by inhibition of the assembly of the protein C complex. They also can inhibit the activity of protein C directly or through its cofactor protein S and through antibodies directed against the substrates of activated protein C, including factors Va and VIIIa, thereby protecting them from inactivation.¹⁶⁵

Whether antiphospholipid antibodies can also cause embryonic loss is controversial. The plausible mechanism for early pregnancy losses includes inhibition of endovascular trophoblast invasion, induction of trophoblast apoptosis, and inhibition of trophoblast hormone production. These theories are strengthened by the fact that heparin attenuates trophoblast apoptosis and facilitates trophoblast invasion. Antiphospholipid antibodies are associated with obstetric complications, including fetal loss, abruption, severe preeclampsia, and intra-uterine growth restriction.

Inherited Thrombophilia Causing Fetal Loss

Inherited thrombophilia is associated with an increased risk for fetal loss and other placenta-mediated pregnancy complications (Tables 33-2 and 33-3) (see Chapter 40). Most studies showing an association between fetal loss and thrombophilia have done so for losses at more than 10 weeks' gestation and for losses at more than 20 weeks in particular.^{166,167} In a meta-analysis, Rey and colleagues¹⁶⁸ found FVL mutation, prothrombin gene mutation, and protein S deficiency to be significantly associated with nonrecurrent late fetal loss. The association is most robust for the FVL mutation, which arises from a point mutation in the factor V gene, causing the substitution of glutamine for arginine at position 506, the site of cleavage for activated protein C, resulting in activated protein C resistance. The European Prospective Cohort on Thrombophilia (EPCOT) study, a multicenter evaluation of patients with inherited thrombophilia, revealed a twofold increased risk for stillbirth for women with combined thrombophilic defects and antithrombin deficiency.¹⁶⁹ Independent of the FVL mutation, activated protein C resistance is associated with second-trimester fetal loss.¹⁷⁰ Combined thrombophilic defects exert a greater influence on fetal loss than only thrombophilia. Women with any of the following factors should be screened for thrombophilia:

TABLE 33-2 DETECTION OF MATERNAL INHERITED THROMBOPHILIA

Thrombophilia	Detection Methods	Reference
Factor V Leiden	Polymerase chain reaction	204
Prothrombin G20201A	Polymerase chain reaction	205
Hyperhomocysteinemia	Fasting assay, enzyme-linked immunosorbent assay	206
Antithrombin deficiency	Functional assay with a cutoff of $<60\%$	205
Protein S deficiency	Measure total free antigen with a cutoff of $<45\%$ in pregnant patients	207, 208
Protein C deficiency	Functional assay with a cutoff of $<50\%$	209
Protein Z antigen	Enzyme-linked immunosorbent assay	208

TABLE 33-3 ASSOCIATIONS OF THROMBOPHILIA TYPES WITH NONRECURRENT FETAL LOSS

Thrombophilia	Intrauterine Fetal Death OR (95% CI)
Factor V Leiden mutation	3.26 (1.82-5.83)
Prothrombin 20210A mutation	2.30 (1.09-4.87)
Protein S deficiency	7.39 (1.28-42.83)
Antithrombin deficiency	1.54 (0.97-2.45)
Protein C deficiency	1.41 (0.96-2.07)
Activated protein C resistance	2.07 (0.40-10.67)

Data from Rey E, Kahn SR, David M, et al: Thrombophilic disorders and fetal loss: A meta-analysis. *Lancet* 361:901-908, 2003.

- Unexplained fetal loss in a current pregnancy
- History of unexplained fetal loss in second or third trimester
- History of recurrent severe preeclampsia or HELLP at less than 36 weeks' gestation
- History of unexplained abruption
- Personal history of thrombosis
- Family history of thrombosis

The risk for stillbirth in the presence of thrombophilia is 3.6 times higher than without the disorder.¹⁷¹ When attributing fetal death to thrombophilia, it is important to consider objective evidence of placental insufficiency, such as placental infarction, or abnormal Doppler velocimetry. Table 33-3 shows the association of different thrombophilias with fetal death. Fetal genetic risk factors for thrombosis (e.g., FVL mutation, prothrombin gene mutation) have also been found to be associated with fetal death. An increased risk for fetal death in the second trimester in fetal carriers of the FVL mutation has been found in several studies.^{172,173}

Thrombophilia may confer an increased likelihood of other pregnancy complications, but the association is weak. There is a lack of evidence for an association between thrombophilia and placenta-mediated thrombophilic complications.¹⁷⁴ Rodger and associates¹⁷⁴ have argued that analysis of case-control, and meta-analyses do not have sufficient power to detect an association between thrombophilia and adverse pregnancy outcomes.¹⁷⁴

Recurrent Second- and Third-Trimester Fetal Loss

Many of the causes previously discussed are more common causes of isolated stillbirth. However, women who had a stillbirth in a previous pregnancy have a 6-fold to 10-fold increased risk for stillbirth in a subsequent pregnancy. In a population-based study to identify the risk of recurrence of fetal death in a low-risk group of women with a history of fetal death in a prior pregnancy at a gestational age of 20 to 44 weeks, the adjusted risk of stillbirth was almost six times higher among women with a prior stillbirth (hazard ratio [HR] = 5.8; 95% CI, 3.7 to 9.0).¹⁷⁵ These investigators found that recurrence risk increased with earlier gestational ages (20 to 28 weeks) in the prior loss. In an analysis across racial groups in the United States, the same group of investigators found that white women had a lower absolute risk for stillbirth recurrence than black women (19.1 versus 35.9 of 1000; $P < .05$).¹⁷⁶

The risk of recurrence is different for different etiologic factors. For example, fetal loss due to cord accidents is less likely to recur compared

with loss due to placental insufficiency or thrombophilic disorders. Coppens and colleagues¹⁷⁷ did not find any significant difference in subsequent pregnancy outcomes for women with or without FVL and prothrombin gene mutations and first pregnancy loss. The live birth rate for the second pregnancy after early loss (<12 weeks' gestation) was 77% (95% CI, 62 to 87) for carriers and 76% (95% CI, 57 to 89) for noncarriers (RR = 1.0; 95% CI, 0.8 to 1.3). In contrast, they found that after a late first loss (>12 weeks), the live birth rates were 68% (95% CI, 46 to 85) and 80% (95% CI, 49 to 94) for carriers and noncarriers, respectively (RR = 0.9; 95% CI, 0.5 to 1.3).¹⁷⁷

Diagnostic Considerations for Second- and Third-Trimester Fetal Loss

Chromosomal abnormalities are responsible for 50% of first-trimester losses, 15% of second-trimester losses, and 5% of third-trimester losses.¹¹⁰ Fetal karyotyping should be performed if either parent is a carrier for a balanced translocation or there is a history of recurrent pregnancy loss or stillbirths in first-degree relatives. ACOG recommends cytogenetic studies for the fetus in the event of dysmorphic features, growth abnormalities, congenital anomalies, and hydrops and when a parent carries a balanced chromosomal rearrangement or has a mosaic karyotype.

The importance of a fetal autopsy in reaching a conclusive diagnosis cannot be underestimated. A fetal autopsy can determine the structural and morphologic abnormalities, and it may help to exclude infection, anemia, and metabolic disorders as causes of fetal death. An autopsy includes invasive and noninvasive components. The noninvasive components include review of premortem medical records, external examination of the fetus and gross and histological examination of the placenta and membranes, cytogenetic and metabolic investigations of cord blood, and radiographs. The invasive diagnosis includes examination and dissection of internal organs. Postmortem fetal MRI can assist in diagnosing the underlying cause without the need for fetal dissection.¹⁷⁸

Histologic examination of the placenta, although often neglected, is an important tool in reaching a diagnosis of the cause of fetal death. Placental pathology can be helpful in differentiating acute from chronic perinatal stress, in diagnosing specific causes in abnormal pregnancies, and in assessing newborn risks. Maternal infections responsible for fetal death can be evaluated by examination of the placenta. Similarly, thromboembolic events, such as caused by a thrombophilia, can be determined by the placental examination. Placental thrombosis and infarction have been identified in the placenta of thrombophilic women with fetal losses.^{173,179} Assessment of maternal TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex) serologies has been traditionally advised, but its utility in the developed world is uncertain. It may be of more significance in areas where these maternal infections are endemic. ACOG guidelines on stillbirth and neonatal deaths recommend screening for parvovirus B-19 IgM and IgG antibodies and syphilis.

Women of reproductive age may use alcohol or other substances such as heroin, cocaine, and amphetamine. The National Institute on Drug Abuse (NIDA), in one of the few large surveys of maternal substance abuse, found that 5.5% of mothers reported taking an illicit substance during gestation.¹⁸⁰ Many of these agents are known to cross human placenta and produce a number of undesirable effects. Drug transfer across the placenta occurs by means of passive diffusion, active transport, and pinocytosis. Movement of a drug across the placenta depends on the size of molecule, solubility, and protein binding. Obstetric complications include placental insufficiency, miscarriage,

intrauterine death, and increased incidence of infectious and sexually transmitted diseases in the drug-abusing mother.¹⁸¹ The increased risk of obstetric complications may be attributed to a lack of prenatal care for this group of women. Only 25% of women with drug abuse seek antenatal care before labor; for those who do, it occurs mostly in the third trimester.¹⁸² Apart from increased susceptibility to sexually transmitted diseases, pregnant drug abusers also suffer from an increased number of medical problems such as anemia, bacteremia, hypertension, nutritional deficiencies, and tuberculosis. The association of maternal alcohol abuse with fetal alcohol syndrome (e.g., dysmorphic features, impaired intellectual development) is well known. Maternal drug use during pregnancy can be monitored with urine, sweat, oral fluid, or hair testing. Toxicologic screening for substance abuse is done in most medical institutions. Urinary analysis is commonly employed, but measurement of stable metabolites can also be carried out using meconium, hair, and umbilical cord samples. Table 33-4 details the suggested evaluation of second- and third-trimester fetal loss.

Management of Fetal and Embryonic Loss

Delivery of the fetus in a woman with embryonic and fetal demise calls for emotional and medical support by a caring physician. The patient can be counseled by the obstetrician, neonatologist, nurse practitioner, or genetic counselor. It is necessary to talk to parents about their wishes, their fears concerning future pregnancies, and their views about postmortem evaluations. The importance of an autopsy should be emphasized to identify the cause of stillbirth and help determine management of future pregnancies. Mothers should be followed in the postpartum period for depression. For losses after 27 weeks, in the absence of any identifiable cause for stillbirth, parents should be reassured that the risk of recurrence is no greater than 3%.¹⁸³ The risk of recurrence is greater for women with losses at less than 27 weeks' gestation.

Most women find it disturbing to carry a nonviable fetus, but others may like to have some time to share the grief with family before pro-

TABLE 33-5 EVALUATION FOR RECURRENT FIRST-TRIMESTER LOSS

Karyotype of miscarried tissue (in all cases of fetal loss)
Parental karyotype
Luteal-phase assessment
Glucose tolerance testing
Thyroid function testing
Uterine cavity assessment by sonohysterography (preferred), hysterosalpingogram, or hysteroscopy
Antiphospholipid antibody screen
Inherited thrombophilias, if losses between 10 and 13 weeks

ceeding to termination. In both cases, the woman's wishes need to be addressed. There is no urgency to evacuate the uterus if surveillance is offered for infection and coagulopathy. A low serum level of fibrinogen (<100 mg/dL) and a low platelet count are considered evidence of coagulopathy. Earlier studies quoted rates of coagulation abnormalities as high as 25% to 30%, whereas later reports state a much lower rate of coagulopathy associated with fetal demise.^{184,185} This change is attributed to early diagnosis by ultrasound. Tables 33-4 and 33-5 detail the suggested evaluation of recurrent fetal and embryonic losses, respectively.

Management of Embryonic and First-Trimester Fetal Loss

Medical and surgical management can be used for first-trimester loss. Surgical management includes vacuum aspiration, dilatation, and aspiration or curettage. Medical management includes the use of prostaglandins, mifepristone, and methotrexate. These drugs can be used alone or in combination. A Cochrane review on medical management of first-trimester loss found oral misoprostol less effective than vaginal misoprostol (RR = 3.00; 95% CI, 1.44 to 6.24).¹⁸⁶ The oral route was also associated with adverse events such as nausea, vomiting, diarrhea, and shivering. Mifepristone alone is less effective than when combined with prostaglandins (RR = 3.76; 95% CI, 2.30 to 6.15).¹⁸⁶ Misoprostol used in combination with mifepristone reduces the induction-delivery interval compared with that for either agent alone.^{187,188} This also is important for women with late fetal demise (>24 weeks' gestation). The optimal doses of misoprostol and mifepristone are not known. A reduced dose (a dose of 200 mg given once) of mifepristone, followed by gemeprost to soften and dilate the cervix and stimulate the uterus to contract, has been found to be cost-effective and efficacious.

Management of Second- and Third-Trimester Fetal Loss

The choice between medical and surgical methods depends on the gestational age of the fetus. Treatment before 14 weeks' gestation has traditionally been surgical, but medical treatments may be equally effective. Surgical treatment in the early part of the second trimester is safe in experienced hands, but the procedure becomes more difficult in the late second and early third trimesters. As the gestation advances, induction of labor becomes a more favorable choice. A Cochrane review found vaginal misoprostol more effective than placebo in the termination of nonviable pregnancies before 24 weeks' gestation.¹⁸⁹ Misoprostol is an effective myometrial stimulant and acts by means of EP-2 and EP-3 prostanoid receptors.¹⁹⁰ It acts through vaginal and oral

routes. Vaginally absorbed serum levels are more prolonged and are associated with fewer side effects. Oral misoprostol (400 µg) was found to be less effective than vaginal misoprostol, but this difference was not seen with an 800-µg dose.¹⁸⁹ Sublingual misoprostol has been found equivalent to the vaginal route in inducing complete miscarriage (RR = 1.00; 95% CI, 0.85 to 1.18). Other doses used include 400, 600, and 800 µg. The dose also depends on gestational age. Wet preparations were as effective as the dry preparations.¹⁸⁹

Other drugs used for medical termination of pregnancy include prostaglandin F_{2α}, prostaglandin E₂, ergometrine, and oxytocin. Side effects of misoprostol include nausea, vomiting, diarrhea, shivering, and elevated temperature. These effects are usually dose related and transitory. The toxic dose for humans is not known, and there is no known antidote for the drug. Misoprostol has been associated with maternal death in a case report.¹⁹¹ It is generally recommended that all prostaglandins for medical induction of labor be avoided in cases of prior cesarean delivery if the uterine size is greater than 24 to 26 weeks' gestation.

Management of Subsequent Pregnancy in Patients with a History of Embryonic or Fetal Loss

Increased antenatal surveillance during future pregnancies is strongly recommended for women with a history of embryonic or fetal loss. Counseling for control or cessation of contributing factors such as weight, smoking, alcohol, and medical conditions (e.g., diabetes mellitus, thyroid disorders, chronic hypertension) plays an important role for this group of women. The risk of recurrent late fetal loss is reduced by 14% with the use of aspirin alone (RR = 0.86; 95% CI, 0.76 to 0.98).¹⁹² In women with antiphospholipid antibodies, thromboprophylaxis with aspirin and heparin increases the live birth rate. In a randomized, double-blind, placebo-controlled study involving 82 patients with recurrent pregnancy loss and without such antibodies by Tulppala and colleagues,¹⁹³ use of low dose aspirin alone was not found to have any effect on the live birth rate (RR = 1.00; 95% CI, 0.78 to 1.29).

Similarly, women with known inherited thrombophilia and recurrent fetal loss may benefit from heparin prophylaxis. In an open-label, quasi-random study of 160 patients with prior losses after 10 weeks associated with known thrombophilic defects, Gris and associates¹⁹⁴ compared low-molecular-weight heparin (LMWH) with aspirin. They found an increased live birth rate with the use of LMWH (RR = 10.00; 95% CI, 1.56 to 64.20). Paidas and coworkers¹⁹⁵ found an 80% reduction in fetal loss with the use of heparin in women with FVL or prothrombin gene mutations and prior fetal loss.¹⁹⁵ Brenner and colleagues¹⁹⁶ showed an increased live birth rate (76% versus 28%) with 80 mg of LMWH compared with 40 mg in a cohort of women with known thrombophilia and fetal loss.¹⁹⁶ Although there is a lack of randomized studies, observational studies and historical cohort analyses have shown an increased live birth rate with the use of heparin in women with inherited thrombophilias and adverse pregnancy outcomes.^{196,197}

Several trials are being conducted to evaluate the role of heparin in improving maternal and fetal outcomes. These include the Thrombophilia in Pregnancy Prophylaxis Study (TIPPS, ISRCTN87441504), Fragmin in Pregnant Women with a History of Uteroplacental Insufficiency and Thrombophilia (FRUIT, ISRCTN87325378) study, Anticoagulants for Living Fetuses (ALIFE, ISRCTN58496168) study, and Scottish Pregnancy Intervention (SPIN, ISRCTN06774126) study. A

consensus panel statement was published to aid clinicians in managing anticoagulant therapy during pregnancy.¹⁹⁸ With respect to preventing adverse pregnancy outcome, the statement authors recognized the limited data that are available. For recurrent and unexplained fetal losses, many authorities offer prophylactic heparin anticoagulation in a subsequent pregnancy if patients are found to have an inherited thrombophilia. In a large, retrospective cohort study, 84 consecutive, multiparous patients with a history of severe preeclampsia and fetal growth restriction were assigned to receive no treatment, low-dose aspirin alone, or low-dose aspirin plus LMWH. The combination of prophylactic heparin and low-dose aspirin protected against an adverse outcome in the index pregnancy.¹⁹⁹ Randomized clinical trials are required to determine the optimal strategy for preventing recurrent adverse outcomes.

Several forms of immunotherapy have been used in the treatment of women with recurrent embryonic or fetal losses because immune aberration was considered to be an etiologic agent. These methods include paternal cell immunization, third-party donor cell immunization, trophoblast membrane infusion, and IVIG. A Cochrane review of the use of immunotherapy for recurrent pregnancy loss did not find any improvement in the live birth rate with the use of immunotherapy compared with placebo.²⁰⁰

Progesterone has been used widely for a long time to prevent recurrent losses. A large number of randomized trials have been conducted to evaluate the efficacy of progesterone in the previously described circumstances. A Cochrane review on the use of progesterone for recurrent miscarriage found a statistically significant improvement in the live birth rate among women with a history of recurrent pregnancy loss (OR = 0.39; 95% CI, 0.17 to 0.91).²⁰¹ Table 33-6 summarizes the other pharmacologic options available to women with prior fetal loss.

Other measures to improve fetal survival in subsequent pregnancies include increased fetal surveillance by means of nonstress testing, serial ultrasound, Doppler velocimetry for growth-restricted fetuses, and amniotic fluid indices. The decision about when to start antenatal testing depends on maternal age, the maternal and fetal risk factors in ongoing pregnancy, and gestational age at which prior fetal death occurred. Antepartum testing in women with advanced maternal age and prior stillbirth has decreased the number of stillbirths in subsequent pregnancies.²⁰² In a study of 300 women with a history of stillbirth in previous pregnancies, Weeks and coworkers²⁰³ started antepartum surveillance at 32 weeks' gestation for adverse pregnancy

TABLE 33-6 EFFICACY OF PHARMACOLOGIC THERAPIES FOR RECURRENT PREGNANCY LOSS AND FETAL DEMISE

Pharmacotherapy	Statistical Significance (95% CI)	Reference
Progesterone	OR = 0.39 (0.17-0.91)	201
Aspirin	RR = 1.00 (0.78-1.29)	210
Intravenous immune globulin	OR = 0.98 (0.45-2.13)	94
Paternal leukocyte immunization	OR = 1.05 (0.75-1.47)	94

outcomes and abnormal antepartum test results. They had only one stillbirth in the cohort group. The study authors concluded that antepartum surveillance of healthy pregnant women with a history of stillbirth should begin by 32 weeks' gestation.²⁰³ Surveillance may be started earlier for women with fetal growth restriction or those who have chronic medical diseases such as hypertension. It should include a twice-weekly nonstress test, amniotic fluid index, and biophysical profile. Similarly, ultrasound scans to evaluate growth should be carried out at intervals of 2 weeks. Fetal kick counts should start at 28 weeks' gestation in this group of women. ACOG guidelines also recommend that antepartum surveillance should start at 32 weeks' gestation. There may be a role for elective induction at the completion of 39 weeks' gestation or at 37 to 38 weeks after fetal lung maturity is documented by amniocentesis.

Conclusion

Embryonic and fetal demise are catastrophic events in a couple's lives. Although there may be no optimal workup for determining the cause of fetal demise, investigations such as fetal autopsy, karyotyping the parents and fetus, placental evaluation, and maternal serology for syphilis and antibody screening may provide answers in most cases. Screening for antiphospholipid antibodies is recommended for embryonic and fetal losses. For fetal losses, screening for inherited thrombophilia and antiphospholipid antibodies is recommended in the event that results of the first-tier tests are inconclusive.

Chapter 34

Intrauterine Growth Restriction

Robert Resnik, MD, and Robert K. Creasy, MD

Human pregnancy, similar to pregnancy in other polytocous animal species, can be affected by conditions that restrict the normal growth of the fetus. The growth-restricted fetus is at higher risk for perinatal morbidity and mortality, the risk rising with the severity of the restriction. This chapter reviews the various causes of fetal growth restriction and considers the methods of antepartum recognition and diagnosis along with clinical management. The term intrauterine growth restriction (IUGR), which we first introduced in the third edition of this text, is preferred over intrauterine growth retardation, which frequently connotes mental retardation to the patient.

Definitions

At the beginning of the 20th century all small newborns were thought to be premature, but by the middle of the century the concept of the undernourished neonate arose, and newborns weighing less than 2500 g were then classified by the World Health Organization as low-birth-weight infants. In the 1960s, Lubchenco, Battaglia and colleagues, in a series of classic papers, published detailed graphs of birth weight as a function of gestational age and associated adverse outcomes.^{1,2} It was then suggested to classify low-birth-weight neonates into three groups^{2,3}:

1. *Preterm neonates*—newborns delivered before 37 completed weeks of gestation who are of appropriate size for gestational age (AGA)
2. *Preterm and growth-restricted neonates*—newborns delivered before 37 completed weeks of gestation who are small for gestational age (SGA)
3. *Term growth-restricted neonates*—newborns delivered after 37 completed weeks of gestation who are SGA. (Not all SGA term neonates are growth restricted; some cases result from the normal distribution of neonatal weight among a normal base population.)

The classification of newborns by birth weight percentile is of prognostic significance in that those of lower percentiles are at increased risk for immediate perinatal morbidity and mortality, as well as subsequent adult disease.

There is continuing debate as to whether the 10th, 5th, or 3rd birth weight percentile should be used as a cutoff for designation of SGA. The lower the percentile, the higher the risk of poor outcome, but also the greater the chance that a neonate with IUGR and poor outcome will not be detected. The *population*-based growth curves that tradi-

tionally have been used in the United States define SGA as a birth weight below the 10th percentile for gestational age. However, it has been shown⁴ that mortality for infants with birth weights between the 10th and 15th percentile are still increased, with an odds ratio approaching 2. Conversely, many newborns whose weights are below the 10th percentile are perfectly normal and simply constitutionally small. An alternative approach, which has sound physiologic and epidemiologic rationale, is that of using *customized* rather than population-based fetal growth curves.⁵ This concept uses optimal birth weight as the end point of a growth curve; it is based on the ability of a fetus to achieve its growth potential, determined prospectively and independently of maternal pathology. This approach uses the known variables affecting fetal weight, such as maternal height, weight, ethnicity, and parity at the beginning of pregnancy, to calculate fetal weight trajectories and optimal fetal weight at delivery. A recent large Spanish study⁶ showed that customized birth weight percentiles more accurately reflect the potential for adverse outcome. Indeed, newborns considered to be of low birth weight by the general standards, but not by the customized percentiles, did very well. These findings were confirmed by studies from New Zealand and France.⁷⁻⁹ Customized growth charts can be downloaded at Gestation Network (<http://www.gestation.net> [accessed February 5, 2008]).

The reliance on only gestational age and birth weight also neglects the issue of body size and length and the clinical observations that there are two main clinical types of IUGR newborns: (1) the infant who is of normal length for gestational age but whose birth weight is below normal (asymmetrically small), and (2) the neonate whose length and weight are both below normal (symmetrically small). Many SGA newborns are merely constitutionally smaller than others and are not at increased risk for either early or remote morbidity and mortality.

One method to evaluate this issue is the ponderal index,^{10,11} which is calculated from the birth weight (in grams) and the crown-heel length (in centimeters):

$$\text{Ponderal index} = (\text{birth weight})/(\text{crown-heel length})^3 \times 100$$

Neonates with a ponderal index of less than the 10th percentile for gestational age are defined as growth restricted. In term infants, this index is not significantly affected by differences in race or sex. The disadvantage of this index is the potential error introduced by cubing the crown-heel length. It is not clear whether asymmetric IUGR and symmetric IUGR are two distinct entities or are merely reflections of the severity of the growth restriction process (excluding chromosomal aberrations and infectious disease).

There is currently no acceptable means, except perhaps by the ponderal index, to classify a newborn whose weight is more than 2500 g as having IUGR. The newborn who weighs 2800 g at birth may be growth restricted if the mother has had three previous infants weighing more than 3700 g, but the classification systems would place such an infant in the normal growth category.¹²

Rate of Fetal Growth

Different standards for fetal growth throughout gestation have been reported. These standards set the normal range, on the basis of statistical considerations, between 2 standard deviations of the mean (2.5th to 97.5th percentile) or between the 10th and 90th percentiles for fixed gestational ages. The standards most widely used in the United States in the 1960s and 1970s were those developed in Denver, Colorado.^{1,2} The Denver standards, however, do not reflect the increase in median birth weight that has occurred over the last 4 decades or the birth weight standards for babies born at sea level. More contemporary standards are available from large geographic regions, such as the state of California, based on data from more than 2 million singleton births between 1970 and 1976.¹³ Brenner and colleagues¹⁴ used data on black and white infants from Cleveland and aborted fetuses from North Carolina. Ott¹⁵ studied newborns from St. Louis. Arbuckle and associates¹⁶ based their study on more than 1 million singleton births and more than 10,000 twin gestations in Canada between 1986 and 1988, and Alexander and colleagues¹⁷ used information from 3.8 million births in the United States in 1991. A comparison of their 1991 U.S. national data with that of previous reports (Fig. 34-1) reveals that most of the latter underestimated fetal growth beginning at about 32 weeks. For example, the use of the Colorado¹ or California¹³ databases would have resulted in only 2.8% and 7.1% of births, respectively, being classified as below the 10th percentile compared with the 1991 data. The gender-specific 10th percentile values from 20 to 44 weeks are listed in Table 34-1.

Data obtained from study of induced abortions and spontaneous deliveries indicate that the rate of fetal growth increases from 5 g/day

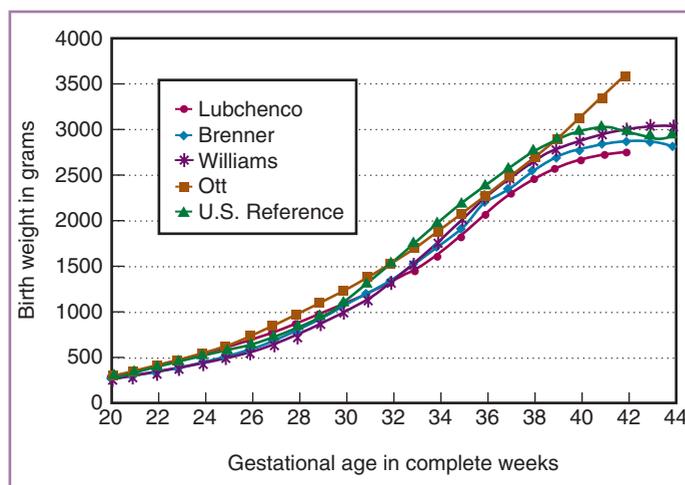

FIGURE 34-1 Fetal weight as a function of gestational age by selected references. Reprinted with permission from the American College of Obstetricians and Gynecologists.)

at 14 to 15 weeks of gestation to 10 g/day at 20 weeks, and to 30 to 35 g/day at 32 to 34 weeks. The total substrate needs of the fetus are thus relatively small in the first half of pregnancy, after which the rate of weight gain rises precipitously. The mean weight gain peaks at approximately 230 to 285 g/wk at 32 to 34 weeks of gestation, after which it decreases, possibly even reaching zero weight gain, or even weight loss, at 41 to 42 weeks of gestation (Fig. 34-2).^{13,17} If growth rate is expressed as the percentage of increase in weight over the previous week, however, the percentage of increase reaches a maximum in the first trimester and decreases steadily thereafter.

Incidence of Intrauterine Growth Restriction

The incidence of IUGR varies according to the population under examination, the geographic location, the standard growth curves used as reference, and the percentile chosen to indicate abnormal growth (i.e., the 3rd, 5th, 10th, or 15th).

Approximately one fourth to one third of all infants weighing less than 2500 g at birth have sustained IUGR, and approximately 4% to 8% of all infants born in developed countries and 6% to 30% of those born in developing countries have been classified as growth restricted.¹⁸

Perinatal Mortality and Morbidity

IUGR is associated with an increase in fetal and neonatal mortality and morbidity rates. Perinatal mortality rates for fetuses and neonates weighing less than the 10th percentile, but between 1500 and 2500 g, were 5 to 30 times greater than those of newborns between the 10th and 90th percentiles; for those weighing less than 1500 g, the rates were 70 to 100 times greater.¹³ In addition, for birth weights below the 10th percentile, the fetal and neonatal mortality rates rise as gestation advances if birth weights do not increase.

As depicted in Figure 34-3, Manning showed that perinatal morbidity and mortality increase if birth weights are below the 10th percentile, and markedly so if below the 6th percentile.¹⁹

In general, fetal mortality rates for IUGR fetuses are 50% higher than neonatal mortality rates, and male fetuses with IUGR have a higher mortality rate than female fetuses. The 10% to 30% increase in incidence of minor and major congenital anomalies associated with IUGR accounts for 30% to 60% of the IUGR perinatal deaths (50% of stillbirths and 20% of neonatal deaths).²⁰ Infants with symmetric IUGR are more likely to die in association with anomalous development or infection. If, however, in the absence of congenital abnormalities, chromosomal defects, and infection, neonates with symmetric IUGR are probably not at increased risk of neonatal morbidity.²¹ The incidence of mortality in the preterm newborn is higher if IUGR is also present.²² The incidence of intrapartum fetal distress with IUGR approximates 25% to 50%.^{23,24}

In addition, IUGR may contribute to perinatal morbidity and mortality by leading to both induced and spontaneous preterm births and

the neonatal problems associated with preterm delivery.²⁵ Specific morbidities are discussed later in this chapter and in Chapter 58.

Long-term sequelae of IUGR, such as various adult diseases including chronic hypertension, heart and lung disease, and type 2 diabetes, are discussed in greater detail in Chapter 59. Lower intelligence quotients, increased mental retardation, and cerebral palsy have also been reported.²⁶⁻²⁸

Etiology of Intrauterine Growth Restriction

IUGR encompasses many different maternal and fetal entities. Some can be detected before birth, whereas others can be found only at autopsy. It is important to discern the cause of IUGR, because in many cases subsequent pregnancies may also be affected.

Genetic Factors

There has been much interest in determining the relative contributions of factors that produce birth weight variation, namely the maternal and fetal genetic factors and the environment of the fetus. Approximately 40% of total birth weight variation is due to the genetic contributions from mother and fetus (approximately half from each), and the other 60% is due to contributions from the fetal environment.²⁹

Although both parents' genes affect childhood growth and final adult size, the maternal genes have the main influence on birth weight. The classic horse-pony cross-breeding experiments by Walton and Hammond demonstrated the important role of the mother.³⁰ Foals of the maternal horse and paternal pony are significantly larger than foals of the maternal pony and paternal horse, and foals of each cross are comparable in size to foals of the pure maternal breed. These results

clearly demonstrated the widely held thesis of a maternally related constraint on fetal growth.

Similar conclusions of maternal constraint to growth are reached from family studies in humans. Low and high birth weights recur in families with seemingly otherwise normal pregnancies. Sisters of women with IUGR babies tend to have IUGR babies, a trend that is not seen in their brothers' babies.³¹ There is also a greater similarity in birth weight between maternal half siblings and full siblings than between paternal half siblings and full siblings. Mothers of IUGR infants were frequently growth restricted at birth themselves.^{32,33} Although the maternal phenotypic expression—particularly maternal height—may affect fetal growth, the evidence for such an influence is not convincing. Social deprivation has also been associated with IUGR, a finding not explained by known physiologic or pathologic factors.³⁴

The one definite paternal influence on fetal growth and size at birth is the contribution of a Y chromosome rather than an X chromosome. The male fetus grows more quickly than the female fetus and weighs approximately 150 to 200 g more than the female at birth.³⁵ There is also a suggestion that paternal size at birth can influence fetal growth, with birth weights potentially increased by 100 to 175 g.³⁶ Also, the greater the antigenic dissimilarity between the parents, the larger the fetus.

Whether it is genetically determined or not, women who were SGA at birth have double the risk of reduced intrauterine growth in their fetuses.³⁷ In similar fashion, fetuses destined to deliver preterm have a higher incidence of reduced fetal growth.^{25,38} The role of the genetic constitution of mother or fetus in these observations is not clear.

Specific maternal genotypic disorders can cause IUGR, one example being phenylketonuria.³⁹ Infants born to homozygously affected mothers almost always have IUGR, but whether the reason is an abnormal amount of metabolite crossing from mother to fetus or an inherent problem in the fetus is unknown.

There is a significant association between IUGR and congenital malformations (see later discussion). Such abnormalities can be caused by established chromosomal disorders or by dysmorphic syndromes, such as various forms of dwarfism. Some of these malformations are the expression of a specific gene abnormality with a known inheritance pattern, whereas others are only presumed to be the result of a gene mutation or an adverse environmental influence.

Although in some reports only 2% to 5% of IUGR infants have a chromosomal abnormality, the incidence rises to 20% if IUGR and mental retardation are both present.⁴⁰ Birth weights in infants with trisomy 13, 18, and 21 are lower than normal,^{41,42} with the decrease in birth weight being less pronounced in trisomy 21. The frequency distribution of birth weights in infants with trisomy 21 is shifted to the left of the normal curve after 34 weeks of gestation, resulting in gestational ages 1 to 1.5 weeks less than normal, and birth weights and lengths are less than in control infants from 34 weeks until term. This effect is more marked after 37 weeks of gestation, but birth weights are still only approximately 1 standard deviation from mean weight. Birth weights in translocation trisomy 21 are comparable to those in primary trisomy 21. Birth weights of newborns who are mosaic for normal and 21-trisomic cells are lower than normal but higher than those of 21-trisomic infants.²⁹ Newborns with other autosomal abnormalities, such as deletions (chromosomes 4, 5, 13, and 18) and ring chromosome structure alterations, also have had impaired fetal growth.

Although abnormalities of the female (X) and male (Y) sex chromosomes are frequently lethal (80% to 95% result in first-trimester spontaneous abortions), they could be a cause of IUGR in a newborn.^{18,28} Infants with XO sex chromosomes have a lower mean birth weight than control infants (approximately 85% of normal for gestational age)

and are approximately 1.5 cm shorter at birth. Mosaics of 45,X and 46,XX cells are affected to a lesser degree. Although a paucity of reports prevents definite conclusions, it appears that the repressive effect on fetal growth is increased with the addition of X chromosomes, each of which results in a 200- to 300-g reduction in birth weight.⁴³

IUGR is associated with numerous other dysmorphic syndromes, particularly those causing abnormal brain development (see Chapters 1 and 17).

The overall contribution that chromosomal and other genetic disorders make to human IUGR is estimated to be 5% to 20%. Approximately 25% of fetuses with early-onset fetal growth restriction could have chromosomal abnormalities, and karyotyping via cordocentesis can be considered (see Chapter 17). A genetic basis should be considered strongly if IUGR is encountered in association with neurologic impairment or early polyhydramnios.

Congenital Anomalies

In a study of more than 13,000 anomalous infants, 22% had IUGR.⁴⁴ Newborns with cardiac malformations are frequently of low birth weight and length for gestation, with the possible exception of those with tetralogy of Fallot and transposition of the great vessels. The subnormal size of many infants with cardiac anomalies (as low as 50% to 80% of normal weight with septal defects) is associated with a subnormal number of parenchymal cells in organs such as the spleen, liver, kidneys, adrenals, and pancreas.⁴⁵ The anencephalic fetus is also usually growth restricted.

Approximately 25% of newborns with a single umbilical artery weigh less than 2500 g at birth, and some of these are born preterm.⁴⁶ Abnormal umbilical cord insertions into the placenta are also occasionally associated with poor fetal growth.⁴⁷ The presence of cord encirclements around the fetal body is also associated with IUGR.⁴⁸

Structural malformations, single umbilical artery, and monozygotic twins are relatively rare and probably account for no more than 1% to 2% of all human instances of IUGR.

Infection

Infectious disease is known to cause IUGR, but the number of organisms having this effect is poorly defined, and the extent of the growth restriction can be variable. There is sufficient evidence for a causal relationship between infectious disease and IUGR for two viruses—rubella and cytomegalovirus,⁴⁹ and there is evidence for a possible relationship with varicella,⁵⁰ severe herpes zoster, and human immunodeficiency virus (HIV) infection, although the latter may be complicated by other problems associated with HIV (see Chapter 38).

With rubella infection, the incidence of IUGR may be as high as 60%, with infected cells remaining viable for many months.⁵¹ There is capillary endothelial damage, hypoplasia, and necrotizing angiopathy in many fetal organs.⁵² With cytomegalovirus infection, there is cytolysis, localized necrosis within various fetal organs, and a decrease in cell number.⁵³

Although there are no bacterial infections known to cause IUGR, histologic chorioamnionitis is strongly associated with symmetric IUGR between 28 and 36 weeks, and with asymmetric IUGR after 36 weeks of gestation.⁵⁴

Protozoan infections resulting from *Toxoplasma gondii*, *Plasmodium* sp., or *Trypanosoma cruzi* (Chagas disease) reportedly can cause IUGR.⁴⁹

Although the incidence of maternal infections with various organisms may be as high as 15%, the incidence of congenital infections is

estimated to be no more than 5%. It is believed that infectious disease can account for no more than 5% to 10% of human IUGR.

Multiple Gestation

It has long been recognized that multiple pregnancies are associated with a high progressive decrease in fetal and placental weight as the number of offspring increases in humans and in various animal species (see Chapter 25).^{55,56} In both singleton and twin gestations, there is a relationship between total fetal mass and maternal mass. The increase in fetal weight in singleton gestations is linear from approximately 22 to 24 weeks until approximately 32 to 36 weeks of gestation.^{13,17} During the last weeks of pregnancy, the increase in fetal weight declines, actually becoming negative after 42 weeks in some pregnancies.

If nutrition is adequate in the neonatal period, the slope of the increase in neonatal weight parallels the increase in fetal weight seen before 34 to 38 weeks. The decline in fetal weight increase occurs when the total fetal mass approximates 3000 to 3500 g for either singleton or twin gestations. When growth rate is expressed incrementally, the weekly gain in singletons peaks at approximately 230 to 285 g/wk between 32 and 34 weeks of gestation (see Fig 34-2). In individual twin fetuses, the incremental weekly gain peaks at 160 to 170 g/wk between 28 and 32 weeks of gestation.¹³ However, recent studies in triplets have indicated that the growth of individual triplets may continue in a linear fashion well beyond a total combined weight of 3500 g.⁵⁷ Others have reported that before 35 weeks of gestation, triplets grow at about the 30th percentile for singletons, and by 38 weeks the average weight of each triplet is at the 10th percentile.⁵⁸ Significant birth weight discordance also occurs if there is unequal sharing of the placental mass.⁵⁹ If multifetal reduction is performed, there is an increase in IUGR in the surviving fetuses.⁶⁰

The decrease in weight of twin fetuses, frequently with mild IUGR, is usually due to decreased cell size; the exception is severe IUGR associated with monozygosity and vascular anastomoses, wherein cell number also may be decreased.⁶¹ These changes in twins are similar to those seen in IUGR secondary to poor uterine perfusion or maternal malnutrition. Twins with mild IUGR have an acceleration of growth after birth, so that their weight equals the median weight of singletons by 1 year of age. This observation supports the thesis that the etiology of poor fetal growth in twin gestations is an inability of the environment to meet fetal needs, rather than an inherent diminished growth capacity of the twin fetus. The example of twin fetuses supports the thesis derived from normal singleton pregnancies that the human fetus is seldom able to express its full potential for growth.

Many components of the environment can limit fetal growth (see later discussions). Twin-to-twin transfusion secondary to vascular anastomoses in monochorionic-monozygotic twins frequently results in IUGR of one twin, usually the donor (see Chapter 25). Maternal complications associated with IUGR occur more frequently with twins, and the incidence of congenital anomalies is almost twice that of singletons, primarily among monozygotic twin gestations. The incidence of IUGR in twins is 15% to 25%^{16,62}; because the incidence of spontaneous multiple gestations approximates 1%, these pregnancies probably account for less than 3% of all cases of human IUGR. The actual incidence could be closer to 5% because of the increase in multiple gestations secondary to assisted reproductive techniques.

Inadequate Maternal Nutrition

Numerous animal studies have demonstrated that undernutrition of the mother caused by protein or caloric restriction can affect fetal

growth adversely. However, information from experiments using small animals, in which the fetomaternal mass is much greater than in human pregnancy and the fetal and neonatal growth rate reaches its maximum after birth, must be extrapolated with caution. Nevertheless, such animal studies have engendered important concepts.

Winick⁶³ reported that there are three phases of fetal growth: cellular hyperplasia, followed by both hyperplasia and hypertrophy, and then predominantly hypertrophy. If there is a decrease in available substrate, the timing of the decrease is reflected in the type of IUGR observed. If the insult occurs early in pregnancy, the fetus is likely to be born with a decrease in cell number and cell size (such as might be observed with severe chronic maternal undernutrition or an inability to increase uteroplacental blood flow during gestation) and to have symmetric IUGR. If the insult occurs late in gestation, such as with twin gestation, the fetus is likely to have a normal cell number but a restriction of cell size (which can be returned to normal with adequate postnatal nutrition) and to have asymmetric IUGR.

The importance of maternal nutrition in fetal growth and birth weight was demonstrated by studies in Russia and Holland, where women suffered inadequate nutrition during World War II. The population in Leningrad underwent a prolonged period of poor nutrition, during which both preconception nutritional status and gestational nutrition were poor and birth weights were reduced by 400 to 600 g.⁶⁴ In Holland, a 6-month famine created conditions that permitted evaluation of the effect of malnutrition during each of the trimesters of pregnancy in a group of women previously well nourished.⁶⁵ Birth weights declined by approximately 10%, and placental weights by 15%, only when undernutrition occurred in the third trimester with daily caloric intake of less than 1500 kcal. The difference in severity of the IUGR in these two populations suggests the importance of prepregnancy nutritional status, an idea that has been substantiated.^{18,66} In addition, animal studies indicate that fetal growth, metabolic and endocrine function, as well as placental status and function in late pregnancy, are significantly altered by the periconception maternal nutritional status, an effect independent of fetal size.⁶⁷ More recent studies have shown that inadequate weight gain in pregnancy (defined as <0.27 kg/wk, or <10 kg at 40 weeks, or based on suggested weight gain for body mass indices; see Chapter 10) is associated with an increased risk of IUGR. Weight gain in the second trimester appears to be particularly important.⁶⁷ Adequate maternal weight gain by 24 to 28 weeks in multiple pregnancies correlates positively with good fetal growth.⁶⁸

It is still unclear whether it is generalized calorie intake reduction or specific substrate limitation (e.g., protein or key mineral restriction), or both, that is important in producing IUGR (see Chapter 10). Glucose uptake by the fetus is critical, because there is the suggestion that little gluconeogenesis occurs in the normal fetus. In the IUGR fetus, the maternal-fetal glucose concentration difference is increased as a function of the severity of the IUGR,⁶⁹ facilitating glucose transfer across the small placenta. Decreases in zinc content of peripheral blood leukocytes also correlate positively with IUGR,⁷⁰ and serum zinc concentrations of less than 60 µg/dL in the third trimester are associated with a fivefold increase in the incidence of low birth weight.⁷¹ Similarly, an association between low serum folate levels and IUGR has been reported.⁷² Although there have been numerous studies on supplementation, there is no convincing evidence that high protein intake or caloric supplementation has a beneficial effect on fetal weight. In addition, if a fetus is receiving decreased oxygen delivery as a result of decreased uteroplacental perfusion and has adapted by slowing metabolism and growth, it may not be advisable to increase substrate delivery. This important issue remains unresolved.

Another maternal nutrient that is important to fetal growth is oxygen. It is probably a primary determinant of fetal growth. IUGR infants have a decrease in the partial pressure of oxygen and decreased oxygen saturation values in the umbilical vein and artery.⁷³ The median birth weight of infants of women living more than 10,000 feet above sea level is approximately 250 g less than that of infants of women living at sea level.⁷⁴ Pregnancies complicated by maternal cyanotic heart disease usually result in IUGR, but it is unclear whether abnormal maternal hemodynamics or the reduction in oxygen saturation (by approximately 40% in the umbilical vein) accounts for the poor fetal growth.⁷⁵ The association between hemoglobinopathies and IUGR could be due to decreased blood viscosity or decreased fetal oxygenation. Patients with chronic pulmonary disease (e.g., poorly controlled asthma, cystic fibrosis, bronchiectasis) and those with severe kyphoscoliosis may be at increased risk of IUGR.

Environmental Toxins

Maternal cigarette smoking decreases birth weight by approximately 135 to 300 g; the fetus is symmetrically smaller.^{76,77} If smoking is stopped before the third trimester, its adverse effect on birth weight is reduced.⁷⁷ More disturbing is the reported dose-response relationship between maternal smoking and a smaller infant head size, specifically a circumference of less than 32 cm, as well as a head circumference more than 2 standard deviations below that expected for gestational age.⁷⁸ The reason why not all women who smoke have IUGR infants could be a function of maternal genetic susceptibility.⁷⁹

Reduction in birth weight also occurs with maternal alcohol ingestion of as little as one to two drinks per day.⁸⁰ Cocaine use in pregnancy similarly decreases birth weight, but there is also a reduction of head circumference that is more pronounced than the reduction in birth weight.⁸¹ Use of other drugs, such as the anticonvulsants phenytoin and trimethadione, warfarin, and heroin, has been implicated in IUGR (see Chapter 20).

Placental Factors

Although placental size does not necessarily equate with function, our inability to clinically properly evaluate human placental function has resulted in studies of the interrelationships of size, morphometry, and clinical outcome. In general, birth weight increases with increasing placental weight in both animals and humans. IUGR without other anomalies is usually associated with a small placenta. Chromosomally normal IUGR newborns have a 24% smaller placenta for gestational age.⁸² A small placenta is not always associated with an IUGR newborn, but a large infant from an otherwise normal pregnancy does not have a small placenta. Placental weight increases throughout normal gestation; with IUGR, the placental weight plateaus after 36 weeks or earlier, and the placenta (after being trimmed of the membranes and cord) weighs less than 350 g.⁸³ As normal gestation advances, there is a greater increase in fetal weight than in placental weight, so there is an increase in the fetal-placental weight ratio in large-for-gestational-age (LGA), AGA, and SGA infants in the last half of gestation. In all three categories, when the fetal-placental weight ratio is greater than 10, there is an increased incidence of depressed newborns; this suggests that it is not only the IUGR fetus that can outgrow the capacity of the placenta to bring about adequate transfer of necessary nutrients.⁸³

Adequate trophoblastic invasion of the uterine decidual bed, and the resultant alteration in uterine blood flow, is a vital necessity, not only for the initial establishment and adherence of the pregnancy, but for also the adequate supply of nutrients to the fetus. The trophoblasts

invade the decidua and myometrium to anchor the placenta, and a subpopulation of cytotrophoblasts invades the uterine blood vessels at the implantation site, resulting in extensive remodeling of the vessels.⁸⁴⁻⁸⁷ There is a replacement of endothelium and uterine smooth muscle cells, which leads to a reduction in uterine arterial resistance and an increase in uteroplacental perfusion. Apoptosis plays an integral role in these vascular changes. It has also been suggested that the cytotrophoblast initiates lymphangiogenesis in the pregnant uterus; this is normally lacking in the nonpregnant state.

A number of reports have revealed that, in many cases of IUGR, particularly in early IUGR, the depth of invasion by the cytotrophoblasts is shallow and the endovascular invasion rudimentary; they have thus confirmed the early classic work of Brosens and colleagues,⁸⁸ who described reduced trophoblastic invasion and decreased pregnancy-associated alterations in the placental bed of IUGR pregnancies. The detailed morphologic studies of Aherne and Dunnill⁸⁹ also demonstrated that the mean surface area and, more importantly, the capillary surface area were reduced in the placentas of IUGR newborns. Apoptosis at the implantation site is increased with IUGR, and this has been suggested to be the mechanism limiting endovascular invasion.^{86,90,91} The placental vascular endothelial growth factor (VEGF) and placenta growth factor (PlGF) were reduced, and antagonists were increased, in studies of early IUGR confirmed by Doppler imaging.⁹² In summary, early abnormal implantation plays a key role in IUGR, but the exact controlling mechanisms behind the impaired placentation remain to be delineated.

The terminal villi are maldeveloped in IUGR pregnancies when absent end-diastolic flow is demonstrated, indicating that these morphologic changes are associated with increased vascular impedance.⁹³ When end-diastolic flow is absent, there are more occlusive lesions of the intraplacental vasculature than when end-diastolic flow is present.⁹⁴

Information from cordocentesis studies has revealed fetal hypoxemia, hypercapnia, acidosis, and hypoglycemia in severe IUGR.^{95,96} There is also a decrease in α -aminonitrogen, particularly branched-chain amino acids, in the plasma of the IUGR fetus.⁹⁷

Abnormal insertions of the cord, placental hemangiomas, abruptio placentae, and placenta previa are also associated with IUGR.⁹⁸⁻¹⁰⁰

Maternal Vascular Disease

Substantial evidence from experimental animal studies suggests that alterations in uteroplacental perfusion affect the growth and status of the placenta as well as the fetus. Ligation of the uterine artery of one horn of the pregnant rat results in IUGR of those fetuses nearest the constriction, and fetal and placental weights in guinea pigs, mice, and rabbits are lowest in the middle of each uterine horn, where arterial perfusion is lowest. Repetitive embolization of the uterine vascular bed during the last quarter of gestation in sheep gives rise to localized hyalinization and fibrinoid changes in the placenta¹⁰¹ and results in a 40% reduction in placental weight and alterations in organ growth patterns similar to those observed in IUGR fetuses from pregnancies complicated by maternal hypertensive disease. In addition, umbilical blood flow is reduced and fetal oxidative metabolism is decreased.^{101,102}

It has been strongly suggested in various studies that uteroplacental blood flow is decreased in pregnancies complicated by maternal hypertensive disease. Defective trophoblastic invasion of the uterine vascular bed results in relatively intact musculoelastic vessels that resist the normal decrease in uterine vascular resistance.¹⁰³ Clearance of radioactive tracers from the intervillous space is reduced in preeclamptic

patients.^{104,105} Because maternal body mass and plasma volume are correlated, reduced plasma volume or prevention of plasma volume expansion could lead to decreased cardiac output and uterine perfusion and a resultant decrease in fetal growth.^{106,107} Alternatively, it may be that abnormal placentation comes first.

The importance of normal trophoblastic invasion leading to normal maternal cardiovascular changes has been indicated by central maternal cardiovascular studies. IUGR below the 3rd percentile at 25 to 37 weeks of gestation is associated with reduced maternal systolic function, increased vascular resistance, and probable lack of volume expansion in otherwise normotensive patients.¹⁰⁸

Uteroplacental flow-velocity waveform studies, using Doppler methods in pregnancies complicated by hypertension, have shown a higher incidence of IUGR in pregnancies in which abnormal waveforms were recorded. These abnormal waveforms are thought to reflect abnormally increased resistance to blood flow.^{109,110} High-resistance hypertension is associated with a marked decrease in fetal weight compared with low-resistance hypertension.¹¹¹ Increasing uteroplacental resistance, recorded with this methodology, has been positively correlated with fetal hypoxemia as determined by cordocentesis in IUGR fetuses.⁹⁵

As discussed in Chapter 40, there is conflicting evidence as to whether the congenital thrombophilias contribute to the clinical development of IUGR, with most recent studies suggesting the lack of an association.¹¹²⁻¹¹⁵

There are only fragmentary suggestions relating abnormal anatomic uterine vascular anatomy and IUGR. IUGR may occur at a higher frequency if the pregnancy is in a unicornuate uterus; vascular abnormalities are likely but unproven in such cases.¹¹⁶ Patients with two (rather than the usual one) ascending uterine arteries on each side of the uterus also have a higher rate of IUGR.¹¹⁷ However, pregnancy after bilateral ligation of the internal iliac and ovarian arteries, or after embolization of leiomyomata, is not associated with IUGR.^{118,119}

Because exercise can affect uterine perfusion, this subject has been studied extensively. A moderate regimen of weight-bearing exercise in early pregnancy probably enhances fetal growth.¹²⁰ However, high levels of exercise (>50% of prepregnancy levels) in middle and late pregnancy result mainly in a symmetric reduction in fetal growth and neonatal fat mass.¹²¹ In assessing levels of aerobic activity, neonates born to women in the highest quartile weighed 600 g less than those in the lowest quartile, an effect mainly seen in taller women.¹²²

Clinical maternal vascular disease and the presumed decrease in uteroplacental perfusion can account for at least 25% to 30% of IUGR infants. Undiagnosed decreased perfusion could also be the cause of IUGR in an otherwise normal pregnancy, such as with recurrent idiopathic fetal growth restriction. A history of a previous low-birth-weight infant is significantly associated with the subsequent birth of an infant with decreased weight, decreased ponderal index, and decreased head circumference.¹²³ This finding of symmetric growth restriction is in contrast to the asymmetric IUGR usually seen with maternal vascular disease.

Vascular disease becomes more prevalent with advancing age. In one recent large study, after controlling for confounding variables, the incidence of SGA births was increased more in nulliparous patients than in multiparous patients older than 30 years of age.¹²⁴

Maternal and Fetal Hormones

In general, there is limited transfer of the various circulating maternal hormones into the fetal compartments (see Chapters 46 through 48).

Although the effects of hypothyroidism or hyperthyroidism on fetal size are not striking, studies in subhuman primates indicate that, when the mother and fetus are athyroid, there is retarded osseous development and reduced protein synthesis in the fetal brain.¹²⁵

Maternal diabetes without vascular disease is frequently associated with excessive fetal size (see Chapter 46). Although insulin does not cross the placenta, fetal hyperinsulinemia as well as hyperplasia of the pancreatic islet cells is seen frequently with maternal diabetes. These changes are thought to occur as a result of maternal hyperglycemia, which leads to fetal hyperglycemia and an increased response of the fetal pancreas. Fetal hypoinsulinemia produced experimentally in the rhesus monkey results in IUGR; rarely, infants have been born with severe IUGR and requiring insulin treatment at birth, suggesting hypoinsulinemia in utero.^{126,127} If nutrient transfer becomes limited owing to placental disease secondary to maternal vascular disease, the fetus of the diabetic mother can sustain IUGR.

Even though human growth hormone is present early in gestation, there is minimal evidence that it regulates fetal weight, although a deficiency could retard skeletal growth.¹²⁸ Convincing evidence is also lacking that adrenal hormones have a role in producing IUGR in humans.

Several small polypeptides with in vitro growth-promoting activity have been purified (e.g., insulin-like growth factor 1 [IGF-1], IGF-2), but the exact role of these peptides and their binding proteins as fetal growth factors and their potential relationship to IUGR are currently not well understood.

Leptin (from Greek *leptos*, “thin”) is a polypeptide hormone discovered in 1994. It has been shown to moderate feeding behavior and adipose stores. It is produced predominantly by adipocytes but can also be produced by the placenta, because neonatal levels fall dramatically after birth.¹²⁸ Reported concentrations in IUGR have varied, and the exact role that this hormone plays in fetal growth remains to be clarified.

Diagnosis of Intrauterine Growth Restriction

Determination of Cause

An attempt should be made to determine the cause of fetal aberrant growth before delivery in order to provide appropriate counseling; perform ultrasonographic evaluation for fetal growth velocity, delineate anatomy and function; and obtain neonatal consultation.

The various disorders associated with suboptimal fetal growth were addressed earlier in this chapter and are summarized in Table 34-2. Often, the cause is readily apparent. Among patients with significant chronic hypertensive disease, those who take prescribed medications known to be associated with prenatal growth deficiency, and those whose fetuses have congenital or chromosomal abnormalities, the diagnosis is easily established and management plans can be made. At times, however, the causal factors can be more elusive. For example, growth restriction associated with preeclampsia may antedate the appearance of hypertension or proteinuria by several weeks. In many instances, a careful history, maternal examination, and ultrasound evaluation reveal the etiology.

History and Physical Examination

Clinical diagnosis of IUGR by physical examination alone is inaccurate; often, the diagnosis is not made until after delivery. Most clinical

TABLE 34-2 DISORDERS AND OTHER FACTORS ASSOCIATED WITH INTRAUTERINE GROWTH RESTRICTION*

Maternal Factors

Hypertensive disease, chronic or preeclampsia
 Renal disease
 Severe nutritional deficiencies (e.g., inflammatory bowel disease, markedly inadequate pregnancy weight gain in the underweight woman, malnutrition)
 Pregnancy at high altitude
 Specific prescribed medications (e.g., antiepileptics)
 Smoking, alcohol use, illicit drug use

Fetal Factors

Multiple gestations
 Placental abnormalities
 Infections
 Aneuploidy or structural abnormalities

***Growth is also strongly influenced by maternal prepregnancy weight and by ethnicity, which must be considered when evaluating overall growth (by use of customized versus population-based growth curves).**

studies demonstrate that, with the use of physical examination alone, the diagnosis of IUGR is missed or incorrectly made almost half the time. Techniques such as measurement of the symphysis-fundal height are helpful in screening for abnormal fetal growth and documenting continued growth if they are performed repeatedly by the same observer, but they are not sensitive enough for accurate detection of most infants with IUGR.^{129,130}

Despite the inaccuracy of such indicators, fetal assessment and specific aspects of the patient's risk factors increase the clinician's index of suspicion about suboptimal fetal growth, without which more definitive laboratory investigation might not be considered. As discussed earlier, maternal disease entities such as hypertension, in particular severe preeclampsia and chronic hypertension with superimposed preeclampsia, carry a high incidence of IUGR. The diagnosis of a multiple gestation suggests the likelihood of diminished fetal growth relative to gestational age, as well as preterm birth. Additional maternal risk factors include documented rubella or cytomegalovirus infection, heavy smoking, heroin or cocaine addiction, alcoholism, and poor nutritional status both before conception and during pregnancy combined with inadequate weight gain during pregnancy.

Ultrasonography

Currently, ultrasonographic evaluation of the fetus is the preferred and accepted modality for the diagnosis of inadequate fetal growth. It offers the advantages of reasonably precise estimations of fetal weight, determination of interval fetal growth velocity, and measurement of several fetal dimensions to describe the pattern of growth abnormality. Use of these ultrasound measurements requires accurate knowledge of gestational age. Accordingly, if a patient is known to be at risk for a fetal growth abnormality, the crown-to-rump length should be determined during the first trimester.

Measurements of biparietal diameter, head circumference, abdominal circumferences, and femur length allow the clinician to use accepted formulas to estimate fetal weight and to determine whether a fetal growth aberration represents an asymmetric, symmetric, or mixed

pattern¹³¹ (Fig. 34-4). As discussed previously, intrinsic fetal insults occurring early in pregnancy (e.g., infection, exposure to certain drugs or other chemical agents, chromosomal abnormalities, other congenital malformations) are likely to affect fetal growth at a time of development when cell division is the predominant mechanism of growth. Consequently, musculoskeletal dimensions and organ size may be adversely affected, and a symmetric pattern of aberrant growth is observed. Given this set of circumstances, one might expect to find that the femur length and head circumference are small for a given gestational age, as are the abdominal circumference and overall fetal weight, all of which are characterized as *symmetric* IUGR. Symmetric IUGR accounts for approximately 20% to 30% of all growth-restricted fetuses.

At the other end of the spectrum, an extrinsic insult occurring later in pregnancy, usually characterized by inadequate fetal nutrition due to placental insufficiency, is more likely to result in *asymmetric* growth restriction. In this type, femur length and head circumference are spared, but abdominal circumference is decreased because of subnormal hepatic growth, and there is a paucity of subcutaneous fat. The most common disorders that limit the availability of fetal substrates for metabolism are the hypertensive complications of pregnancy, which are associated with decreased uteroplacental perfusion, and placental infarcts, which limit the trophoblastic surface area available for substrate transfer. In fact, a falloff in the interval growth of the *abdominal circumference* is one of the earliest findings in extrinsic or asymmetric IUGR^{132,133}; conversely, the finding of an abdominal circumference in the normal range for gestational age markedly decreases the likelihood of IUGR. Frequently, these patterns of growth abnormality merge, particularly after long-standing fetal nutritional deprivation.

Distinguishing between symmetric and asymmetric IUGR is also of considerable clinical significance and may provide useful information for both diagnostic and counseling purposes. For example, a diagnosis of symmetric IUGR in early pregnancy suggests a poor prognosis when the diagnostic possibilities are considered (e.g., fetal infection, aneuploidy); conversely, asymmetric IUGR observed in the third trimester, particularly if it is associated with maternal hypertension or placental dysfunction, usually imparts a more favorable prognosis with careful fetal evaluation, appropriate delivery timing, and skillful neonatal management.

Considerable attention has been directed at early ultrasound findings that may provide for the early prediction of IUGR. In a study of 976 women whose pregnancies were the product of assisted reproductive technologies, the risk of delivering an SGA fetus decreased as a function of increasing crown-rump length in the first trimester.¹³⁴ This confirmed previous findings suggesting that suboptimal growth in the first trimester is associated with IUGR.¹³⁵

Efforts have also been made to correlate Doppler findings in the uterine artery with subsequent pregnancy complications, including IUGR. Utilizing transvaginal color Doppler at 23 weeks' gestation, Papageorgiou and colleagues observed that increases in the uterine artery pulsatility index and "notching" were associated with subsequent development of IUGR, although the predictive value was low.¹³⁶ In a more recent study of uterine artery pulsatility index at 11 to 14 weeks' gestation, a value greater than the 95th percentile predicted SGA with accuracy in 23% of the cases, and with increased sensitivity if the maternal serum concentration of plasma-associated pregnancy protein A (PAPP-A) was low. However, this parameter did not reach statistical significance.¹³⁷ The eventual practical role that uterine artery Doppler ultrasound may play in the prediction of IUGR, if any, awaits more extensive evaluation.

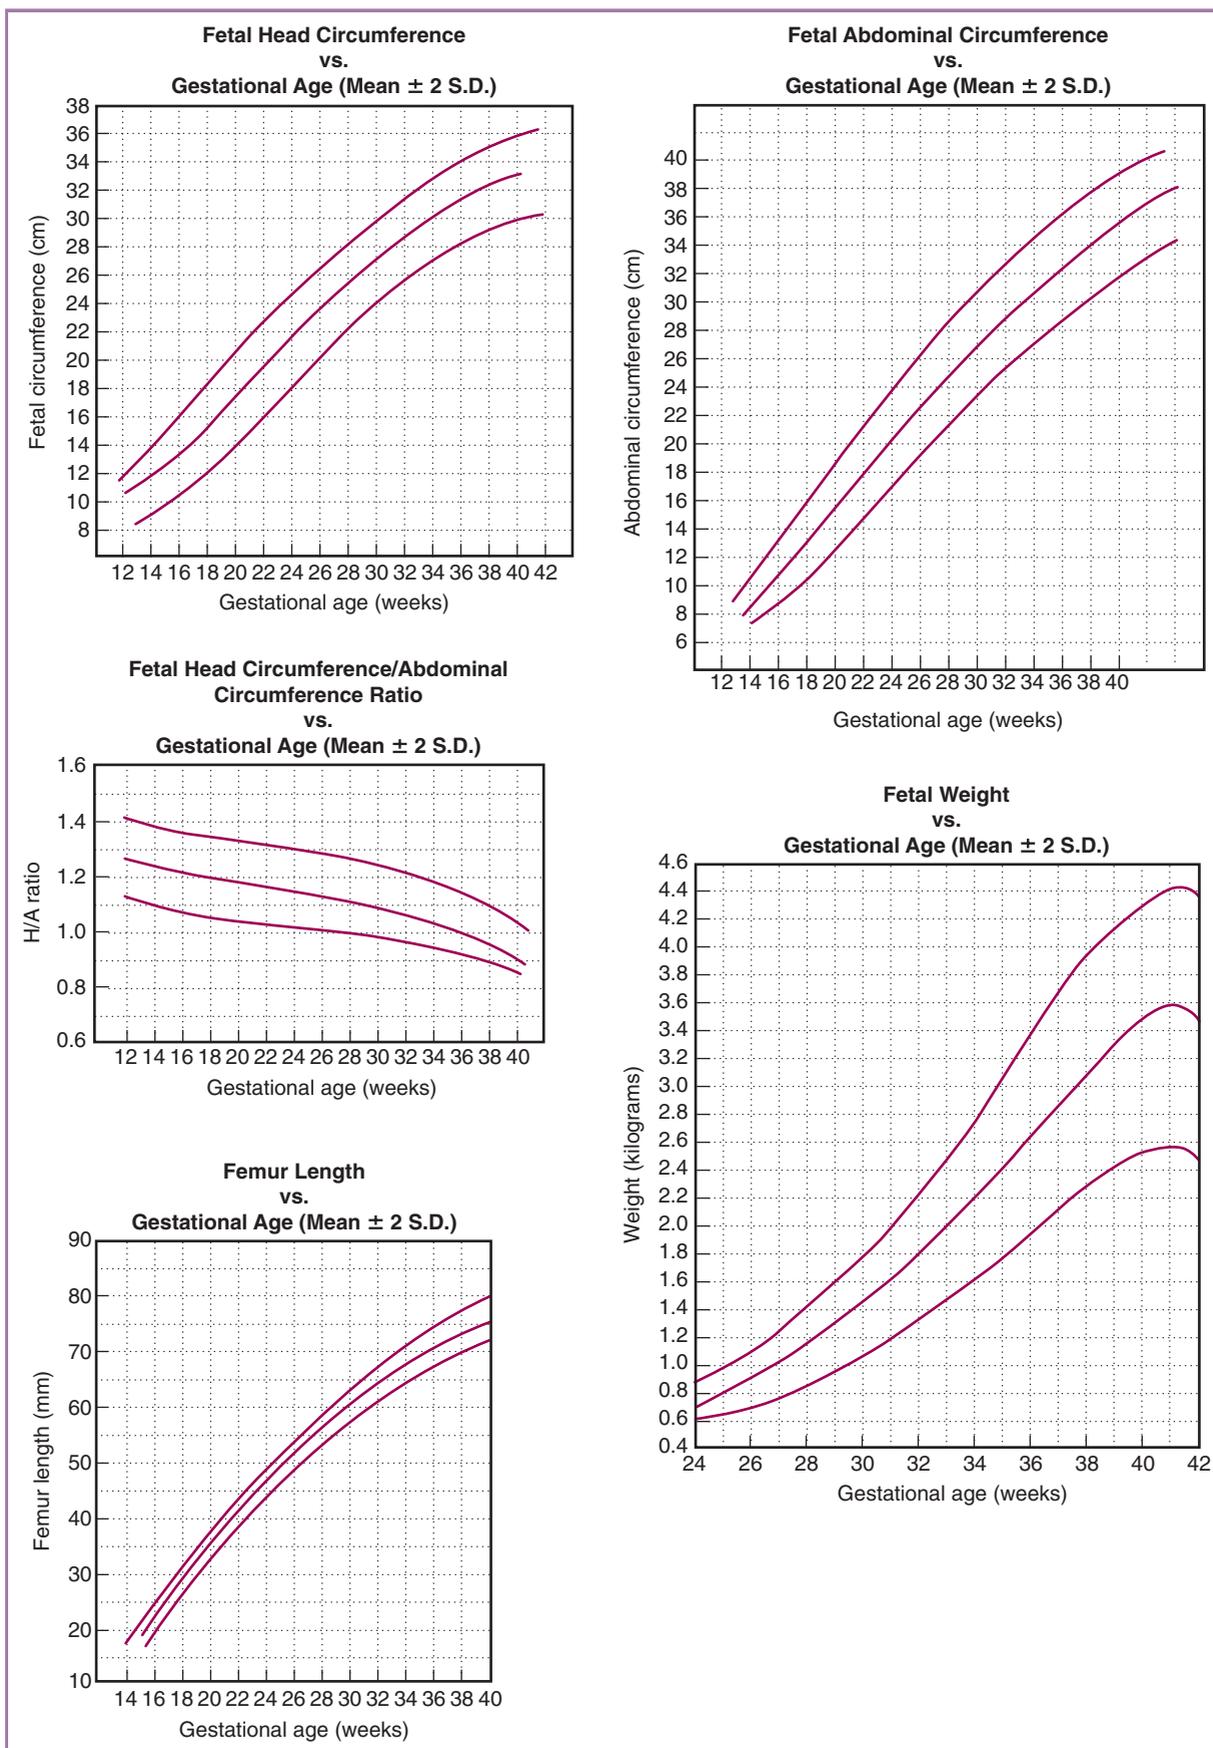

FIGURE 34-4 Composite of fetal body measurements used for serial evaluations of fetal growth.

Management of Pregnancy

The cornerstones of management for the pregnancy complicated by IUGR are surveillance of fetal growth velocity and function (well-being) and determination of appropriate delivery timing. Delivery at or near term is usually indicated if fetal growth has continued to be adequate and antenatal testing results have been normal. Management is far more challenging remote from term and requires use of the biophysical profile (BPP), measurement of amniotic fluid volume (AFV), and Doppler assessment of the fetal circulation, combined with good clinical judgment. The comments in the following sections pertain primarily to the use of antenatal testing in the *preterm* fetus with IUGR.

Antenatal Fetal Testing

The various diagnostic modalities used for fetal assessment are discussed in detail in Chapter 21, but specific points are reemphasized here.

Biophysical Profile and Amniotic Fluid Volume

The BPP is appealing, inasmuch as it provides a multidimensional survey of fetal physiologic parameters. In particular, AFV assessment is an important aspect of the BPP, because oligohydramnios is a frequent finding in the IUGR pregnancy caused by placental insufficiency. This is presumably a result of diminished fetal blood volume, renal blood flow, and urinary output. Human fetal urinary production rates can be measured with considerable accuracy,¹³⁸ and three separate studies have shown decreased rates in the presence of fetal growth restriction.¹³⁹⁻¹⁴¹

The significance of AFV with respect to fetal outcome has been well documented. Manning and coworkers reported the diagnostic value of AFV measurement in discriminating normal from aberrant fetal growth. Among 91 patients with normal AFV, 86 delivered infants whose birth weights were appropriate for gestational age. In contrast, 26 of 29 patients with decreased AFV delivered growth-restricted infants.¹⁴² Severe oligohydramnios is associated with a high risk of fetal compromise.^{143,144}

It is likely that the chronic hypoxic state frequently observed in the fetus with IUGR is responsible for diverting blood flow from the kidney to other organs that are more critical during fetal life (see Chapters 12 and 14). Nicolaides and associates¹⁴¹ observed reduced fetal urinary flow rates in IUGR, and the degree of reduction was well correlated with the degree of fetal hypoxemia as reflected by fetal blood PO₂ measured after cordocentesis.

The most appropriate technique for assessment of AFV, as well as the arguments for and against each technique, are addressed in Chapters 21 and 32. It is reasonable to conclude at this time that a single vertical pocket smaller than 2 cm, or an amniotic fluid index of less than 5 cm, or both, suggests that there is a clinically significant decrease in AFV; conversely, a normal AFV is very reassuring with respect to fetal well-being and also suggests the possibility of a normal but constitutionally small fetus.

There is a paucity of evidence from randomized trials to validate the use of the BPP.¹⁴⁵ However, its usefulness was suggested by several large observational reports. In a study of 19,221 high-risk pregnancies, Manning and colleagues¹⁴⁶ observed that the fetal death rate after a normal BPP score (≥ 8) was 0.726 in 1000 births; only 14 such fetuses died. Of the total patient population, approximately 4380 pregnancies were complicated by IUGR, and only 4 of those infants died after a normal test, yielding a false-negative test rate of less than 1 in 1000. In

a subsequent analysis of perinatal morbidity and mortality among patients monitored with the BPP, a highly significant inverse correlation was observed for IUGR and last test score. If the last test score was 8 or higher, only 3.4% of 6500 high-risk patients had infants with IUGR. Conversely, if the last test score was 4 or 2, the incidence of IUGR increased to 29% and 41%, respectively.¹⁴⁷

Doppler Ultrasound Assessment of the Fetal Vasculature

ARTERIAL CIRCULATION

There has been great interest in the role of Doppler assessment of the fetal arterial and venous circulation in predicting and evaluating fetal growth restriction as well as other fetal complications (see Chapter 21). It is now clear that umbilical arterial velocimetry is of considerable value in predicting perinatal outcome in the fetus with IUGR, and it is the only modality validated by randomized trials. A substantial pathologic correlation helps to explain the increased vascular resistance in IUGR. Specifically, fetuses demonstrating an absence of end-diastolic flow exhibited maldevelopment of the placental terminal villous tree. The correlations among placental pathology, abnormal umbilical artery velocimetry, and IUGR were reviewed by Kingdom and coworkers.¹⁴⁸

Several randomized trials have been reported which, taken together, demonstrated a decrease in perinatal deaths when umbilical arterial Doppler assessment was used in conjunction with other types of antenatal testing.¹⁴⁹⁻¹⁵¹ A meta-analysis of 12 randomized, controlled trials showed that clinical action guided by umbilical Doppler velocimetry reduced the odds of perinatal death by 38% and decreased the risk of inappropriate intervention in pregnancies thought to be at risk of IUGR.¹⁵² Although the authors hypothesized that this beneficial effect depended on the incidence of absent end-diastolic velocity rather than simply decreased flow, the number of studies with sufficient data was inadequate to draw this conclusion. A recent retrospective cohort study of 151 IUGR fetuses comparing abnormal umbilical artery Doppler, a “nonreactive” nonstress test, and a BPP value of 6 or less confirmed that abnormal Doppler flow was the best predictor of adverse outcome.¹⁵³

Therefore, umbilical artery velocimetry plays a significant role in the management of IUGR. A normal velocimetry result in the suspect small fetus is usually indicative of a constitutionally small but otherwise normal baby,¹⁵⁴ although a normal finding is also observed in the chromosomally or structurally abnormal fetus.¹⁵⁵ Diminished end-diastolic flow is rarely associated with significant neonatal morbidity, but the absence or reversal of end-diastolic flow predicts significantly increased perinatal morbidity and mortality and long-term poor neurologic outcome, compared with continuing diastolic flow.^{156,157} Furthermore, markedly diminished end-diastolic flow can be observed at very premature gestational ages, well before the BPP demonstrates abnormalities. Consequently, abnormal umbilical velocimetry findings should be interpreted in conjunction with other tests of fetal well-being and in the context of the gestational age.

There also has been interest in the evaluation of middle cerebral artery flow, inasmuch as the normal adaptive response to hypoxia within the fetus is to increase cerebral blood flow (“brain-sparing”). However, the results from several studies have been contradictory, and the focus of attention has been on umbilical artery flow and the venous circulation.

VENOUS CIRCULATION

In contrast to abnormalities in arterial circulation, abnormalities observed in the venous circulation presumably reflect central cardiac

failure, and multiple current studies suggest that specific aberrations of flow through the ductus venosus and umbilical vein are indicative of imminent fetal demise, as well as substantial morbidity among survivors. The temporal sequence of Doppler-measured flow abnormalities in the arterial and venous circulations of the IUGR fetus has been delineated.^{158,159} The fetus with severe IUGR first demonstrates changes in the umbilical and middle cerebral arteries. This is followed by alterations in the venous circulation, including the ductus venosus (abnormalities in the atrial portion of the flow) and the umbilical vein (pulsatile flow). These changes and their pathophysiology have been summarized in detail by Baschat and Harman.¹⁶⁰ What has become clear is that abnormal venous Doppler waveforms in the preterm IUGR fetus are indicative of poor acid-base status and outcome.^{161,162} Therefore, the challenge for the clinician is to try to optimize delivery timing in the very preterm fetus, before significant abnormalities in the venous circulation occur.

Antepartum Therapy

Maternal hyperoxia has been shown to increase umbilical PO₂ and pH in the hypoxemic, acidotic, growth-restricted fetus.¹⁶³ Among surviving fetuses, there was also an improvement in mean velocity of blood flow through the thoracic aorta. In support of these findings, Battaglia and coworkers treated 17 of 36 women whose pregnancies were complicated by IUGR with maternal hyperoxia and confirmed improvement in both blood gases and Doppler flow. They also observed a significant improvement in perinatal mortality in the oxygen-treated patients.¹⁶⁴ However, the evidence is inconclusive regarding whether chronic maternal oxygen therapy is of value, and any differences reported in outcome could be due to more advanced gestational age in oxygen-treated groups.¹⁶⁵

Nutritional supplements, including antioxidants such as vitamins C and E, have not been shown to be effective in reducing the risk of IUGR.¹⁶⁶ There has also been considerable interest in the role of fish oil supplements, but a Cochrane Database Review of six trials revealed no significant difference in the proportion of SGA infants in treated versus untreated groups.¹⁶⁷

The role of low-dose aspirin remains controversial, and most studies have examined subsets of women treated for the prevention of preeclampsia. A meticulous analysis of the current data revealed a 10% reduction in SGA infants, but this strong trend did not achieve statistical significance.¹⁶⁸ This subject was recently reviewed by Berghella.¹⁶⁹

Timing of Delivery

The prohibitive perinatal morbidity and mortality rates among IUGR infants were discussed previously. Controversy continues with regard to the timing of delivery for such infants to ensure that neurologic damage or fetal intrauterine death does not occur because of chronic oxygen deprivation. This problem is underscored by the fact that, if deaths among congenitally infected and anomalous infants are excluded, the perinatal risk is still higher for growth-restricted infants than for AGA newborns. Although opinions vary as to the role of preterm versus term delivery of the IUGR fetus, it is usually prudent to deliver the growth-restricted infant close to term, as long as growth continues and antenatal tests are reassuring. Tests of fetal lung maturation may be of value if the course of action is not entirely clear. In the case of the preterm fetus, delivery is indicated in the presence of worsening maternal hypertensive disease, failure of continuing growth, or reversal of umbilical artery flow as assessed by Doppler ultrasound. The preterm fetus (<34 weeks' gestation) should receive the benefit of corticosteroids for lung maturation.

The Growth Restriction Intervention Trial (GRIT) study underscored the difficulty in selecting the most appropriate delivery time to prevent morbidity.¹⁷⁰ In a randomized trial of 548 preterm IUGR pregnancies (24 to 36 weeks' gestation) in which fetal compromise was identified but uncertainty regarding delivery persisted, approximately half of the pregnancies were delivered and the other half continued until the clinical course was clear. There was no difference in mortality between the two groups. However, among infants with less than 31 weeks' gestation, severe disabilities were observed in 13% of the immediate deliveries, compared with 5% of those that were delayed.

The overall findings and guidelines for evaluation and management of the fetus with IUGR are summarized in Table 34-3.

TABLE 34-3 EVALUATION AND MANAGEMENT OF THE FETUS WITH INTRAUTERINE GROWTH RESTRICTION

Intrapartum Management

It has long been recognized that lower Apgar scores and meconium aspiration, as well as other manifestations of poor oxygenation during labor, occur with greater frequency among IUGR infants. The problem of intrapartum asphyxia has been further elucidated by studies demonstrating the acid-base status of growth-restricted infants at the time of delivery. If moderate-to-severe metabolic acidosis is defined as an umbilical artery buffer base value of less than 37 mEq/L (normal, >40 mEq/L), almost 50% of IUGR neonates show signs of acidosis at the time of delivery.¹⁷¹ These findings document the problems of oxygenation during labor in such fetuses and emphasize that meticulous fetal surveillance is required during this critical period.

Consequently, the clinician should proceed to cesarean delivery if there is evidence of deteriorating fetal status or an unripe cervix or if there is any indication of additional fetal compromise during labor.

Neonatal Complications and Long-term Sequelae

The growth-restricted fetus can experience numerous complications in the neonatal period related to the etiology of the growth insult as well as antepartum and intrapartum factors. These include neonatal asphyxia, meconium aspiration, hypoglycemia and other metabolic abnormalities, and polycythemia (see Chapter 58). After correction for gestational age, a large population-based outcomes analysis showed that the premature IUGR infant is at increased risk of mortality, necrotizing enterocolitis, and need for respiratory support at 28 days of age.¹⁷² This observation takes on more significance inasmuch as prematurity and IUGR frequently coexist.

Beyond the neonatal period, data by Low and colleagues¹⁷³ showed that fetal growth restriction has a deleterious effect on cognitive function, independent of other variables. With the use of numerous standardized tests to evaluate learning ability, and excluding those children with genetic or major organ system malformations, they found that almost 50% (37/77) of SGA children had learning deficits at ages 9 to 11 years. Blair and Stanley¹⁷⁴ also reported a strong association between IUGR and spastic cerebral palsy in newborns born after 33 weeks of gestation. This association was highest in IUGR infants who were short, thin, and of small head size. Newborns who were at or above the 10th percentile for weight but had abnormal ponderal indices were also at risk for spastic cerebral palsy.¹⁷⁵ In a recent Danish autopsy study, investigators observed a significantly lower cell number in the cortex of IUGR fetuses and infants compared with normal controls, a finding that may, in part, explain the clinical observations.¹⁷⁶ Other investigators have reported more favorable neurologic outcomes in IUGR infants.^{177,178}

There is currently substantial research effort to explore the role of IUGR and adult disease: the so-called “fetal origins of disease” hypothesis. This subject is addressed in Chapter 11. The epidemiologic studies of Barker’s group have indicated that IUGR is a significant risk factor for the subsequent development of chronic hypertension, ischemic heart disease, type 2 diabetes, and obstructive lung disease.¹⁷⁹ Maternal and fetal malnutrition seem to have both short- and long-term effects. The concept of programming during intrauterine life, however, needs to include a host of other factors, such as the genotype of both mother and fetus, maternal size and obstetric history, and postnatal and life-style factors.

Chapter 35

Pregnancy-Related Hypertension

James M. Roberts, MD, and Edmund F. Funai, MD

Classification of Hypertensive Disorders

Interpreting epidemiologic studies of the hypertensive disorders of pregnancy is difficult because the terminology is inconsistent.¹ Several systems of nomenclature are in use around the world. The system prepared by the National Institutes of Health (NIH) Working Group on Hypertension in Pregnancy,² although imperfect, has the advantage of clarity and is available in published form for investigators throughout the world. The NIH system has four main classes: chronic hypertension, preeclampsia and eclampsia, preeclampsia superimposed on chronic hypertension, and gestational hypertension.

Chronic Hypertension

Chronic hypertension is defined as hypertension that is observable before pregnancy or that is diagnosed before the 20th week of gestation. Hypertension is defined as a persistent blood pressure greater than 140/90 mm Hg. Hypertension for which a diagnosis is confirmed for the first time during pregnancy and that persists beyond the 84th day after delivery is also classified as chronic hypertension.

Preeclampsia and Eclampsia

The diagnosis of preeclampsia is determined by increased blood pressure accompanied by proteinuria. The diagnosis requires a systolic pressure of 140 mm Hg or higher or a diastolic pressure of 90 mm Hg or higher. Diastolic blood pressure is defined as the Korotkoff phase V value (i.e., disappearance of sounds). Gestational blood pressure elevation should be determined by at least two measurements, with the repeat blood pressure performed in a manner that reduces the likelihood of artifact and patient anxiety.³ Absent from the diagnostic criteria is the former inclusion of an increment of 30 mm Hg in systolic or 15 mm Hg in diastolic blood pressure, even when absolute values are below 140/90 mm Hg. This definition was excluded because available evidence shows that women in this group are not likely to suffer increased adverse outcomes.^{4,5} Nonetheless, women who have an increase of 30 mm Hg in systolic or 15 mm Hg in diastolic blood pressure warrant close observation, especially if proteinuria and hyperuricemia (i.e., uric acid ≥ 5.5 mg/dL)⁶ are also present.³

Proteinuria is defined as the urinary excretion of at least 300 mg of protein in a 24-hour specimen. This usually correlates with 30 mg/dL of protein (i.e., 1+ dipstick reading) or more in a random urine deter-

mination. Because of the discrepancy between random protein determinations and 24-hour urine protein values in women with preeclampsia (which can be higher or lower),⁷⁻⁹ the diagnosis should be based on a 24-hour urine specimen or on a timed collection corrected for creatinine excretion if a 24-hour collection is not feasible.³

Preeclampsia occurs as a spectrum but is arbitrarily divided into mild and severe forms. This terminology is useful for descriptive purposes but does not indicate specific diseases, nor should it indicate arbitrary cutoff points for therapy. The diagnosis of severe preeclampsia is confirmed when any of the following criteria are met¹⁰:

- Blood pressure of 160 mm Hg systolic or higher or 110 mm Hg diastolic or higher on two occasions at least 6 hours apart while the patient is on bed rest
- Proteinuria of 5 g or higher in a 24-hour urine specimen or 3+ or greater on two random urine samples collected at least 4 hours apart
- Oliguria of less than 500 mL in 24 hours
- Cerebral or visual disturbances
- Pulmonary edema or cyanosis
- Epigastric or right upper quadrant pain
- Impaired liver function
- Thrombocytopenia
- Fetal growth restriction

Eclampsia is the occurrence of seizures that cannot be attributed to other causes in a woman with preeclampsia.

Edema occurs in too many normal pregnant women to be discriminant and has been abandoned as a marker in preeclampsia by the National High Blood Pressure Education Program and by other classification schemes.^{11,12} Edema of the hands and face occurs in 10% to 15% of women whose blood pressure remains normal throughout pregnancy.¹³ Edema can be massive in women with severe preeclampsia, rendering the patient virtually unrecognizable (Fig. 35-1).

Preeclampsia Superimposed on Chronic Hypertension

There is ample evidence that preeclampsia can occur in women who are already hypertensive and that the prognosis for mother and fetus is much worse with both conditions than with either alone. Distinguishing superimposed preeclampsia from worsening chronic hypertension tests the skills of the clinician. For clinical management, the principles of high sensitivity and unavoidable overdiagnosis are appro-

FIGURE 35-1 Facial edema in severe preeclampsia. Markedly edematous facies of this severely preeclamptic woman (A) is especially evident when compared with her appearance 6 weeks after delivery (B).

appropriate, especially with advancing gestational age. The suspicion of superimposed preeclampsia mandates close observation, with delivery indicated by the overall assessment of maternal and fetal well-being rather than by any fixed end point. The diagnosis of superimposed preeclampsia is highly likely with the following findings:

1. In women with documented hypertension and no proteinuria before 20 weeks' gestation
 - New-onset proteinuria, defined as the urinary excretion of 0.3 g of protein or more in a 24-hour specimen
2. In women with hypertension and proteinuria before 20 weeks' gestation
 - A sudden increase in proteinuria
 - A sudden increase in blood pressure in a woman whose blood pressure has previously been well controlled
 - Objective evidence of involvement of multiple organ systems, such as thrombocytopenia (platelet count $< 100,000/\text{mm}^3$), an increase in liver transaminases to abnormal levels,³ or sudden worsening of renal function

Gestational Hypertension

A woman who has no proteinuria and a blood pressure elevation detected for the first time during pregnancy is classified as having gestational hypertension. This is a provisional diagnosis that includes women with preeclampsia who have not yet manifested proteinuria and women who do not have preeclampsia. The hypertension may be accompanied by other concerning signs or symptoms that can influence management. A final determination that the woman does not have preeclampsia can be made only after delivery. If preeclampsia has not developed and blood pressure has returned to normal by 12 weeks after delivery, the diagnosis of transient hypertension of pregnancy can

be assigned. If blood pressure elevation persists, the diagnosis is chronic hypertension. The diagnosis of gestational hypertension is used during pregnancy only until a more specific diagnosis can be assigned after delivery.³

Problems with Classification

The degree of blood pressure elevation that constitutes gestational hypertension is controversial. Because average blood pressure in women younger than 30 years is 120/60 mm Hg, the standard definition of hypertension (i.e., blood pressure $> 140/90$ mm Hg) is judged by some to be too high,¹⁴ resulting in the suggestion that women with blood pressure increases greater than 30 mm Hg systolic or 15 mm Hg diastolic should be observed closely even if absolute blood pressure has not exceeded 140/90 mm Hg.³

Blood pressures measured in early pregnancy to diagnose chronic hypertension are problematic. Blood pressure usually decreases early in pregnancy, reaching its nadir at about the time women often present for obstetric care (Fig. 35-2). The decrease averages 7 mm Hg for diastolic and systolic readings. In some women, blood pressure may decline by more than 7 mm Hg; in others, the early decline and subsequent return of blood pressure to pre-pregnant levels in late gestation may satisfy criteria for a diagnosis of preeclampsia. Women with hypertension before pregnancy have a greater decrease in blood pressure in early pregnancy than do normotensive women,¹⁵ and they are more likely to be misdiagnosed as preeclamptic according to blood pressure criteria.

The diagnosis of chronic hypertension based on the failure of blood pressure to return to normal by 84 days after delivery can be in error. In a long-range, prospective study by Chesley,¹⁶ many women who remained hypertensive 6 weeks after delivery were normotensive at long-term follow-up. Neither proteinuria nor hypertension is specific

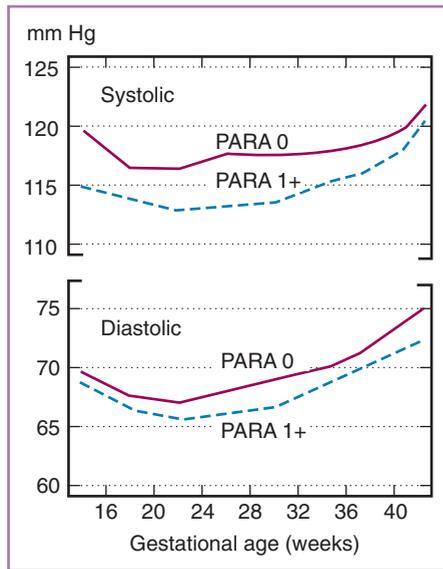

FIGURE 35-2 Blood pressure correlated with gestational age. The mean blood pressure was plotted against gestational age for 6000 white women between the ages of 25 and 34 years who delivered singleton term infants. TABLE 35-1 RENAL BIOPSY FINDINGS IN PATIENTS WITH A CLINICAL DIAGNOSIS OF PREECLAMPSIA		
Biopsy Findings	Primigravidas (n = 62)	Multigravidas (n = 152)
Glomeruloendotheliosis with or without nephrosclerosis	70%	14%
Normal histology	5%	53%
Chronic renal disease, chronic glomerulonephritis, or chronic pyelonephritis	25%	21%
Arteriolar nephrosclerosis	0%	12%

Modified from McCartney CP: Pathological anatomy of acute hypertension of pregnancy. *Circulation* 30(Suppl II):37, 1964; by permission of the American Heart Association, Inc.

to preeclampsia, and their presence in pregnancy can have other explanations.

Renal biopsy specimens from women with preeclampsia demonstrate these diagnostic difficulties (Table 35-1).¹⁷ Of 62 women with a diagnosis of preeclampsia in their first pregnancies, 70% had a glomerular lesion believed to be characteristic of the disorder, but 24% had evidence of chronic renal disease that was not previously suspected. Renal biopsy specimens of multiparous women with a clinical diagnosis of superimposed preeclampsia also demonstrate the uncertainty of diagnosis. Of 152 subjects, only 3% had the characteristic glomerular lesion, but 43% had evidence of preexisting renal or vascular disease.

Preeclampsia has a clinical spectrum ranging from mild to severe forms. The illness in affected women does not begin with eclampsia or the severe manifestations of preeclampsia. Rather, the disease pro-

gresses at various rates. In most cases, progression is slow, and the disorder may remain mild. In others, the disease can progress rapidly, changing from mild to severe over days to weeks or, in fulminant cases, progressing in days or hours.

In a series of eclamptic women analyzed by Chesley,¹⁸ 25% had evidence of only mild preeclampsia in the days preceding convulsions. For purposes of clinical management, overdiagnosis must be accepted because prevention of the serious complications of preeclampsia and eclampsia requires increased sensitivity and early treatment, primarily through the timing of delivery. For this reason, studies of preeclampsia are necessarily confounded by inclusion of women diagnosed as preeclamptic who have another cardiovascular or renal disorder.

HELLP Syndrome

The pathophysiologic changes of preeclampsia can occur in the absence of hypertension and proteinuria. This is not surprising, because the traditional diagnostic criteria have more historical than pathophysiologic relevance.¹⁸ This situation presents a challenge to clinicians and demands that they remain alert to the possibility of preeclampsia in pregnant women with signs and symptoms that may be explained by reduced organ perfusion. One clear setting in which this occurs is the HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*), a combination of findings that defines a reasonably consistent syndrome.¹⁹

For management purposes, it is appropriate to consider HELLP as a variant of preeclampsia, but they may be different entities. Women with HELLP are more often older, white, and multiparous than preeclamptic women. Not all women with HELLP have hypertension.²⁰ From a pathophysiologic perspective, changes in the renin-angiotensin system characteristic of preeclampsia are not present in HELLP.²¹ Nonetheless, progression of the disease and its termination with delivery argue for an observation and management strategy similar to that for preeclampsia.

Preeclampsia and Eclampsia

Epidemiology of Preeclampsia and Eclampsia

Despite the difficulties in clinical diagnosis, there exists a disorder unique to pregnancy characterized by poor perfusion of many vital organs (including the fetoplacental unit) that is completely reversible with the termination of pregnancy. Pathologic, pathophysiologic, and prognostic findings indicate that preeclampsia is not merely an unmasking of preexisting, underlying hypertension. Although the unique nature of preeclampsia has been well documented for many years, controversies in therapy persist because of management strategies based on principles used to treat hypertension in nonpregnant individuals. The successful management of preeclampsia requires an understanding of the pathophysiologic changes in this condition and recognition that the signs of preeclampsia (i.e., increased blood pressure and proteinuria) are only signs and do not cause the other features of preeclampsia.

Women at Risk

Preeclampsia occurs in about 4% of pregnancies that continue past the first trimester. Nulliparity is the most common feature of women who develop preeclampsia. At least two thirds of cases occur in the first pregnancy that progresses beyond the first trimester. Other risk

factors for preeclampsia are similar in nulliparous and parous women.²²

Although preeclampsia was thought to be more common among women of lower socioeconomic status, this impression may be a consequence of the associations of preeclampsia with age, race, and parity. Studies of pregnant women in Scotland²³ from Aberdeen,²⁴ Finland,²⁵ and Israel²⁶ found that preeclampsia was not related to socioeconomic status. Eclampsia, in contrast, is clearly more common in women of lower socioeconomic status,^{23,25,26} related to the lack of availability of quality obstetric care for indigent women. Remarkably, preeclampsia and eclampsia were once thought to occur more frequently in women of higher socioeconomic status.¹⁸

There is a relationship between the extremes of childbearing age and the incidence of eclampsia and preeclampsia. Because most first pregnancies occur in young women, most cases of preeclampsia and eclampsia occur in this age group, but the association with young maternal age is lost when parity is considered. In the studies cited,^{23,25,26} a higher incidence of preeclampsia was found in older women independent of parity.

The relationship of preeclampsia and eclampsia to race is complicated by the higher prevalence of chronic hypertension in African Americans and the difficulty in differentiating preeclampsia from unrecognized preexisting chronic hypertension. Some studies indicate a relationship.^{26,27} In a small case-control study of carefully defined preeclampsia, black race was a significant risk factor only in nulliparous women (odds ratio [OR] = 12.3; 95% confidence interval [CI], 1.6 to 100.8).²⁸ Other studies support a more modest increased risk in African-American women.^{29,30} Studies that include the more severe forms of preeclampsia more often suggest an increased incidence among African-American women.²⁸

In contrast, the incidence of rigorously defined preeclampsia did not differ by race after other risk factors were controlled in two large, prospective trials of medical prophylaxis that enrolled 2947³¹ and 4314³² nulliparous women. Maternal nonwhite race appears to be related more to the severity than the incidence of disease.

A diverse array of medical disorders that often coexist with pregnancy, including diabetes, chronic hypertension, chronic renal disorders, and rheumatologic conditions, have been associated with preeclampsia. The existence and severity of diabetes have been associated with an increased risk for preeclampsia, and diabetic microvascular disease further increases this risk. This relationship has been found in Sweden³³ and in the United States.³⁴ Both studies^{33,34} demonstrated that the risk of preeclampsia was approximately 20% and 21% in 491 and 462 pregnancies, respectively. This estimate is far more modest than the 50% incidence reported in historical cohorts.¹⁸ The preeclampsia risk increased according to the severity of disease, with an 11% to 12% risk among women with class B diabetes and 21% to 23% with class C and D diabetes. Microvascular disease increased this risk to 36% to 54% in diabetics with class F or R disease.^{33,34}

Chronic renal insufficiency and hypertension are well-recognized risk factors. Of women with hypertension antedating pregnancy, 25% develop preeclampsia.^{35,36} Renal insufficiency with^{33,37} and without diabetes³⁸⁻⁴⁰ also is an important risk factor.^{38,40}

Connective tissue disorders such as systemic lupus erythematosus^{41,42} and antiphospholipid antibody syndrome⁴³⁻⁴⁵ have been reported as risk factors for preeclampsia. With lupus, the risk is particularly elevated with hypertension or nephropathy.^{46,47} However, data concerning an association between isolated antiphospholipid antibodies and preeclampsia have been conflicting, with some studies demonstrating no relationship^{48,49} and others confirming the association.^{44,50}

Obesity is a risk factor for preeclampsia.^{28,51} In the National Institute of Child Health and Human Development (NICHD) study of aspirin to prevent preeclampsia in low-risk pregnancies,³¹ the incidence of preeclampsia increased with maternal body mass index. Even in women of normal weight, there is a linear relationship between pre-pregnancy body mass index and the frequency of preeclampsia.⁵² The mechanism may be related to increased insulin resistance, because preeclampsia is more common in another setting of increased insulin resistance: gestational diabetes.⁵³ With a threefold increased risk for obese women and with 35% to 50% of women of reproductive age in the United States being obese, obesity has become a major attributable risk factor for preeclampsia, which is associated with more than one third of cases of preeclampsia.

Certain conditions of pregnancy increase the risk of preeclampsia. The incidence is increased among parous and nulliparous women with multiple gestations, although to a larger degree in the latter.^{36,54} In a study of 34,374 pregnancies with singleton, twin, triplet, or quadruplet pregnancies, the incidence of preeclampsia increased with each additional fetus. The incidences were 6.7%, 12.7%, 20.0%, and 19.6%, respectively.⁵⁵ The disease process may be initiated earlier and may be more severe in these cases.⁵⁴

Preeclampsia affects 70% of women with large, rapidly growing hydatidiform moles and occurs earlier than usual during gestation.⁵⁶ In cases of preeclampsia occurring before 24 weeks' gestation, hydatidiform mole should be suspected and sought.

An interesting variant of preeclampsia is the *mirror syndrome*, in which the mother's peripheral edema mirrors the fetal hydrops. It occurs with fetal hydrops, although not with erythroblastosis uncomplicated by hydrops. The incidence approaches 50% of pregnancies complicated by hydrops. The mirror syndrome is not confined to hydrops resulting from isoimmunization. In one series, mirror syndrome occurred in 9 of 11 pregnancies with hydropic infants of non-immune origin.⁵⁷ This condition can manifest early in pregnancy with severe signs and symptoms of preeclampsia, and it has resolved with treatment of the underlying process.⁵⁸⁻⁶⁰ Proteinuria is massive, and blood pressure elevation and edema are marked. Eclampsia occurs rarely (see Chapter 26).

Short-Term Prognosis for Preeclampsia PERINATAL MORTALITY

The perinatal mortality rate is increased in infants of preeclamptic women.⁶¹⁻⁶³ In a study that examined 10,614,679 singleton pregnancies in the United States from 1995 to 1997 after 24 weeks' gestation, the relative risk for fetal death was 1.4 for infants born to women with any of the gestational hypertensive disorders and 2.7 for those born to women with chronic hypertensive disorders compared with low-risk controls. Causes of perinatal death are placental insufficiency and abruptio placentae,⁶⁴ which cause intrauterine death before or during labor, and prematurity. Predictably, the mortality rate is higher for infants of women with more severe forms of the disorder. At any level of disease severity, the perinatal mortality rate is greatest for women with preeclampsia superimposed on preexisting vascular disease.

The stillbirth rate attributable to preeclampsia has declined dramatically in the past 35 years. However, infants born of preeclamptic pregnancies continue to have an approximately twofold increased risk for neonatal death.⁶⁵ Although neonatal survival rates have improved dramatically, delivery before 34 weeks' gestation continues to be associated with an increased risk of long-range neurologic disability (see Chapter 58).

Growth restriction is more common in infants born to preeclamptic women (see Chapter 34) and more pronounced with increasing

severity and earlier diagnosis.⁶⁶ As with perinatal mortality, intrauterine growth restriction (IUGR) is more common in infants of chronically hypertensive women with superimposed preeclampsia.⁶⁷

The dramatic decrease in perinatal mortality rate among infants of preeclamptic women is the result in part of improved medical and obstetric management, including improved assessment of fetal well-being in the antepartum and intrapartum periods. The primary effect on the perinatal mortality rate, however, has come from improvements in neonatal care.

MATERNAL MORTALITY

Maternal death associated with preeclampsia predominantly results from complications of abruptio placentae, hepatic rupture, and eclampsia. Historically, the mortality rate of eclamptic women was most effectively reduced by avoiding iatrogenic complications related to overmedication and overzealous attempts at vaginal delivery. In series from the late 19th century, when immediate delivery was the practice, the mortality rate of eclamptic women was 20% to 30%. Expectant management with profound maternal sedation with narcotics and hypnotics in the early 20th century was associated with a 10% to 15% mortality rate. The change to magnesium as the exclusive agent in the 1920s and 1930s resulted in a maternal mortality rate of 5%. Although magnesium was undoubtedly helpful, the primary factor responsible for improved mortality was decreased maternal sedation.¹⁸ The currently used combination of magnesium sulfate (MgSO₄) and antihypertensive drugs as sole pharmacologic agents, followed by timely delivery, has produced a maternal mortality rate of almost zero^{68,69} because of an appreciation of the profound pathophysiologic abnormalities of preeclampsia, careful cardiopulmonary monitoring, and limitation of unproven interventions.

RECURRENCE IN SUBSEQUENT PREGNANCIES

Data from classic series indicate that the likelihood of recurrent preeclampsia is influenced by the certainty of the clinical diagnosis in the first pregnancy. Of 225 women with hypertension during pregnancy chosen for study without regard to parity, 70% had a recurrence of preeclampsia in their next pregnancy.⁷⁰ In a study of primiparas with severe preeclampsia, the recurrence rate was 45%.⁷¹ Because the diagnosis in these studies was based solely on clinical findings, these groups probably included patients with unrecognized preexisting blood pressure elevation or underlying renal or cardiovascular disease.

Recurrence rates were reported in 2006 for 896 parous women in Iceland according to standardized diagnostic criteria in both pregnancies (i.e., National High Blood Pressure Criteria³). The rates of recurrence differed substantially by the diagnosis in the first pregnancy, as seen in Table 35-2.⁷²

To determine the subsequent pregnancy outcomes of women who clearly had preeclampsia, Chesley and colleagues⁷⁴ followed 270 women with eclampsia for more than 40 years; only two were lost to follow-up. Among 187 women who had eclampsia in the first pregnancy, 33% had a hypertensive disorder in any subsequent pregnancy. In most, the condition was not severe, but 5% had recurrent eclampsia. Twenty women with eclampsia as multiparas had recurrent hypertension in 50% of subsequent pregnancies.

Women with a clinical diagnosis of preeclampsia have increased risk for hypertensive disorders in subsequent pregnancies. The chances of recurrence decrease as the likelihood of true preeclampsia increases. If the condition does recur, it will usually not be worse, and if preeclampsia truly arose de novo, it probably will be less severe in subsequent pregnancies. Some women, however, are normotensive between pregnancies but have recurrent preeclampsia. The risk of such recurrence is increased when preeclampsia occurs in the late second or early third trimester.⁷³ The recurrence of severe preeclampsia or eclampsia in one pregnancy predicts its likely recurrence in subsequent pregnancies.

Preeclampsia and Cardiovascular Disease in Later Life

Evidence that preeclampsia is associated with long-term maternal health consequences is based on the work of Chesley and coworkers,⁷⁴ who followed a cohort of white women with eclampsia in their first pregnancy and reported no increased risk of subsequent chronic hypertension. However, mortality was twofold to fivefold higher over the next 35 years among women with eclampsia in any pregnancy after the first (Fig. 35-3). The findings of Chesley and colleagues⁷⁴ led to speculation that multiparous women with preeclampsia or eclampsia were more likely to have had unrecognized underlying chronic hypertension and that this, not preeclampsia, caused the subsequent increase in mortality. Sibai and associates⁷¹ also found that women with recurrent preeclampsia were more likely to develop chronic hypertension. These studies are the basis for a statement by The National High Blood Pressure Education Program’s Working Group on High Blood Pressure during Pregnancy that recurrent hypertension in pregnancy, preeclampsia in a multipara, and early-onset disease in any pregnancy may all herald increased future health risks.²

Women with idiopathic preeclampsia (i.e., preeclampsia occurring in nulliparous women without underlying renal or cardiovascular disease, including chronic hypertension) were not thought to have increased risk of later vascular disease until a report from Norway⁷⁵ found modest (1.65-fold) increased cardiovascular mortality for nulliparous women with preeclampsia at term and an eightfold increased risk when preeclampsia was severe enough to lead to preterm delivery.

TABLE 35-2 TYPE OF RECURRENT HYPERTENSION DURING THE SECOND PREGNANCY BY TYPE OF HYPERTENSION IN THE FIRST PREGNANCY

First Pregnancy	Second Pregnancy*					
	Normal	Gestational Hypertension	Preeclampsia	Chronic Hypertension	Superimposed Preeclampsia	All Recurrences
Gestational hypertension (n = 511)	153 (29.9%)	239 (46.8%)	25 (4.9%)	82 (16%)	12 (2.3%)	358 (70.1%)
Preeclampsia/eclampsia (n = 151)	63 (41.7%)	52 (34.4%)	17 (11.3%)	16 (10.6%)	3 (2%)	88 (58.3%)
Chronic hypertension (n = 200)	24 (12%)	69 (34.5%)	6 (3%)	91 (45.5%)	10 (5%)	176 (88%)
Superimposed preeclampsia (n = 34)	2 (5.9%)	10 (29.4%)	4 (11.8%)	14 (41.2%)	4 (11.8%)	32 (94%)
Total (N = 896)	242 (27%)	370 (41.3%)	52 (5.8%)	203 (22.7%)	29 (3.2%)	654 (73%)

*No women had eclampsia in the second pregnancy.

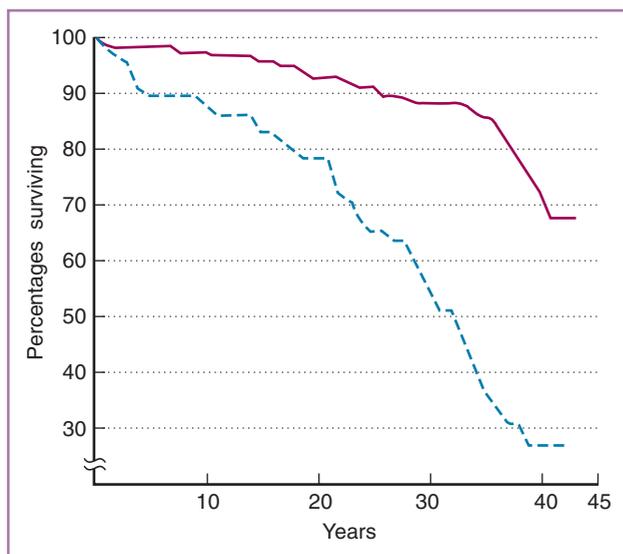

FIGURE 35-3 Eclampsia survivorship. Survival times are plotted for women with eclampsia in the first pregnancy (*solid line*) and those with eclampsia in a later pregnancy (*dashed line*). Survival of women with first-pregnancy eclampsia was not different from survival of a control group. (From Chesley LC, Anitto JE, Cosgrove RA: The remote prognosis of eclamptic women: Sixth periodic report. *Am J Obstet Gynecol* 124:446, 1976, Courtesy of the American College of Obstetricians and Gynecologists.)

Scottish investigators reported a fourfold increased risk of subsequent hypertension in nulliparous women with preeclampsia^{2,76,77} (OR = 3.98; CI, 2.82 to 5.61). Funai and colleagues⁷⁸ described excess long-term mortality in women with prior preeclampsia that was largely attributed to a threefold increase in deaths due to cardiovascular disease. Other reports support a link between preeclampsia and maternal ischemic heart disease,^{79,80} which is sometimes evident 20 years after the preeclamptic pregnancy and coincident with the onset of menopause.^{78,80} A family history of cardiovascular disease increases the association between preeclampsia and cardiovascular outcomes.⁸¹ Obesity is a known risk factor for preeclampsia and cardiovascular disease. Although controlling for obesity attenuates the increased risk of death for postmenopausal women, this risk is not fully explained by obesity alone.⁸²

The relationships among obesity, insulin resistance, and preeclampsia are part of an interesting relationship of preeclampsia to the metabolic or insulin resistance syndrome.⁸³ This syndrome predisposes to cardiovascular disease in later life and consists of obesity, hypertension, dyslipidemia (i.e., increased low-density lipoprotein [LDL] cholesterol, decreased high-density lipoprotein [HDL] cholesterol, and increased triglycerides), and increased uric acid, all of which are found in women with preeclampsia.⁸³ Other conditions predisposing to later-life cardiovascular disease—including elevated levels of homocysteine,⁸⁴ evidence of androgen excess (including polycystic ovarian syndrome),⁸⁵ elevated testosterone levels,⁸⁶ male fat distribution (i.e., increased waist-to-hip ratio),⁸⁷ and lipoprotein lipase mutations⁸⁸—are also linked to an increased risk for preeclampsia.

Women who appear normal years after a preeclamptic pregnancy may nevertheless demonstrate subtle metabolic and cardiovascular abnormalities. Compared with women with uncomplicated pregnancies, formerly preeclamptic women have evidence of endothelial dysfunction,^{89,90} higher blood pressures,⁸⁹ increased insulin resistance,⁹¹

TABLE 35-3 SIGNS AND SYMPTOMS OF PREECLAMPSIA OR ECLAMPSIA

Cerebral	Blurred vision
Headache	Amaurosis
Dizziness	Gastrointestinal
Tinnitus	Nausea
Drowsiness	Vomiting
Change in respiratory rate	Epigastric pain
Tachycardia	Hematemesis
Fever	Renal
Visual	Oliguria
Diplopia	Anuria
Scotomata	Hematuria
	Hemoglobinuria

dyslipidemia,⁹² altered angiogenic factors,⁹³ and increased antibodies to the angiotensin-2 receptor.⁹⁴ These data may explain the common risk factors for preeclampsia and cardiovascular disease, but alternative explanations, such as that preeclampsia causes vascular injury that increases cardiovascular risk or that normal pregnancies have a protective effect, cannot be excluded.

Clinical Presentation

Preeclampsia can manifest with a wide spectrum of disease, ranging from life-threatening neurologic, renal, hepatic, and coagulation abnormalities to mild findings of preeclampsia with minimal end-organ involvement. The fetus may be severely compromised by the maternal condition and by extreme preterm delivery or only minimally affected. These variations have puzzled clinicians and researchers for many years. An understanding of the pathophysiology of the disorder provides insight into the diverse clinical presentations.

Symptoms

Most women with early preeclampsia are asymptomatic. The absence of symptoms is the rationale for frequent obstetric visits in late pregnancy. In most cases, signs such as increased blood pressure and proteinuria antedate overt symptoms.

The various symptoms associated with preeclampsia, especially preeclampsia of increasing severity, are listed in Table 35-3. Because preeclampsia is a disease of generalized poor perfusion, the diversity of symptoms related to many organ systems is not surprising. Symptoms suggesting hepatic, neurologic, and visual involvement are particularly worrisome. They include epigastric pain, “stomach upset,” and pain penetrating to the back. Headache and mental confusion indicate poor cerebral perfusion and may be precursors of convulsions. Visual symptoms ranging from scotomata to blindness indicate retinal arterial spasm and edema. Symptoms suggesting congestive heart failure or abruptio placentae also represent significant complications of preeclampsia. Other symptoms, such as tightness of hands and feet and paresthesias resulting from medial or ulnar nerve compression, may alarm the patient but have little prognostic significance.

Signs

Signs of preeclampsia usually antedate symptoms. The most common sequence is increased blood pressure followed by proteinuria.¹⁸

BLOOD PRESSURE CHANGE

An increase in blood pressure is required for the diagnosis of preeclampsia. Blood pressure variation in normal pregnancy can

lead to misdiagnosis. In clinical practice, the serious effects of preeclampsia on the mother and fetus warrant such overdiagnosis. The primary pathophysiologic alteration, poor tissue perfusion resulting from vasospasm, is revealed more by blood pressure changes than by absolute blood pressure levels. Although a diagnosis of preeclampsia is not made without absolute blood pressure increases to 140 mm Hg systolic or 90 mm Hg diastolic, women who reach this level from a low early pregnancy value typically manifest more vasospasm than those for whom 140/90 mm Hg represents a smaller increase.

Although maternal and fetal risks rise with increasing blood pressure,⁹⁵ serious complications can occur in women who experience only modest blood pressure elevation. In two series, 20% of women with eclampsia never had a systolic blood pressure above 140 mm Hg.^{18,96} In a large, prospective study from the United Kingdom, there were 383 confirmed cases of eclampsia, of which 77% were hospitalized before seizures occurred. Of these, 38% of the cases were not preceded by documented proteinuria or hypertension.⁹⁷ Others have noticed similar findings.^{98,99}

PROTEINURIA

Among the diagnostic signs of preeclampsia, proteinuria in the presence of hypertension is the most reliable indicator of fetal jeopardy. In two studies of preeclampsia, the perinatal mortality rate tripled for women with proteinuria,¹⁰⁰ and the amount of proteinuria correlated with increased perinatal mortality rate and the number of growth-restricted infants.¹⁰¹ A later study demonstrated that the risk for delivering a small-for-gestational-age fetus was higher in women with hypertension and proteinuria (52%) compared with women with new-onset gestational hypertension (15%) or chronic hypertension (12%). The perinatal mortality rate was fourfold higher with proteinuria and hypertension than in pregnancies complicated by hypertension alone.¹⁰²

RETINAL CHANGES

Retinal vascular changes on fundoscopic examination occur in retinal arterioles in at least 50% of women with preeclampsia, and they are important because they correlate best with renal biopsy-proven changes of preeclampsia.¹⁰³ Localized retinal vascular narrowing is visualized as segmental spasm, and the generalized narrowing is indicated by a decrease in the ratio of arteriolar-venous diameter from the usual 3:5 to 1:2 or even 1:3. It can occur in all vessels or, in early stages, in single vessels.¹⁰⁴ Preeclampsia does not cause chronic arteriolar changes; the presence of arteriolar sclerosis detected by increased light reflex, copper wiring, or arteriovenous nicking indicates preexisting vascular disease.

HYPERREFLEXIA

Although hyperreflexia is given much clinical attention and deep tendon reflexes are increased in many women before seizures, convulsions can occur in the absence of hyperreflexia,⁶⁸ and many pregnant women are consistently hyperreflexic without being preeclamptic. Changes, or lack thereof, in deep tendon reflexes are not part of the diagnosis of preeclampsia.

OTHER SIGNS

Other signs that occur less commonly in preeclampsia are indicators of involvement of specific organs in the preeclamptic process. Women with marked edema may have ascites and hydrothorax, and those with congestive heart failure display increased neck vein distention, gallop rhythm, and pulmonary rales. Hepatic capsular distention, manifested by hepatic enlargement and tenderness, is a particular concern, as is disseminated intravascular coagulation (DIC) sufficient to cause petechiae or generalized bruising and bleeding.

Laboratory Findings

Major changes revealed by laboratory studies occur in severe preeclampsia and eclampsia. In the patient with mild preeclampsia, changes in most of these indicators may be minimal or absent.

RENAL FUNCTION STUDIES

Serum Uric Acid Concentration and Urate Clearance. Uric acid is the most sensitive laboratory indicator of preeclampsia available to clinicians. A decrease in uric acid clearance precedes a measurable decrease in the glomerular filtration rate (GFR). Hypertension with hyperuricemia but without proteinuria was associated with growth restriction as commonly as hypertension and proteinuria without elevated uric acid in one series.¹⁰⁵ Although increased serum uric acid concentration is often attributed to altered renal function, an alternative view favors increased production caused by oxidative stress.¹⁰⁶ An elevated uric acid level may itself have pathogenic effects.¹⁰⁷ Table 35-4 shows normal uric acid levels during gestation and levels associated with preeclampsia.

Serum Creatinine Concentration and Creatinine Clearance. Creatinine clearance is decreased in most patients with severe preeclampsia, but it can be normal in women with mild disease. Serial serum creatinine determinations may indicate decreased clearance, but single values are not helpful unless markedly elevated because of the wide range of normal values. The serum creatinine concentration varies as a geometric function of creatinine clearance so that small changes in glomerular filtration are best determined by measurements of creatinine clearance.

TABLE 35-4 PLASMA URATE CONCENTRATIONS IN NORMOTENSIVE AND HYPERTENSIVE PREGNANT WOMEN

Weeks of Gestation	Normotensive Patients			Hypertensive Patients		
	mmol/L	SD*	mg/dL	mmol/L	SD*	mg/dL
24-28	0.18	(20%)	3.02	0.24	(20%)	4.03
29-32	0.18	(35%)	3.02	0.28	(25%)	4.7
33-36	0.20	(30%)	3.36	0.30	(20%)	5.04
37-40	0.26	(20%)	4.4	0.31	(23%)	5.28
41-42	0.25	(24%)	4.2	0.32	(12%)	5.38

*Each number in parentheses is the standard deviation given as a percentage of the mean values shown. Values for hypertensive and normotensive women are statistically different at all gestational ages ($P < .05$).

Modified from Shuster E, Weppelman B: Plasma urate measurements and fetal outcome in preeclampsia. *Gynecol Obstet Invest* 12:162, 1981.

LIVER FUNCTION TESTS

Although most tests of liver function are not highly predictive of severity of preeclampsia,¹⁸ the association between microangiopathic anemia and elevations in aspartate aminotransferase (AST) and alanine aminotransferase (ALT) carries an especially disturbing prognosis for the mother and infant.^{19,108} These findings usually correlate with the severity of disease and, when associated with hepatic enlargement, may be a sign of impending hepatic rupture.

COAGULATION FACTORS

Although overt DIC is rare, subtle evidence of activation of the coagulation cascade occurs in many women with preeclampsia. The average platelet count in the patient with mild preeclampsia is similar to the platelet count in normal pregnant women.¹⁰⁹ However, careful platelet counts performed sequentially may reveal decreased platelets in many patients.¹¹⁰ Highly sensitive indicators of activation of the clotting system, reduced serum concentrations of antithrombin III,¹¹¹ a decrease in the ratio of factor VIII bioactivity to factor VIII antigen,¹¹² and subtle indicators of platelet dysfunction, including alteration of turnover,⁶ activation,¹¹³ size,¹¹⁴ and content,¹¹⁵ exist in even mild preeclampsia and may antedate clinically evident disease.

METABOLIC CHANGES

Preeclampsia is characterized by an increase in the insulin resistance of normal pregnancy. Signs of the insulin resistance syndrome are exaggerated.¹¹⁰ Levels of circulating lipids already elevated in normal pregnancy¹¹⁶ are accentuated in women with preeclampsia.¹¹⁷ Triglycerides and fatty acid levels are elevated, changes that antedate clinically evident disease by weeks to months.^{118,119} Levels of the cardioprotective HDL cholesterol are reduced in preeclamptic women,¹²⁰ whereas levels of a variant of LDL cholesterol (i.e., small, dense cholesterol that is strongly associated with cardiovascular disease) are increased.^{121,122} These changes resolve after delivery.

Pathologic Changes in Preeclampsia

The pathologic changes found in organs of women dying of eclampsia and in biopsy specimens from women with preeclampsia provide strong evidence that preeclampsia is not merely an unmasking of essential hypertension or a variant of malignant hypertension. These findings also indicate that the elevation of blood pressure probably does not have primary pathogenetic importance.

Brain

Cerebral edema, once thought to be a common finding in women dying of eclampsia, was uncommon among postmortem examinations performed within 2 to 3 hours of death.¹²³ However, studies using computed tomography again raised the possibility that cerebral edema is an important pathophysiologic event in some women with preeclampsia.¹²⁴ Noninvasive studies of cerebral blood flow and resistance suggest that vascular barotrauma and loss of cerebral vascular autoregulation contribute to the pathogenesis of cerebral vascular pathology in cases of preeclampsia or eclampsia.¹²⁵

Liver

Gross lesions of the liver are visible in about 60% of women dying of eclampsia, and one third of the remaining livers are microscopically abnormal. Many early investigators thought that the hepatic changes were pathognomonic for eclampsia,¹²⁶ but similar changes have been described in women dying of abruptio placentae.¹²⁷

Two temporally and etiologically distinct hepatic lesions have been described.¹²³ Initially, hemorrhage into the hepatic cellular columns

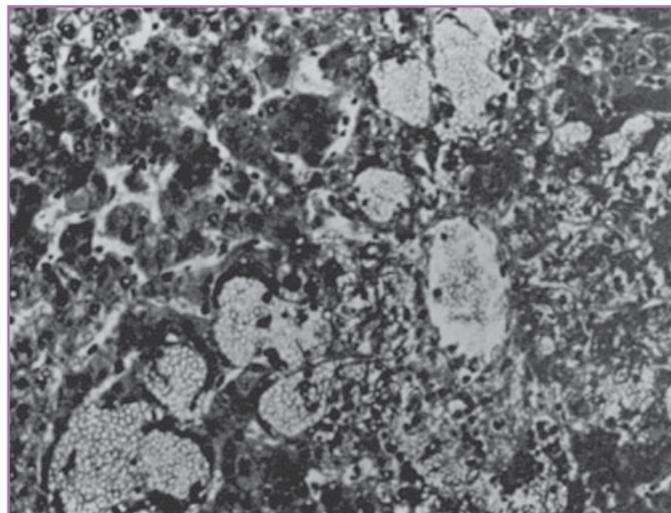

FIGURE 35-4 Hemorrhagic hepatic lesions in eclampsia. Hemorrhage into the periportal area occurred with crescentic compression of liver cells. (From Sheehan HL, Lynch JB: *Pathology of Toxemia in Pregnancy*. London, Churchill Livingstone, 1973.)

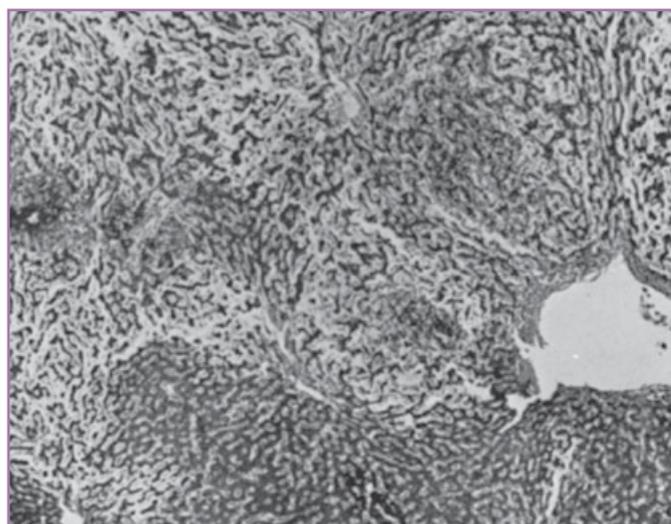

FIGURE 35-5 Hepatic infarction in eclampsia. Hepatic infarction caused by intense vasospasm manifests as small to large areas beginning near the sinusoids and extending into the area near the portal vessels. (From Sheehan HL, Lynch JB: *Pathology of Toxemia in Pregnancy*. London, Churchill Livingstone, 1973.)

results from vasodilatation of arterioles, producing dislocation and deformation of the hepatocytes in their stromal sleeves (Fig. 35-4). Later, intense vasospasm causes hepatic infarction, ranging from small to large areas beginning near the sinusoids and extending into the area near the portal vessels (Fig. 35-5). Hemorrhagic changes are present in 66% and necrotic changes in 40% of eclamptic women and in about one half as many preeclamptic women. Hyalinization and thrombosis of hepatic vessels have been cited as evidence of DIC, but they may be the result of hemorrhage.

Kidney

The pathologic renal changes of preeclampsia and eclampsia are clearly different from those seen in other hypertensive or renal disorders.

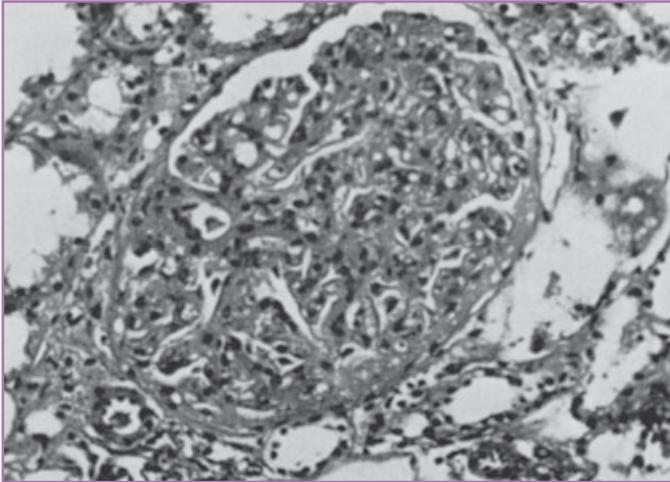

FIGURE 35-6 Glomerular changes in preeclampsia are identified by light microscopy. The enlarged glomerulus completely fills Bowman's capsule. Diffuse edema of the glomerular wall is indicated by the vacuolated appearance. The visible capillary loops are extremely narrow, and there are virtually no red blood cells in the capillary tuft.

Glomerular, tubular, and arteriolar changes have been described. The glomerular lesion is considered by some to be pathognomonic of preeclampsia and eclampsia, but identical changes have been seen in placental abruption without evident preeclampsia.¹²⁸ This change is not seen in any other form of hypertension.

GLOMERULAR CHANGES

Changes seen by light microscopy in glomeruli that are characteristic of preeclampsia include¹⁰³ decreased glomerular size, with protrusion of the glomerular tuft into the proximal tubule. The diameter of the glomerular capillary lumen is decreased and contains few blood cells. The endothelial-mesangial cells have increased cytoplasmic volume and can contain lipid droplets (Fig. 35-6).

Electron microscopic examination of glomeruli provides more evidence that the primary pathologic change occurs in endothelial cells, which are greatly increased in size and can occlude the capillary lumen; their cytoplasm contains electron-dense material.¹²⁹ The basement membrane bordering the epithelial cell may be slightly thickened, and it also contains electron-dense material. The epithelial cell podocytes are not altered (Fig. 35-7). These changes are collectively called *glomerular capillary endotheliosis*.

Characteristic glomerular changes occur in 70% of primiparas but in only 14% of multiparas with a diagnosis of preeclampsia.¹⁷ The more likely the diagnosis of preeclampsia, the more common the glomerular lesion. As the clinical condition worsens, the magnitude of the glomerular lesion increases. The glomerular lesions are reversible after delivery and are not present in subsequent biopsy specimens obtained 5 to 10 weeks later.¹⁰³

The glomerular changes correlate more consistently with proteinuria than with hypertension, suggesting that proteins identified immunohistochemically may be trapped in the glomerulus. These staining patterns are not found in other renal disorders with proteinuria. The glomerular changes of preeclampsia can be mimicked in animal studies by reducing the renal concentration of vascular endothelial growth factor (VEGF), which usually exists in high concentration in this tissue by increasing the synthesis of the VEGF antagonist soluble Fms-like tyrosine kinase 1 (sFlt1).¹³⁰

NONGLOMERULAR CHANGES

Pathologic changes in renal tubules include dilatation of proximal tubules with thinning of the epithelium,¹²³ tubular necrosis,¹⁰³ enlargement of the juxtaglomerular apparatus,¹³¹ and hyaline deposition in renal tubules.¹²³ Fat deposition in women with prolonged heavy proteinuria has been reported.¹²³ Necrosis of the loop of Henle, a change that correlates with the degree of hyperuricemia, has also been described.¹³¹

Thickening of renal arterioles may be seen in preeclampsia, especially in women with preexisting hypertension. Unlike the glomerular

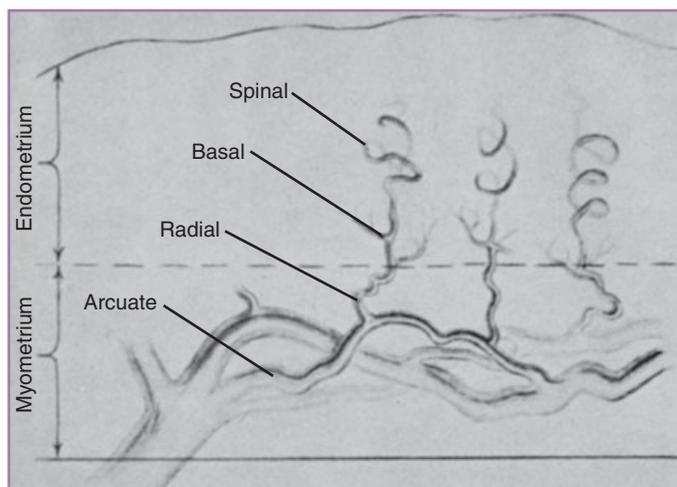

FIGURE 35-8 Schematic representation of uterine arteries. The characteristic changes occur in the decidual vessels supplying the placental site in a normal pregnancy. (From Okkels H, Engle ET: Studies of the finer structure of the uterine vessels of the *Macacus* monkey. *Acta Pathol Microbiol Scand* 15:150, 1938.)

lesion, it does not regress after delivery,¹⁰³ suggesting that the arteriolar change results from coincident disease, not preeclampsia.

Vascular Changes in the Placental Site

The characteristic changes in the decidual vessels supplying the placental site in normal pregnancy are depicted in Figure 35-8. In normal pregnancy, the spiral arteries (Fig. 35-9) increase greatly in diameter.¹³² Morphologically, the endothelium is replaced by trophoblast, and the internal elastic lamina and smooth muscle of the media are replaced by trophoblast and an amorphous matrix-containing fibrin (see Fig. 35-9).¹³³ These changes occur originally in the decidual portion of the spiral arteries but extend into the myometrium as pregnancy advances and can even involve the distal portion of the uterine radial artery. The basal arteries are not affected. These morphologic changes are considered to be a vascular reaction to the trophoblast, occurring directly or humorally, that results in increased perfusion of the placental site.

In placental-site vessels of women with preeclampsia, the normal physiologic changes do not occur, or they are limited to the decidual portion of the vessels. Myometrial segments of spiral arteries retain the nonpregnant component of intima and smooth muscle, and the diameter of these arteries is about 40% that of vessels in normal pregnancy.¹³⁴ Spiral arterioles in decidua and myometrium and basal and radial arterioles may become necrotic, with components of the normal vessel wall replaced by amorphous material and foam cells, a change called *acute atherosclerosis* (Fig. 35-10).¹³⁵ This lesion is best seen in the basal arteries because they do not undergo the normal changes of pregnancy. It is also present in decidual and myometrial spiral arteries and can progress to vessel obliteration. The obliterated vessels correspond to areas of placental infarction.

Failed vascular remodeling and atherotic changes may be seen with fetal growth restriction in women without clinical evidence of preeclampsia. Atherotic changes occur in decidual vessels of some diabetic women,¹³⁶ and failed vascular remodeling is present in about one third of women who experience preterm labor.¹³⁷ It appears that abnormal invasion may be necessary but is not sufficient to cause preeclampsia.

Baltimore, University Park Press, 1980, p 205.)

Changes characteristic of preeclampsia have been observed in the decidual vessels of one in seven primiparous women and in a lower percentage of multiparous women at the time of first-trimester abortion.^{138,139} These findings suggest that disordered placentation precedes the clinical presentation of preeclampsia. The cause of the decidual vascular lesions is unknown. The appearance of the atherotic vessels resembles vessels in transplanted kidneys that have undergone rejection, suggesting an immunologic cause, which is consistent with findings of a study that demonstrated components of complement (e.g., C3) in decidual vessels with the lesion.¹⁴⁰

The vascular remodeling of spiral arteries supplying the intervillous space is intimately related to normal trophoblast invasion.¹⁴¹ The expression of adhesion molecules and their receptors that characterizes implantation is abnormal in preeclampsia.¹⁴² The trophoblast that lines the decidual vessels of normal pregnant women begins to express molecules usually present only on endothelium,¹⁴³ a phenomenon that does not occur in preeclampsia.¹⁴⁴ Potential mechanisms responsible for the normal and abnormal changes include decidually produced cytokines¹⁴⁵⁻¹⁴⁷ and local oxygen tension.^{148,149} There may be interactions of specific molecules on trophoblast and maternal decidual cells that drive invasion. Invasive cytotrophoblasts express a human leukocyte antigen (HLA) molecule (HLA-C) that is minimally heterogeneous. Interaction of this molecule with a receptor on maternal decidual cells, killer immunoglobulin receptors (KIRs), causes various degrees of activation of the trophoblast cell, depending on the combination of KIR and HLA-C subtypes. Mothers with the minimally activating KIR subtype who have a fetus with a specific HLA-C subtype (HLA-C2) have an increased frequency of preeclampsia. This is not an immune interaction because the relationship persists regardless of maternal HLA-C subtype. Researchers propose that this combination does not favor trophoblast invasion and vascular remodeling. Population studies indicate that populations in which HLA-C2 is common have a reduced frequency of the specific inhibitory KIR subtype and vice versa.¹⁵⁰

Placental Pathologic Changes

Ultrastructural examination of placentas from women with preeclampsia reveals an abnormal syncytiotrophoblast containing areas of cell death and degeneration. Viable-appearing syncytiotrophoblast is also abnormal, with decreased density of microvilli, dilated endoplasmic reticulum, and decreased pinocytotic and secretory activity. The cells of the villous cytotrophoblast cells are increased in number and have higher mitotic activity. The basement membrane of the trophoblast is irregularly thickened, with fine fibrillary inclusions.¹⁵¹

The changes may be caused by local hypoxia. Similar syncytiotrophoblastic changes are present in placental segments maintained under hypoxic conditions *in vitro*.¹⁵² The cytotrophoblastic alterations are also consistent with hypoxia. The cytotrophoblasts comprise the stem cells of the trophoblast and responds to damage by proliferation. The trophoblast of the preeclamptic placenta is characterized by increased apoptosis and necrosis,^{153,154} possibly caused by hypoxia or hypoxia reperfusion injury,¹⁵⁵ and this may be the origin of the increased circulating syncytiotrophoblast microparticles in preeclampsia.¹⁵⁶

Summary of Pathologic Changes in Preeclampsia

Structural changes associated with preeclampsia and eclampsia lead to two important conclusions. First, preeclampsia is not an alternate form of malignant hypertension. The renal changes in preeclamptic and eclamptic women and the structural changes in other organs of women dying of eclampsia differ from the alterations caused by malignant

hypertension. Second, the pathologic findings indicate that the primary pathology is poor tissue perfusion, not blood pressure elevation. The histologic data support the clinical impression that the poor perfusion results from profound vasospasm, which increases total peripheral resistance and blood pressure.

Pathophysiologic Changes in Preeclampsia

Preeclampsia can cause changes in virtually all organ systems. Several organ systems are consistently and characteristically involved, and these are discussed in the following sections.

Cardiovascular Changes

Blood pressure is the product of cardiac output and systemic vascular resistance. Cardiac output is increased by up to 50% in normal pregnancy, but blood pressure does not usually increase, indicating that systemic vascular resistance decreases. Blood pressure is lower in the first half of pregnancy than in the postpartum period, when cardiac output returns to nonpregnant levels (see Fig. 35-2). Some women destined to develop preeclampsia have a higher cardiac output before clinically evident disease. However, cardiac output is reduced to pre-pregnancy levels with the onset of clinical preeclampsia.^{157,158} Although some studies suggest increased cardiac output,¹⁵⁹ most have found normal or slightly reduced cardiac output in women with untreated preeclampsia.¹⁶⁰ Increased systemic vascular resistance is the mechanism for the increase in blood pressure in clinical preeclampsia.

There is substantial evidence that arteriolar narrowing occurs in preeclampsia. Changes in the caliber of retinal arterioles correlate with the clinical severity of the disorder and with renal biopsy-confirmed diagnosis of preeclampsia.¹⁰³ Similar findings occur in vessels of the nail bed and conjunctiva. Measurements of forearm blood flow indicate higher resistance in preeclamptic than in normal pregnant women.^{161,162} It is unlikely that this effect is determined by the autonomic nervous system. Although normal pregnant women are exquisitely sensitive to the interruption of autonomic neurotransmission by ganglionic blockade and high spinal anesthesia, preeclamptic women are less sensitive.¹⁶³ This finding suggests that the arteriolar constriction of preeclampsia is not maintained by the autonomic nervous system and that humoral factors are implicated. The increased sympathetic activity in preeclampsia, however, raises questions about these older findings.¹⁶⁴ Assays of concentrations of recognized endogenous vasoconstrictors are limited to determinations of catecholamines and angiotensin II. Results suggest minimal or no change in catecholamines, whereas circulating angiotensin II concentrations are lower in preeclamptic women.¹⁶⁵

Levels of endothelin-1, a vasoconstrictor produced by endothelial cells, are increased in the blood of preeclamptic women¹⁶⁶ at concentrations much lower than those necessary to stimulate vascular smooth muscle contraction *in vitro*. It is not clear whether these circulating concentrations reflect endothelial production sufficient to stimulate local vasoconstriction or low concentrations of endothelin potentiate contractile responses to other agonists.

As indicated by the older term *toxemia*, early investigators suspected that preeclampsia was caused by circulating humors. Early reports suggesting etiologic agents such as pressor substances in blood, decidual extracts, placental extracts, and amniotic fluid of preeclamptic patients have not been replicated. The explanation for the pressor effects was, in some studies, normal endogenous pressors; in others, the explanation was faulty methodology and failure to recognize the immunologic difference between the source of the extract and the

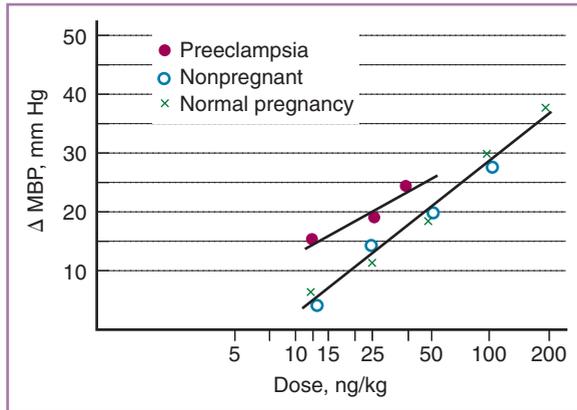

FIGURE 35-11 Mean dose-response graphs for norepinephrine. Women with preeclampsia have an increased sensitivity to all endogenous pressors. MBP, mean blood pressure. animals tested. In other experiments, no defect is obvious. The hypothesis that arteriolar constriction of preeclampsia is caused by new circulating pressors has largely been abandoned.¹⁸

A more compelling explanation for vasospasm in preeclampsia is increased response to normal concentrations of endogenous pressors. Women with preeclampsia have higher sensitivity to all the endogenous pressors that have been tested. They are exquisitely sensitive to vasopressin.^{167,168} Vasopressin can elicit marked blood pressure elevation, seizures, and oliguria in some patients.¹⁶⁸ Sensitivity to epinephrine¹⁶⁹ and norepinephrine¹⁷⁰ is also increased (Fig. 35-11). The most striking difference is seen in the sensitivity of the preeclamptic woman to angiotensin II. Normal pregnant women are less sensitive to angiotensin II than nonpregnant women, requiring approximately 2.5 times as much angiotensin to raise the blood pressure by a similar increment.¹⁷¹ In contrast, preeclamptic women are much more sensitive to angiotensin II than are normal pregnant and nonpregnant women (Fig. 35-12).¹⁷⁰

In a classic study, angiotensin II sensitivity was significantly increased many weeks before the development of elevated blood pressure (Fig. 35-13).¹⁷² Although resistance to angiotensin II does not decrease to nonpregnant levels until 32 weeks' gestation, significant differences in sensitivity between women who later become hypertensive and those who remain normotensive have been observed as early as 14 weeks. However, a large British study did not confirm this classic finding,¹⁷³ perhaps reflecting the heterogeneity of preeclampsia.¹⁷⁴

The decreased sensitivity of normal pregnant women to angiotensin II and the lower systemic vascular resistance in normal pregnancy suggest that arteriolar narrowing in preeclamptic women may result from decreased levels of circulating or local vasodilator substances, rather than from increased levels of circulating pressors. This attractive hypothesis, however, is not consistent with the unchanged sensitivities to norepinephrine, epinephrine, and vasopressin in normal pregnancy.¹⁶⁸⁻¹⁷⁰

Coagulation Changes

The syndrome of DIC occurs in preeclampsia and has been suggested as a primary pathogenetic factor¹⁷⁵ (see Chapter 40). Activation of the

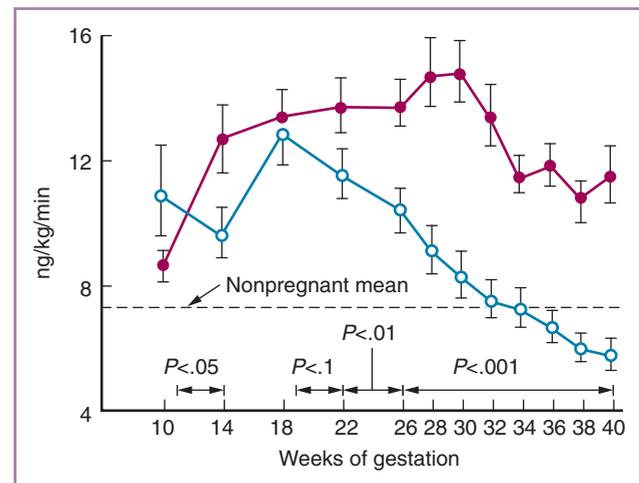

FIGURE 35-13 Angiotensin sensitivity throughout pregnancy. The dose of angiotensin II necessary to increase diastolic blood pressure 20 mm Hg in women who developed elevated blood pressure in late pregnancy (blue line, open circles) was compared with the dose for those who remained normotensive (red line, solid circles). The graph demonstrates that a significantly lower dose was required in the former group as early as 10 to 14 weeks' gestation. (From Gant NF, Daley GL, Chand S, et al: A study of angiotensin II pressor response throughout primigravid pregnancy. *J Clin Invest* 49:82, 1973. With permission of the American Society for Clinical Investigation.)

coagulation system manifests as the intravascular disappearance of procoagulants, intravascular appearance of degradation products of fibrin, and end-organ damage from the formation of microthrombi.¹⁷⁶ In the most advanced form of DIC, procoagulants—especially fibrinogen and platelets—decrease to a degree sufficient to produce spontaneous hemorrhage. In milder forms, only highly sensitive indicators of clotting system activation are present. Decreasing platelet concentrations is such a sign but may be evident only by serial observations.⁹⁶ Sensitive indicators of intravascular coagulation, such as an elevated

level of fibrin degradation products; increased platelet turnover,⁶ volume,¹¹⁴ and activation¹⁷⁷; reduced platelet content¹⁷⁸; increased platelet content in plasma¹⁷⁹; reduced levels of antithrombin III¹¹¹; and a reduced ratio of factor VIII activity to factor VIII antigen,¹⁸⁰ are common when concentrations of procoagulants remain normal. Subtle signs of platelet dysfunction,^{6,114,177-179} reduced antithrombin III,¹¹¹ and reduction in the ratio of factor VIII bioactivity to factor VIII antigen¹¹² are present in women with mild preeclampsia and may precede its clinical signs.

Abnormalities of blood coagulation sufficient to make a diagnosis of DIC are present in approximately 10% of women with severe preeclampsia or eclampsia.¹⁸¹ Results of highly sensitive assays of coagulation activation suggest, however, that abnormalities of the coagulation system are present in many patients with mild to moderate preeclampsia. Coagulation changes are thought to be secondary rather than primary pathogenetic factors¹⁸² because levels of procoagulants are usually normal, and another early sign of preeclampsia—increased serum uric acid—may precede changes in coagulation.¹¹⁰

The cause of the change in coagulation factors is uncertain. Vascular damage resulting from vasospasm may initiate DIC¹⁸² and probably contributes to activation of the clotting system in severe preeclampsia. Signs of endothelial dysfunction also antedate clinical disease,¹⁸³ and activation of platelets and other components of the coagulation cascade is a well-recognized consequence of endothelial dysfunction.¹⁸⁴ Vascular changes in the implantation site that appear to antedate blood pressure elevation may be pathogenetically important.

Whether coagulation changes measured in preeclamptic patients represent true DIC or a localized consumption of procoagulants in the intervillous space is not clear. Microthrombi and the presence of fibrin antigen have been inconsistently observed in liver, placenta, and kidney.¹⁸⁵⁻¹⁸⁷ Early coagulation changes such as factor VIII activity-antigen ratios and platelet count correlate better with the fetal outcome as measured by mortality and growth restriction rates than with the clinical severity of preeclampsia. Identical coagulation changes occur in normotensive women with growth-restricted fetuses,¹⁸⁸ suggesting that localized coagulation in the intervillous space is important. Similarly, an increased concentration of fibrin antigen has been reported in the placentas of preeclamptic patients.¹⁸⁵

Endothelial Cell Dysfunction

There is increasing support for endothelial dysfunction as a pathophysiologic component of preeclampsia.^{183,189,190} Alterations of glomerular endothelial cells are a consistent feature of preeclampsia. Levels of cellular fibronectin,^{191,192} growth factors,¹⁹³ vascular cell adhesion molecule 1 (VCAM-1),¹⁹⁴ factor VIII antigen, and peptides released from injured endothelial cells are increased in preeclamptic women before the appearance of clinical disease.¹¹² Examination showed that the endothelial function of vessels of preeclamptic women was impaired *in vitro*.^{195,196}

The endothelium is a complex tissue with many important functions. Prevention of coagulation and modulation of vascular tone have special relevance to preeclampsia. Intact vascular endothelium is resistant to thrombus formation.¹⁹⁷ With vascular injury, endothelial cells can initiate coagulation by the intrinsic pathway (i.e., contact activation)¹⁹⁸ or by the extrinsic pathway (i.e., tissue factor).¹⁹⁹ Platelet adhesion can also occur after injury with exposure of subendothelial components, such as collagen²⁰⁰ and microfibrils.

Endothelium profoundly influences the response of vascular smooth muscle to vasoactive agents. The response to some agents²⁰¹ can change from dilation to constriction with the removal of endothelium. Prostacyclin, a highly potent vasodilator, is produced by endo-

thelium. Vessels from preeclamptic women and the umbilical vessels of their neonates generate less prostacyclin than similar vessels from normal pregnant women.²⁰²⁻²⁰⁴ If potent inhibitors preventing the synthesis of all prostaglandins (including prostacyclin) are administered to pregnant women, the usual resistance to the vasoconstrictor effect of angiotensin II is abolished.²⁰⁵ Conversely, if aspirin is used as an inhibitor of prostaglandin synthesis in a manner determined to specifically reduce contractile prostanoids (e.g., thromboxane A₂) much more than prostacyclin, the increased angiotensin II sensitivity of preeclamptic women is reduced.²⁰⁶

Nitric oxide (NO) is another bioactive material produced by normal endothelium.²⁰⁷ Its release is stimulated by several hormones and neurotransmitters and by hydrodynamic shear stress. NO is quite labile and acts synergistically with prostacyclin as a local vasodilator and inhibitor of platelet aggregation. Current thinking favors NO as an endogenous vasodilator of pregnancy. Administration of inhibitors of NO synthesis reduces blood flow much more strikingly in pregnant than in nonpregnant women.²⁰⁸ Production of NO is reduced with endothelial cell injury. Information about NO production in preeclampsia is conflicting,²⁰⁹⁻²¹⁴ in part because of the use of blood concentrations of NO metabolites to determine production in the setting of the reduced renal function of preeclampsia.²¹⁵ Two studies have documented reduced urinary NO excretion in preeclampsia,^{212,216} and another found increased excretion.²¹⁷ Perhaps the most compelling data are from estimates of the tissue concentrations of nitrotyrosine (i.e., product of the interaction of NO and superoxide). Nitrotyrosine residues are increased in the placenta²¹⁸ and vessels²¹⁹ of women with preeclampsia. It is posited that the placenta directly or indirectly produces factors that alter endothelial function. Candidate molecules include the following:

- Cytokines²²⁰ (with increasing evidence that endothelial dysfunction is part of a generalized increased inflammatory response²²¹)
- Placental fragments (i.e., syncytiotrophoblast microvillous membranes)²²²
- Free radicals
- Reactive oxygen species²²³

The latter hypothesis—that oxidative stress causes endothelial dysfunction—is especially interesting in view of the similarities of the lipid changes of preeclampsia to those of atherosclerosis,¹¹⁸ an endothelial disorder in which oxidative stress is thought to play a key role.²²⁴

The information available indicates that endothelial cell dysfunction can alter vascular responses and intravascular coagulation in a manner consistent with the pathophysiologic abnormalities of preeclampsia. Evidence is accumulating that endothelial injury may play a central role in the pathogenesis of preeclampsia.

Renal Function Changes

Renal function changes characteristic of women with preeclampsia or eclampsia include decreased glomerular filtration and proteinuria. Changes in components of the renin-angiotensin system probably differ from those of normal pregnancy. Sodium excretion is decreased, resulting in fluid retention and edema.

GLOMERULAR FUNCTIONAL CHANGES

Glomerular Filtration Rate. Decreased glomerular filtration frequently complicates preeclampsia, and it is explained only partially by decreased renal plasma flow (RPF). The filtration fraction (GFR/RPF)

may be decreased¹⁸ because of intrarenal redistribution of blood flow.²²⁵ A more obvious explanation is glomeruloendotheliosis, in which the occlusion of glomerular capillaries by swollen endothelial cells probably renders many glomeruli nonfunctional.

Protein Leakage. The pathogenesis of proteinuria in preeclampsia is primarily explained by glomerular changes. The normal absence of protein in urine results from a relative impermeability of glomeruli to large protein molecules and from the tubular resorption of smaller proteins that cross the glomeruli. As glomerular damage occurs, permeability to proteins increases. As damage increases, so does the size of the protein molecule that can cross the glomerular membrane. Increased permeability results in decreased selectivity. With minimal glomerular damage or tubular dysfunction, only small protein molecules are excreted, but with greater damage, large and small proteins are present in urine.

In women with preeclampsia, selectivity is low, indicating increased permeability and glomerular damage.²²⁶ The well-known clinical observation that the magnitude of proteinuria in preeclamptic women varies greatly over time was quantitated by Chesley,²²⁷ who noticed hourly variation in the urinary creatinine-to-protein ratio in women with preeclampsia that was not present in the urine of individuals with other proteinuric conditions.

Because structural glomerular changes are constant, proteinuria in preeclamptic women must in part depend on a varying functional cause (e.g., a variation in the intensity of the renal vascular spasm). That vascular spasm can cause proteinuria has been demonstrated by measuring urinary excretion of protein in individuals subjected to the cold pressor test. Immersing a patient's hand in ice water for 60 seconds increases blood pressure by more than 16 mm Hg (systolic and diastolic), and an increase in protein excretion almost invariably occurs.²²⁸

RENAL TUBULAR FUNCTIONAL CHANGES

Uric Acid Clearance. Three separate processes are involved in the renal excretion of urate. Urate is completely filtered at the glomerulus. It is not bound to plasma proteins under physiologic conditions,²²⁹ and glomerular urate concentration is equal to renal arterial plasma concentration. Urate is secreted and reabsorbed by renal tubules. Most urate (98%) is reabsorbed, and about 80% of excreted urate is accounted for by urate secretion. Both processes occur predominantly in the proximal tubule. Reabsorption occurs to a greater extent than secretion, and urate clearance is about 10% of creatinine clearance.²³⁰

Abnormalities of uric acid clearance have long been recognized as a consistent phenomenon in preeclampsia²³¹ and have been regarded as a function of decreased glomerular filtration.²³² Several studies have demonstrated the discrepancy between uric acid clearance and both inulin clearance and creatinine clearance.^{233,234} Serial studies also reveal that decreased uric acid clearance precedes decreases in the GFR.²³⁵

Urate clearance is decreased by hypovolemia, presumably as a result of nonspecific stimulation of proximal tubular reabsorption.²³⁶ Plasma volume depletion is coincident with urate clearance changes,²³⁷ suggesting that volume change may account for the abnormality in urate clearance. However, the correlation between the degree of volume depletion and the decrease in urate clearance is poor.²³⁷

Angiotensin II infusion decreases urate clearance even in the presence of normal blood volume.²³⁸ The increase in angiotensin II sensitivity seen in preeclampsia may account for the change in renal function. Local effects of angiotensin II may also be important because this substance can be produced locally,²³⁹ unassociated with increased circulating angiotensin II.

In summary, uric acid clearance changes earlier in preeclamptic pregnancy than does the GFR, suggesting a tubular rather than a glomerular functional explanation. Although the exact mechanism for the urate clearance change is not established, the common feature in the suggested mechanisms is decreased renal perfusion; however, increased production by poorly perfused tissue cannot be excluded.^{106,240}

Urinary Concentrating Capacity. Although the issue is not fully settled, the tubular concentrating capacity is probably unchanged in normal pregnancies.²⁴¹ Assali and associates²⁴² suggested that urinary concentrating ability is decreased in hypertensive women. The limitations of these studies include the failure to account for parallel changes in the concentrating capacity and GFR²⁴³ and the use of specific gravity—an unreliable estimate of osmolality—as the measure of concentration.¹⁸

Normal pregnant women were found to have decreased capacity to concentrate urine (measured as osmolar concentration and corrected for the GFR) in response to vasopressin administration, a decrease similar to that seen in pregnant women who were or later became hypertensive.²⁴⁴ Conflicting study results suggesting that tubular concentrating capacity is unchanged in normal pregnancy are confounded by a failure to correct for the increased GFR of normal pregnancy, which concomitantly increases concentrating capacity.²⁴³

Excretion of Phenolsulfonphthalein. Because phenolsulfonphthalein is secreted by proximal tubular cells, its excretion can be used as an indicator of proximal tubular function.²³⁵ However, phenolsulfonphthalein excretion is altered independently of tubular secretory capacity with increased²⁴⁵ or decreased²⁴⁶ renal plasma flow or reduced GFR²⁴⁷ and with increased urinary dead space (a problem pertinent in pregnancy). When these factors are controlled, reduced phenolsulfonphthalein excretion precedes changes in the GFR and clinically evident disease in women with preeclampsia.²³⁵

Renin-Angiotensin-Aldosterone System. The renin-angiotensin-aldosterone system (RAAS) is important in pressure and volume regulation in normal pregnancy (Fig. 35-14).²⁴⁸ Dramatic changes occur in the RAAS during pregnancy.²⁴⁹ The following components are increased:

- Angiotensinogen (i.e., renin substrate)
- Plasma renin activity²⁵⁰

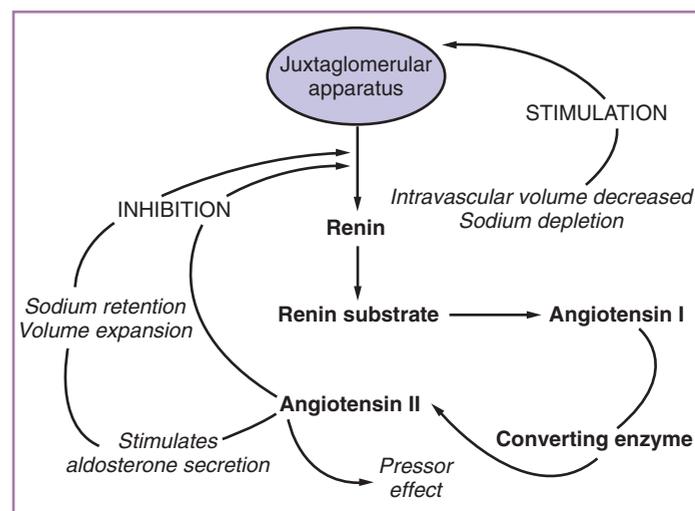

FIGURE 35-14 Schematic representation of the renin-angiotensin system. The system regulates pressure and volume in normal pregnancies, and abnormalities contribute to preeclampsia.

- Plasma renin concentration
- Angiotensin II concentration^{250,251}
- Aldosterone²⁵²

Abnormalities of the RAAS have been proposed as causal factors in preeclampsia²⁵³ because angiotensin II is a potent vasoconstrictor, it influences aldosterone secretion and consequent sodium retention, and at high concentrations, it can cause proteinuria. Myometrium and chorion can synthesize renin, which is stimulated in experimental animals by uterine ischemia.²⁵⁴

Most investigators agree that the angiotensinogen level remains elevated in preeclampsia.^{250,255} The plasma renin activity and plasma renin concentration are reduced in preeclampsia compared with normal pregnancy.²⁵⁶ In a prospective study of women with chronic hypertension, plasma renin activity was lower when superimposed preeclampsia developed (i.e., diagnostic blood pressure increase and proteinuria) than in chronic hypertensive women without superimposed preeclampsia and in normal pregnant women. Concentrations were similar in early pregnancy in all groups and decreased only slightly before the increase in blood pressure.²⁵⁷

The reduced renin activity in preeclampsia suggests suppression of renin release. This is puzzling in view of the reduced plasma volume that is characteristic of preeclampsia. There is no apparent nonphysiologic suppression of renin activity, because usual physiologic perturbations result in appropriately increased and decreased concentrations of plasma renin activity (i.e., renin is increased with upright posture and head-up tilt²⁵⁸ and falls with volume expansion²⁵⁹). Despite the reduced content of the vascular compartment in preeclampsia, the intense vasoconstriction characteristic of preeclampsia results in a physiologic perception of overfill, suppressing renin release. The reduced renin activity in preeclampsia results in reduced angiotensin II¹⁶⁵ and aldosterone concentrations²⁶⁰ compared with concentrations in normal pregnancy.

Attempts to test the role of the renin-angiotensin system (RAS) by using angiotensin II antagonists or by converting enzyme inhibitors have not clarified this point. Administration of the angiotensin antagonist (1-Sar-8-Ile-angiotensin II) to pregnant hypertensive women increases blood pressure,²⁶¹ and because this antagonist is a partial agonist, the increase in blood pressure may reflect the increased angiotensin sensitivity of hypertensive pregnant women. The administration of the angiotensin antagonist saralasin²⁶² or the angiotensin-converting enzyme inhibitor SQ 20,881²⁶³ in the postpartum period did not have significant effects on blood pressure in a mixed group of women with hypertension.

Interest in the role of the RAS in preeclampsia has increased as the effects of angiotensin on responses other than blood pressure have been recognized.²⁶⁴ The activation of NADPH oxidase in several tissues by angiotensin II can generate oxidative stress.²⁶⁴⁻²⁶⁶ Hypoxia-inducing factors (HIFs) induce molecules responsible for many of the responses to hypoxia. These factors are upregulated in the placenta of a woman with preeclampsia²⁶⁷ and can be activated by angiotensin II.²⁶⁸ Antibodies to angiotensin II that activate angiotensin receptors and likely increase the sensitivity of these receptors to angiotensin II are present in women with preeclampsia.²⁶⁹

Studies indicate that no simple relationship exists between components of the RAS and preeclampsia. The significance, however, of reduced plasma renin activity, plasma renin concentration, and angiotensin II concentration on blood pressure and sodium excretion in this group of women—who show apparent volume constriction and who are exquisitely sensitive to angiotensin II—deserves elucidation.

Atrial Natriuretic Factor. Atrial natriuretic factor (ANF), a peptide produced in response to atrial stretch with hypervolemia, regulates intravascular volume by several mechanisms. ANF increases sodium excretion and the egress of fluid from the intravascular compartment. Although the reduced plasma volume of preeclampsia predicts reduced ANF concentration, the concentration is increased,²⁷⁰ and the increase precedes clinical disease.²⁷¹ The stimulus for this increase is unclear, but the paradoxical finding of increased circulating ANF levels and reduced renin concentration with reduced plasma volume in preeclamptic women suggests that the reduced plasma volume is increased relative to the constricted vascular compartment.

Changes in Sodium Excretion. Sodium retention has long been considered an integral part of the pathophysiology of preeclampsia. Women with eclampsia and severe preeclampsia have very little chloride and sodium in the urine.²⁷² After delivery, however, chloride excretion increases dramatically. Infusion of hypertonic saline into preeclamptic women results in excretion of the infused sodium at about one half of the rate seen in normal pregnant women.¹⁶⁷ Similar results occur in women with glomeruloendotheliosis identified on renal biopsy.²⁷³ Most studies of exchangeable sodium have indicated an increase in total body sodium in preeclamptic patients.^{274,275}

The cause of sodium retention in preeclamptic women is difficult to determine because of the enormous number of factors that influence sodium excretion in normal pregnancy and because of the many demonstrated anomalies of renal function in preeclampsia that can cause sodium retention (Table 35-5). Any or all of the demonstrated changes in plasma volume, angiotensin sensitivity, and renal function may act on several of the factors listed in Table 35-5 to cause sodium retention.

Several investigators have considered the increased sodium retention to be a primary factor inciting the pathogenetic changes in pre-

TABLE 35-5 FACTORS AFFECTING SODIUM BALANCE IN NORMAL PREGNANCY

Factors Affecting Glomerular Filtration

Blood pressure in critical areas of the kidney
Relative tonus of afferent and efferent glomerular arterioles
Plasma oncotic pressure
Intrarenal redistribution of blood flow
Central nervous system effects

Factors Affecting Tubular Reabsorption

Aldosterone
Progesterone (an aldosterone antagonist)
Renal vascular resistance
Perfusion pressure in peritubular capillaries
Oncotic pressure in peritubular capillaries
Non-reabsorbable anions in the filtrate
Velocity of flow in tubules
Reabsorptive capacity of tubules
Estrogens (stimulate sodium reabsorption, possibly indirectly, by effects on vascular permeability)
Plasma sodium concentration
Hematocrit (viscosity effects)
Changes of plasma volume
Angiotensin
Sympathetic nervous system
Possibly a natriuretic hormone (“third factor”)

Modified from Chesley LC: *Hypertensive Disorders in Pregnancy*. New York, Appleton-Century-Crofts, 1978.

eclampsia. Although this possibility cannot be definitely excluded, it is not likely for several reasons:

1. Angiotensin sensitivity precedes obvious fluid retention by months.
2. Thiocyanate space, an indicator of sodium space, does not reliably predict preeclampsia.²⁷⁶
3. Restriction of dietary sodium or increasing sodium excretion with diuretics does not affect the occurrence of preeclampsia.²⁷⁷⁻²⁷⁹

SUMMARY OF RENAL FUNCTION CHANGES

Renal function changes in preeclampsia are consistent and characteristic. Changes in tubular function precede the more widely appreciated changes in glomerular function. These functional changes return to normal within weeks to months after the conclusion of pregnancy. Prospective, sequential studies of renal function indicate that some of these changes antedate the clinical diagnosis of preeclampsia, but they do not necessarily antedate other indicators of preeclampsia such as changes in coagulation and plasma volume. They are therefore unlikely to be causal abnormalities. Although the cause of renal functional changes is not clear, they may be explained by systemic or regional abnormalities of renal perfusion.

Immunologic Changes and Activation of Inflammatory Responses

Epidemiologic and laboratory observations suggest that fetal-maternal immunologic interactions may be etiologically important in the pathogenesis of preeclampsia. The increased incidence of preeclampsia in first pregnancies and the protective effect even of miscarriage suggest that maternal exposure to fetal antigens may be protective, an effect that appears to be lost if the father is not the same man who fathered the prior pregnancy.^{280,281} The increased risk of preeclampsia with a new father is affected by the interpregnancy interval, which tends to be longer in pregnancies with new fathers. This finding is compatible with an immunoprotective effect of antigen exposure, which is also lost when antigen exposure is minimal for a prolonged period.²⁸² Exposure to paternal components of fetal antigen through sexual activity with the potential father before the first pregnancy is also associated with reduced risk of preeclampsia.^{283,284} The pathologic changes in decidual vessels at the placental site in preeclampsia are similar to the vascular changes of acute immunologic rejection.¹⁴⁰

Several immunologic mechanisms have been suggested.^{285,286} Preeclampsia may be an immune complex disease. There is an efflux of fetal antigen into the maternal circulation during pregnancy. If the maternal antibody response is adequate, the complexes are cleared by the reticuloendothelial system, and no damage occurs. If the antibody response or clearance mechanisms are inadequate,²⁸⁷ the pathologic immune complexes formed can cause vasculitis, glomerular damage, and activation of the coagulation system. An inadequate maternal antibody response also can be suggested by HLA typing that demonstrates an increased concordance of the major histocompatibility antigens in maternal-paternal pairs that result in preeclamptic pregnancies.²⁸⁶ However, preeclampsia is less common in consanguineous marriages, a finding incompatible with this concept.²⁸⁸ Alternatively, the maternal antibody system may be overwhelmed by an excess of fetal antigen, a theory supported by the increased incidence of preeclampsia when trophoblastic tissue is increased (e.g., twins, hydatidiform mole, hydropic placenta). Few data support this concept.

Actual measurements of immune complexes in women with preeclampsia are inconsistent because of broadly different methodologies and definitions of preeclampsia. Increased immune complexes are a

feature of normal pregnancy, with further increases in women with mild preeclampsia and significant elevations observed in women with severe preeclampsia.²⁸⁹

Another hypothesis about the immunologic cause of preeclampsia is that vascular changes in the spiral arterioles of the placental implantation site are the result of an allograft rejection between mother and fetus. However, who is rejecting whom?²⁸⁶ Should the spiral arteries lined with trophoblast be thought of as fetal vessels, with the fetus rejecting the mother, or as maternal vessels, with the mother rejecting the fetus?

If preeclampsia represents a rejection of the fetus by the mother, the protective effect of previous exposure to antigen indicates that the preeclamptic mother has a deficit of blocking antibodies or of suppressor cell function. The recognition of a unique HLA antigen, HLA-G, on the trophoblast²⁹⁰ suggests other possible causes of rejection of the fetus. HLA-G is a class I antigen present almost exclusively on the cytotrophoblast with minimal heterogeneity. Unlike classic HLA antigens, which exhibit numerous epitopes, fetal HLA-G in the trophoblast is likely to be identical in most fetuses, and the fetus would exhibit the same antigen as that expressed by the mother during her fetal life. Because an immune cell (i.e., natural killer lymphocyte) found in maternal decidua in high numbers is postulated to destroy cells not bearing HLA antigens, a reduced level of HLA-G may render the fetus a target for these cells. Unusual epitopes of HLA-G also can activate maternal immune defenses. Although there are suggestions that polymorphisms of HLA-G may be more common in preeclampsia,²⁹¹ the data are minimal, and findings are not universally accepted.²⁹²

If preeclampsia represents a rejection of the mother by the fetus, the preeclamptic mother would have to be deficient in the capacity to destroy fetal immune cells. These alternative hypotheses—one requiring active intervention and the other passive intervention by the maternal immune system—should give disparate results in *in vitro* testing of maternal immune function. The experimental evidence available is not consistent enough to confirm or to contradict either hypothesis.

The innate immune response system may also play a role.²⁹³ Normal pregnancy is associated with an activation of inflammatory response that is similar to that seen in sepsis. This inflammatory response is further increased in preeclampsia.²⁹⁴ Materials released from the placenta, perhaps microvillus particles associated with apoptosis, interact with maternal immune cells to produce inflammatory activation.²⁹⁵ Increased release of these materials in preeclampsia is posited to augment the immune response with secondary pathogenetic effects of this inflammatory activation.

An immunologic cause of preeclampsia is consistent with much that is known about the disorder. Increased delineation of the changes in the immunologic activity in preeclampsia may provide insight into the cause of preeclampsia and normal fetal-maternal compatibility during pregnancy.

Oxidative Stress

Oxidative stress occurs when there is an excess of active oxygen products beyond the capacity of buffering mechanisms, antioxidants, and antioxidant enzymes. This phenomenon can occur with excess production of reactive oxygen products or with deficiency of antioxidant mechanisms.²⁹⁶ Reactive oxygen products can damage proteins, lipids, and DNA, and the endothelium is particularly vulnerable. Levels of lipid markers of oxidative stress are increased in women with preeclampsia.^{297,298} Lipid oxidation products, protein products of oxidation, protein carbonyls,²⁹⁹ and nitrotyrosine are present in the circulation, blood vessels,²¹⁹ and placenta²¹⁸ of preeclamptic women

and their fetuses. Reduced levels of antioxidants^{300,301} and increased levels of antibodies to oxidized LDL cholesterol³⁰² are found in excess in women with preeclampsia. These changes are not likely the result of preeclampsia, because reduced antioxidants and increased lipid peroxidation products are present in women destined to develop preeclampsia.^{303,304}

The excess oxidative species relevant to preeclampsia have several origins. Transition metals such as iron catalyze the formation of reactive oxygen species, and free iron and redox active copper³⁰⁵ are increased in the blood of women with preeclampsia.³⁰⁶ Reduced tissue perfusion sufficient to result in hypoxia and followed by restored perfusion and reoxygenation leads to the formation of reactive oxygen species.³⁰⁷ This mechanism is compatible with pregnancy and preeclampsia. Uterine and placental blood flow is not privileged, and flow is reduced when blood is shunted to other organs during exercise, eating, and other normal activities. In late pregnancy, uterine and placental blood flow is reduced profoundly by postural effects on uterine perfusion. All of these changes are reversible and are followed by restored perfusion. In normal pregnancy, reduced placental perfusion as described is not sufficient to generate free radicals. In preeclampsia, however, free radicals are generated in the intervillous space.^{218,308} Reduced placental perfusion may result in maternal systemic disease as the products of oxidative stress are transferred to the maternal circulation.³⁰⁹

Genetics of Preeclampsia

The tendency of preeclampsia and eclampsia to occur in daughters and sisters of women with preeclampsia is frequently overlooked. In Aberdeen, Scotland, the incidence of proteinuric preeclampsia was increased fourfold among sisters of women who had preeclampsia in their first pregnancy compared with sisters of women who did not.³¹⁰ The incidence of preeclampsia was 15% among mothers but only 4% among mothers-in-law of preeclamptic women.³¹¹ Chesley and Cooper³¹² evaluated preeclampsia in the first pregnancy of sisters, daughters, granddaughters, and daughters-in-law of women who had been eclamptic. The incidence of preeclampsia was 37% among sisters, 26% among daughters, and 16% among granddaughters. The incidence was 6% among daughters-in-law. The fetal genome is also related to the occurrence of preeclampsia. Men who have fathered preeclamptic pregnancies are more likely to father preeclamptic pregnancies with new partners than are men who have never been fathers in preeclamptic pregnancies.³¹³ Men born to preeclamptic pregnancies are more likely to be fathers of preeclamptic pregnancies than are men who are born of non-preeclamptic pregnancies.³¹⁴

What is inherited in preeclampsia? Possibilities include immunologic differences, features that compromise implantation, and an increased response to the systemic insult caused by reduced placental perfusion. Examinations of candidate genes support all possibilities. In some populations, certain HLA types are more common in the mother and the fetus from preeclamptic pregnancies.^{315,316} A variant of the angiotensinogen gene—reported to be more common in some studies³¹⁷⁻³¹⁹—is speculated to influence blood pressure and spiral artery remodeling.³²⁰ Gene variants potentially leading to aberrations of endothelial function are more common in preeclamptic women.³²¹⁻³²³ Mutations leading to increased risk factors for later-life cardiovascular disease, including function-perturbing mutations of lipoprotein lipase genes⁸⁸ and methylene tetrahydrofolate reductase (MTHFR, an enzyme abnormality associated with increased circulating homocysteine),³²² are associated with preeclampsia. As is common in studies of genetic polymorphisms, the results vary according to the population studied.³²⁴

Although these and other studies³²⁵ support the genetic heterogeneity of preeclampsia,¹⁷⁴ the literature may be underpowered and subject to publication bias.³²⁶

In the Genetics of Preeclampsia study of 1000 paternal, maternal, and fetal triads, none of the usual candidates was related to preeclampsia.³²⁶ The results of linkage analyses to perform hypothesis-free testing of genetic associations have varied. Associations of preeclampsia have been found with loci on chromosomes 2p,^{327,328} 2q,^{327,328} 4q,^{325,329} 9,³²⁹ and 10³³⁰ in different populations. A novel study from the Netherlands³³⁰ combined physical localization of a candidate gene with a search for functionally relevant genes in this chromosomal region. This methodology identified *STOX1*, a paternally imprinted gene involved in trophoblast differentiation. As a paternally imprinted gene, *STOX1* is active only when coming from the mother. A mutated version of this gene was consistently present in affected sisters in preeclamptic pedigrees. Although *STOX1* was localized to chromosome 10 in the Netherlands study, a paralogue of this gene, *STOX2*, is located on chromosome 4q, close to the suggestive region identified in genome-wide searches in Finland and Australia. The use of high-throughput genetic and gene expression and proteomic studies is just beginning to be applied to the study of preeclampsia.³²⁶

Management of Preeclampsia

Philosophy of Management

The optimal philosophy of management is a product of the current knowledge about the pathophysiologic changes of and prognosis for preeclampsia. Three principles can be applied.

First, delivery is always appropriate therapy for the mother but may not be so for the fetus. Because we do not understand its cause, attempts to prevent preeclampsia by conventional medical approaches have been understandably unsuccessful. The primary goal of therapy is to prevent maternal morbidity and mortality. Preeclampsia is progressive at variable rates, and careful antepartum observation can identify the woman at risk. Preeclampsia is completely reversible and begins to abate with delivery. If only maternal well-being were considered, delivery of all preeclamptic women, regardless of severity of process or stage of gestation, would be appropriate. Expectant management is appropriate in some circumstances to attain an optimal outcome for the fetus. The goal of any therapy for preeclampsia other than delivery must be improved rates of perinatal and long-term mortality and morbidity for the fetus, infant, and child.

Second, the signs and symptoms of preeclampsia are not pathogenetically important. The pathologic and pathophysiologic changes of preeclampsia indicate that poor perfusion, caused at least in part by vasospasm, is the major factor leading to the derangement of maternal physiologic function and ultimately leading to perinatal mortality and morbidity. This same abnormality causes increased total peripheral resistance, with subsequent elevation of blood pressure and decreased renal perfusion leading to sodium retention and edema. The proteinuria of preeclampsia is at least partially explained by vasospasm and by reversible glomerular damage. Attempts to treat preeclampsia by natriuresis or by lowering blood pressure do not alleviate the important pathophysiologic changes. Natriuresis may be counterproductive and may adversely affect fetal outcome because the plasma volume is already reduced in preeclamptic women.

Third, the pathogenic changes of preeclampsia are present long before clinical criteria for diagnosis are evident. Changes in vascular reactivity, plasma volume, and renal function antedate—in some cases by months—the increases in blood pressure, protein excretion,

and sodium retention. Irreversible changes affecting fetal well-being therefore may be present before the clinical diagnosis is made. This likely explains the failure of dietary, pharmacologic, and postural therapy instituted after the recognition of clinical disease to reduce perinatal morbidity and mortality. The only rationale for therapy other than immediate delivery is to palliate the maternal condition to allow fetal maturation, and even this rationale is controversial.

Delivery

Delivery is the definitive treatment for preeclampsia.

DELIVERY REMOTE FROM TERM

Delivery in the setting of severe preeclampsia usually is chosen for the maternal and fetal indications described previously. Fetal indications for intervention include the following:

- Non-reassuring fetal test results
- Estimated fetal weight less than the 5th percentile for gestational age
- Oligohydramnios (i.e., amniotic fluid index below 5.0 cm or maximal vertical pocket of fluid less than 2.0 cm)
- Persistent absent or reversed diastolic flow on umbilical artery Doppler velocimetry in a growth-restricted fetus

Delivery should be considered for all women with severe preeclampsia who have reached a favorable gestational age, which usually is defined as more than 32 to 34 weeks' gestation.

DELIVERY AT OR NEAR TERM

The treatment of choice for preeclampsia at term is delivery. Expectant management may be considered when preeclampsia is diagnosed at less than 32 to 34 weeks' gestation, even if disease is severe. However, as gestational age approaches 34 weeks, short- and long-term neonatal outcomes are excellent, and the potential benefits of expectant management become less compelling. At 34 to 37 weeks, decisions regarding delivery are not guided by good evidence, and clinical judgment must consider the neonatal prognosis, severity of maternal disease, and the wishes of the patient.

ROUTE OF DELIVERY

Delivery is usually accomplished by the vaginal route, with cesarean delivery reserved for obstetric indications. The decision to expedite delivery in the setting of severe preeclampsia does not mandate immediate cesarean birth.³³¹ Cervical ripening agents may be used if the cervix is not favorable before induction³³² and if the fetus can be satisfactorily monitored; however, a prolonged induction is best avoided, especially in the presence of IUGR or oligohydramnios. The rate of vaginal delivery after labor induction decreases to about 33% at less than 28 to 34 weeks' gestation because of the high frequency of non-reassuring fetal heart rate tracings and failure of induction.³³³ Some physicians recommend scheduled cesarean delivery for women with severe preeclampsia with a pregnancy of less than 30 weeks' gestation and with an unfavorable Bishop score.³³⁴

After the decision for delivery is made, induction should be carried out aggressively and expeditiously. Cesarean delivery should be reserved for obstetric indications. Because the probability of fetal compromise in preeclampsia is high, it is mandatory in all vaginal deliveries that the fetus be monitored adequately. When feasible, internal monitoring is preferable to allow determination of variability; however, external monitoring, if technically good, is adequate until internal monitoring

is possible. Magnesium sulfate may reduce fetal heart rate variability,³³⁵ but if normal variability was never evident, fetal scalp blood sampling may be necessary to ensure that decreased variability is not related to fetal compromise. For the woman with marked hepatic capsular distention, cesarean delivery is indicated if vaginal delivery is not imminent. Even several extra hours can threaten the life of the mother, and liver rupture is difficult to predict and to treat. In some cases of severe preeclampsia, especially those with HELLP syndrome, rapidly worsening thrombocytopenia or other signs of maternal instability may preclude a trial of labor.

Regional anesthesia offers its usual advantages for vaginal and cesarean delivery but does carry the possibility of extensive sympathetic blockade with consequent decreased cardiac output, hypotension, and impairment of already compromised uteroplacental perfusion. This problem can be avoided by meticulous attention to anesthetic technique and volume expansion. Regional anesthesia is not a rational means of lowering blood pressure because it does so at the expense of cardiac output. Similarly, although analgesia with narcotics is not contraindicated and may be used when necessary, attempting to manage or prevent eclampsia with profound maternal sedation has been ineffective and even dangerous.

Antepartum Management

When preeclampsia is suspected, a careful evaluation of mother and fetus is essential. Maternal blood pressure, laboratory values, and fetal well-being should be assessed. If the diagnosis of preeclampsia is confirmed, maternal seizure prophylaxis should be considered, blood pressure should be controlled to a level that minimizes risk of maternal stroke, and plans for delivery should be made according to the gestational age.

ASSESSMENT AND MONITORING OF THE MOTHER AND FETUS

Maternal Monitoring. There are two goals for antepartum monitoring of the mother:

- Recognizing the condition early, because infants of mothers with even mild preeclampsia are at increased risk for adverse outcomes.
- Gauging the rate of progression of the condition to prevent severe morbidity by delivery and to determine whether fetal well-being can be monitored safely by the usual intermittent observations

Ideally, identification of early changes allows intervention before the advent of clinical symptoms. Although many hemodynamic, volume, and metabolic changes antedate the diagnostic clinical signs in women destined to develop preeclampsia, none is sensitive enough to be clinically useful.^{7,33,112,167,235,336-338} The increased blood pressure response to angiotensin II^{172,339,340} in women destined to have elevated blood pressure in late pregnancy was once the gold standard against which other predictors were judged, but a large study failed to confirm the predictive value of the test,^{112,173} and it is neither simple nor safe enough for extensive clinical use. Abnormal uterine artery Doppler velocimetry in the second trimester has a positive predictive value for preeclampsia of about 20%. Although useful for research identification of subjects, the low sensitivity and positive predictive value limit its use in clinical care.³⁴¹ The role of Doppler velocimetry in patient management remains uncertain. Other suggested markers include angiogenic and antiangiogenic factors, but clinical use awaits additional evaluation.³⁴²

Clinical management is dictated by the overt clinical signs of preeclampsia. Proteinuria—the most valid clinical indicator of preeclampsia—is often a late change, sometimes even preceded by seizures, and it is therefore not useful for early recognition of disease. Although rapid weight gain and edema of the hands and face suggest fluid and sodium retention characteristic of preeclampsia, they are not universally present in or uniquely characteristic of preeclampsia. These signs are at most a reason for close observation of blood pressure and urinary protein levels. Early recognition of preeclampsia is necessarily based primarily on diagnostic blood pressure increases in the late second and early third trimesters compared with pressures in early pregnancy. Blood pressure changes without proteinuria undoubtedly occur in some normal women and in some with underlying renal or vascular disease. Because the goal of early diagnosis is to identify patients requiring more careful observation, overdiagnosis is preferable to underdiagnosis.

After blood pressure changes diagnostic of preeclampsia occur, evidence of multiorgan involvement should be sought through laboratory assessment. A 24-hour or timed urine specimen should be collected,³⁴³ regardless of findings on urine dipstick evaluation.⁹ Because of the hectic protein excretion characteristic of the disorder,³⁴⁴ 24-hour urine collections may reveal excretion of more than 300 mg of protein, even with only trace proteinuria identified on the dipstick evaluation.⁹ Platelet count and liver enzyme tests should also be obtained.² To rule out fulminant progression, repeated examination of pressure and urinary protein is suggested within 24 hours. The frequency of subsequent observations is determined by these initial observations and the ensuing clinical progression. If the condition appears stable, once- or twice-weekly observations may be appropriate. Any evidence of progression merits more frequent observations, perhaps in the hospital. The appearance of proteinuria is an especially important sign of progression and requires frequent observation.

If deterioration in laboratory findings, symptoms, or clinical signs occurs, the decision to continue the pregnancy is determined day by day. Subjective evidence of central nervous system involvement (i.e., headache, disorientation, and visual symptoms) and hepatic distention (i.e., abdominal pain and right upper quadrant or epigastric tenderness) indicates worsening preeclampsia. Important clinical signs are blood pressure, urinary output, and fluid retention as evidenced by daily weight increase.

Laboratory studies are performed at intervals of no less often than every 48 hours. Tests should include a platelet count and fibrin split products, urinary protein excretion and serum creatinine levels, and serum levels of transaminases.

Fetal Observation. Assessment of fetal well-being is required to determine whether continuing the pregnancy is safe (see Chapter 21). With the diagnosis of gestational hypertension, fetal assessment for size by sonography and for function by nonstress testing is indicated. After the diagnosis of preeclampsia is made, it is mandatory to monitor the fetal condition. Ultrasound evaluation of fetal weight and amniotic fluid volume and a nonstress test of the fetal heart rate should be performed. Alternatively, a complete biophysical profile may be performed. Doppler velocimetry is not recommended unless fetal growth restriction is identified.

As long as the maternal condition is mild and stable, weekly monitoring of the fetus appears to be adequate. Unfortunately, no test of fetal well-being is satisfactory when the mother's condition is unstable, and testing should be repeated whenever the maternal status changes. Management of fetal growth restriction, a common complication of preeclampsia, is discussed in Chapter 34. Amniotic fluid testing for fetal lung maturity (see Chapter 23) may aid the decision to deliver the

fetus with growth restriction. Fetal jeopardy, rather than lung maturity, is the fetal criterion to determine delivery when preeclampsia occurs remote from term.

Expectant Management of Severe Preeclampsia Remote from Term

Prolonged expectant antepartum management of women with severe preeclampsia is not practiced in most centers. With improvements in neonatal care, many clinicians regard delivery of women with severe preeclampsia beyond 32 to 34 weeks' gestation to be in the best interests of the mother and fetus. When gestational age is critical (<32 weeks), the physician may consider control of maternal blood pressure along with meticulous observation of maternal and fetal conditions. This approach requires personnel and facilities for very close assessment of both patients.

The initial evaluation and management of a woman suspected to have severe preeclampsia between 24 and 32 to 34 weeks' gestation includes the following components:

- The pregnant woman is admitted to the hospital.
- A course of antenatal corticosteroids is administered (see Chapter 23). Barring rapid deterioration of the maternal or fetal status, reasonable efforts should be made to delay delivery for 48 hours to complete a full course of antenatal corticosteroids. Neonates from preeclamptic pregnancies may have a reduced incidence of respiratory distress syndrome, but this does not justify withholding antenatal corticosteroid therapy.^{345,346}
- Seizure prophylaxis is undertaken with magnesium sulfate.
- Blood pressure is monitored at least every 1 to 2 hours.
- Fluid intake and urine output are strictly monitored.
- A 24-hour urine collection is used to determine protein excretion and creatinine clearance.
- Laboratory studies include a complete blood cell count with a platelet count and smear and determinations of electrolytes, creatinine, ALT, AST, lactic acid dehydrogenase (LDH), uric acid, and albumin. A coagulopathy profile (i.e., prothrombin time [PT], partial thromboplastin time [PTT], and fibrinogen) should be obtained if the ALT and AST values are more than twice normal or if the platelet count is less than 100,000 cells/ μ L.
- Assessment of fetal well-being includes a nonstress test, amniotic fluid volume determination, and estimation of fetal size. If growth restriction is recognized, umbilical artery Doppler velocimetry is suggested.

After the complete assessment of the fetus and mother, the safety and potential utility of expectant management should be reassessed daily. Several factors mandate delivery regardless of gestational age. Under these circumstances, the initial dose of antenatal steroids should be administered, but pregnancy should not be unnecessarily prolonged to give the second dose.

CONTRAINDICATIONS TO EXPECTANT MANAGEMENT

Immediate delivery should be considered if any of the following conditions are present:

- Maternal hemodynamic instability (e.g., shock)
- Non-reassuring fetal test results (e.g., persistently abnormal fetal heart rate testing, estimated fetal weight less than the 5th percentile for gestational age, oligohydramnios with amniotic

fluid index <5.0 cm or maximal vertical pocket <2.0 cm, persistent absent or reversed diastolic flow on umbilical artery Doppler velocimetry in a growth-restricted fetus)

- Persistent, severe hypertension unresponsive to medical therapy
- Persistent headache, visual aberrations, or epigastric or right upper quadrant pain
- Eclampsia
- Pulmonary edema
- Renal failure with a marked rise in serum creatinine (i.e., serum creatinine concentration increased by 1 mg/dL over baseline) or urine output less than 0.5 mL/kg/hr for 2 hours that is unresponsive to hydration with two intravenous boluses of 500 mL of fluid
- Laboratory abnormalities (e.g., rapid increase in aminotransferases that exceeds twice the upper limit of normal, progressive decrease in the platelet count to less than 100,000 cells/ μ L, coagulopathy in the absence of an alternative explanation) that worsen over a period of 6 to 12 hours
- Abruption placentae
- Gestational age more than 34 weeks
- HELLP syndrome (Some studies have reported that serious maternal complications in the setting of expectant management of HELLP syndrome are uncommon with careful maternal monitoring.^{347,348} However, the aim of expectant management is to improve neonatal morbidity and mortality, and it has not been shown that overall perinatal outcome is improved with expectant management compared with pregnancies delivered after a course of corticosteroids. Expectant management remains an investigational approach.^{349,350})
- Patient who does not want to undergo risks of expectant management

If the fetus and mother have none of these signs or symptoms and the informed woman agrees, expectant management may be considered.

CANDIDATES FOR EXPECTANT MANAGEMENT

In women with severe preeclampsia remote from term, the decision to continue pregnancy beyond that required for corticosteroids depends on the results of frequent maternal and fetal assessment and continual review of the ongoing risks of conservative management versus the benefit of further fetal maturation. These women should be cared for in a hospital setting and cared for by or in consultation with a maternal-fetal medicine specialist. In this environment, expectant management of severe preeclampsia remote from term may be considered in four circumstances.

The first is transient abnormal laboratory test results. Asymptomatic women before 34 weeks' gestation with severe preeclampsia on the basis of laboratory abnormalities that improve or resolve within 24 to 48 hours after hospitalization may be managed expectantly.^{351,352} If initial laboratory abnormalities include elevated liver function test results (e.g., ALT, AST) less than twice the upper limit of normal, a platelet count of less than 100,000 cells/ μ L but greater than 75,000 cells/ μ L, and coagulopathy in the absence of an alternative explanation, it is reasonable to delay delivery, administer antenatal corticosteroids, and repeat laboratory tests every 6 to 12 hours. If the laboratory values show a trend toward improvement, or if they resolve, expectant management may be continued until a more favorable gestational age. Delivery is warranted if liver function test values or platelet counts deteriorate or coagulopathy occurs.

The second reason to consider expectant management of severe preeclampsia remote from term is severe preeclampsia based solely on

proteinuria. In the absence of other features of severe preeclampsia, proteinuria greater than 5 g in 24 hours is not an indication for delivery. Several clinical studies have shown that neither the rate of increase nor the amount of proteinuria affects maternal or perinatal outcome in the setting of preeclampsia.^{353,354} For this reason, after the threshold of 300 mg in 24 hours for the diagnosis of preeclampsia has been exceeded, 24-hour urinary protein estimations do not bear repeating.

The third reason is severe preeclampsia based solely on fetal growth restriction. Women with severe preeclampsia based only on the presence of IUGR in the setting of preeclampsia may be managed expectantly if they meet the following criteria³⁵⁵:

- Mild IUGR, defined as an estimated fetal weight between the 5th and 10th percentile for gestational age (see Chapter 34)
- Gestational age less than 32 weeks
- Reassuring fetal test results, defined as a reassuring nonstress test result, adequate amniotic fluid volume (AFI > 5.0 cm or maximal vertical pocket >2.0 cm), and no persistent absent or reversed diastolic flow on umbilical artery Doppler velocimetry (see Chapter 21)

These women should be admitted to the hospital for close maternal surveillance and daily fetal testing.³⁵⁶ The admission-to-delivery interval in such pregnancies averages only 3 days, and more than 85% of these women require delivery within 1 week of presentation.^{350,355}

The fourth reason to consider expectant management is severe preeclampsia based solely on blood pressure criteria. Two studies have established a precedent for expectant management of patients with severe preeclampsia by blood pressure criteria alone in pregnancies less than 32 weeks with reassuring fetal testing.^{351,352}

COMPONENTS OF EXPECTANT MANAGEMENT

Expectant management of severe preeclampsia is not associated with any direct maternal benefits. The mother is assuming a small but significant risk to her own health to delay delivery until a more favorable gestational age is reached for her child.

If the contraindications to expectant management described previously are absent, the following protocol may minimize the risk of maternal and fetal complications:

- Close supervision of the mother and fetus is crucial because it is impossible to predict the clinical course the disease will take after admission.³⁴⁹
- The mother is hospitalized until delivery.
- The patient is kept on bed rest with bathroom privileges.
- Blood pressure is monitored every 2 to 4 hours while the patient is awake.
- Maternal symptoms are assessed every 2 to 4 hours while she is awake.
- Fluid intake and urine output are strictly recorded.
- Complete blood cell count, electrolyte determinations, and liver and renal function tests are performed at least twice weekly, if not daily.
- The mother is given antenatal corticosteroids, if not previously given.
- Regular assessment of fetal well-being (at least daily nonstress tests with a biophysical profile if nonreactive)³
- Delivery occurs after 32 to 34 weeks' gestation, depending on the clinical scenario.

If abnormal laboratory test results are obtained on admission, tests should be repeated every 6 to 12 hours. Delivery should be considered if there is no trend toward improvement within 12 hours of admission or if the condition worsens after an initial improvement.

There is no standardized protocol for fetal assessment in this setting. We perform fetal kick counts and nonstress tests at least daily, ultrasound assessment of amniotic fluid volume once or twice per week, ultrasound estimation of fetal growth every 10 to 14 days, and weekly Doppler velocimetry of the umbilical artery if the fetus is growth restricted.

Several management strategies with no proven benefit in the setting of severe preeclampsia are often recommended, but they are best avoided. They include the routine use of continuous fetal heart rate monitoring, routine initiation of antihypertensive therapy (antihypertensive therapy should be avoided, with the exception of women with chronic hypertension and those being managed according to standard protocols for severe preeclampsia by blood pressure criteria only remote from term),³⁵² prolonged (>48 hours) antepartum administration of magnesium sulfate for seizure prophylaxis, serial 24-hour urine collections for protein quantitation, and routine assessment of fetal lung maturity. However, the latter may be useful between 30 and 34 weeks when there is contradictory or equivocal evidence of maternal or fetal deterioration.

Postpartum administration of intravenous dexamethasone does not reduce the severity or duration of disease. The serendipitous observation that women who had received antepartum steroids appeared to evidence improvement in the HELLP syndrome³⁵⁷ stimulated several retrospective and observational studies.³⁵⁸⁻³⁶³ These studies and a small, randomized, controlled trial³⁶⁴ suggest improvement in laboratory findings and prolongation of pregnancy. The determination of appropriate dosing and whether the benefit of therapy exceeds risks await larger, randomized, controlled trials. Its benefit for patients with HELLP syndrome remains controversial.³⁶⁵

OUTCOMES OF EXPECTANT MANAGEMENT

Several studies have shown that with close monitoring, pregnancies complicated by severe preeclampsia could be managed expectantly and extended by 5 to 19 days, on average, with good maternal and neonatal outcomes. However, pregnancies with a growth-restricted fetus typically deliver in 3 to 5 days.^{351,352,366,367}

Intrapartum Management

The intrapartum management of women with preeclampsia tests the obstetric and medical skills of the health care team. The patient with severe preeclampsia or eclampsia is acutely ill, with functional derangements of many organ systems.³⁶⁸ Improved appreciation of the gravity of this situation and enhanced methods of maternal monitoring have reduced mortality rates. One study from the United Kingdom demonstrated a significant reduction in maternal death due to eclampsia from 15.1% in the 1940s to less than 3.9% after 1950.³⁶⁸ Failure to recognize and appropriately manage this grave condition probably accounts for most deaths. Even mildly preeclamptic women can experience an acceleration of disease during labor.

Baseline information should be obtained to determine renal function, coagulation status, and liver function. Determination of the serum protein concentration informs the choice of appropriate fluid administration. Some investigators advocate the use of intensive cardiovascular monitoring, with Swan-Ganz catheters or with central venous pressure catheters in all women with severe preeclampsia or eclampsia (see Chapter 57). Such a practice is probably indicated in oliguric patients whose urinary output does not improve with a modest

fluid challenge. The major problems to be managed are those of high blood pressure, intravascular volume, and convulsions. Less commonly, patients with DIC and myocardial dysfunction require treatment.

SEIZURE PROPHYLAXIS AND TREATMENT

Most seizures occur during the intrapartum and postpartum periods, when the preeclamptic process is most likely to accelerate. In the Magpie study, 10,000 preeclamptic women were randomized to receive magnesium sulfate or placebo. Magnesium sulfate clearly reduced the risk of eclampsia in this trial,³⁶⁹ and it was shown in separate trials to be superior for this purpose to other prophylactic medications, including phenytoin^{370,371} and diazepam.^{372,373}

Despite the demonstrated efficacy of magnesium sulfate, it is difficult to select preeclamptic women for whom the risks of seizure exceed the risk of prophylaxis. In the Magpie study, treatment was effective and safe even in developing countries, but most of these women had significant disease. Twenty-five percent were defined as having severe preeclampsia, and 75% required antihypertensive therapy. Although the use of magnesium prophylaxis in so-called mild preeclampsia is controversial, the incidence of eclampsia increased by 50% in a large obstetric service when magnesium prophylaxis was limited to women with severe disease.³⁷⁴ A review of eclamptic patients from another large U.S. center indicates the difficulty in selecting preeclamptic women with disease severe enough to warrant therapy. None of the clinical signs and symptoms considered to be prognostic of seizures was absolutely reliable. Seventeen percent of women who had seizures did not have headache, 80% did not have epigastric pain, and 20% had normal deep tendon reflexes (Table 35-6). The lack of absolute correlation with proteinuria is consistent with the observations by Chesley and Chesley²⁷⁶ more than 50 years ago that 24% of patients do not have proteinuria before seizures.

Most U.S. investigators recommend prophylactic anticonvulsant therapy for all women with a blood pressure elevation diagnostic of preeclampsia, regardless of whether other signs and symptoms, including proteinuria, are present. This approach includes women for whom the risks of treatment may exceed the risks from seizures. The first requirement for anticonvulsant prophylaxis is that the agent and dosage schedule must be extremely safe for the mother. Safety for the fetus and neonate is the next criterion.

Magnesium Sulfate. Magnesium sulfate offers considerable advantages for prophylaxis in women with preeclampsia. Its pharmacokinetic processes during pregnancy are well established, as are its efficacy and safety for the mother and fetus.

TABLE 35-6 FREQUENCY OF SYMPTOMS PRECEDING ECLAMPSIA

Symptom	Frequency (%)
Headache	83
Hyperreflexia	80
Proteinuria	80

TABLE 35-7 EFFECTS ASSOCIATED WITH VARIOUS SERUM MAGNESIUM LEVELS

Effect	Serum Level (mEq/L)
Anticonvulsant prophylaxis	4-6
Electrocardiographic changes	5-10
Loss of deep tendon reflexes	10
Respiratory paralysis	15
Cardiac arrest	>25

The volume of distribution of magnesium is greater than that of sucrose, indicating that the distribution of this ion goes beyond extracellular fluid and enters bones and cells.³⁷⁵ Magnesium circulates largely unbound to protein and is almost exclusively excreted in urine. It is reabsorbed in the proximal tubule by a process limited by transport maximum (T_{max}), and its excretion increases as the filtered load increases above the T_{max} .³⁷⁶ In women with normal renal function, the half-time for excretion is about 4 hours.³⁷⁵ Because excretion depends on delivery of a filtered load of magnesium that exceeds the T_{max} , the half-time of excretion is prolonged in women with a decreased GFR.

The clinically relevant effects of elevated serum magnesium concentrations are related primarily to the membrane effects. Magnesium slows or blocks neuromuscular and cardiac conducting system transmission, decreases smooth muscle contractility, and depresses central nervous system irritability. These actions produce the desired anticonvulsant effect and cause decreased uterine and myocardial contractility, depressed respirations, and interference with cardiac conduction. These effects occur at different serum magnesium concentrations (Table 35-7). Doses of magnesium sulfate sufficient for anticonvulsant therapy cause little change in blood pressure.

Depression of deep tendon reflexes occurs at serum concentrations lower than those associated with adverse cardiac and respiratory effects. The presence of deep tendon reflexes indicates that the serum magnesium concentration is not dangerously high. If deep tendon reflexes are lost, the serum magnesium concentration may be greater than 10 mEq/L, but brisk deep tendon reflexes do not signify inadequate magnesium dosage. Any attempt to titrate magnesium therapy until deep tendon reflexes are eliminated is irrational and dangerous.

In the United States, magnesium sulfate is routinely given intravenously, rather than by more painful intramuscular injections. A typical loading dose is 4 to 6 g given intravenously over about 15 to 30 minutes, followed by 1 to 2 g/hr as a continuous infusion. Magnesium is administered by continuous infusion because intermittent bolus infusions result in only transient elevations of magnesium level. To ensure consistent infusion and to avoid inadvertent administration of large doses of magnesium, mechanically controlled infusion is mandatory. In all patients, deep tendon reflexes should be checked regularly (at least every 2 hours) to make sure they remain present, and the respiratory rate must be monitored.

The rate of infusion is modified for patients with compromised renal function. If the maternal creatinine level is greater than 1.0 mg/dL, serum magnesium levels should be obtained and the infusion rate limited to no more than 1 g/hr if there is further evidence of renal impairment. If overdosage occurs, especially with apnea, calcium gluconate (10 mL of a 10% solution injected intravenously over 3 minutes) is an effective antidote. The "therapeutic concentrations" of magnesium have been empirically determined and are the levels attained with

TABLE 35-8 SAFETY AND EFFICACY OF INTRAVENOUS MAGNESIUM SULFATE THERAPY

Factor	Number (%)
Number of women treated	1870
Number of women with seizures	11 (0.6)
Number with seizure morbidity	1 (0.05)

dosages found to be usually effective and safe (Table 35-8). No study has compared magnesium concentrations in patients successfully or unsuccessfully treated with $MgSO_4 \cdot 7 H_2O$. We do not recommend titrating levels to any specific therapeutic range, and there is no evidence that levels greater than 6 mEq/L increase efficacy. Magnesium is not a perfect anticonvulsant, and some women have convulsions even with high serum concentrations.³⁷⁷

Based on extensive experience, intravenous administration of magnesium at doses up to 2 g/hr appears to be safe if renal function is normal. In the Magpie study, doses of 1 g/hr given intravenously were effective without serious complications in 5000 treated women; some were treated in underdeveloped nations.

Magnesium sulfate therapy at effective anticonvulsant doses is safe for the fetus and neonate. Neonatal serum magnesium concentrations are almost identical to those of the mother.³⁷⁸ Although amniotic fluid magnesium concentrations increase with prolonged infusion because of fetal renal excretion, fetal serum magnesium levels do not increase, and there is no evidence of cumulative effects on the neonate of prolonged magnesium administration for seizure prophylaxis.

In a study of 118 infants of mothers treated with magnesium sulfate, the average serum magnesium concentration was 3.7 mEq/L. There was no correlation of magnesium levels with Apgar scores.³⁷⁹ Administration of magnesium to the mother may have additional beneficial effects for the fetus, which are being tested in controlled trials (see Chapter 29).

Phenytoin. Phenytoin is an effective anticonvulsant with pharmacologic effects that would not be predicted to produce adverse effects on the fetus or neonate. In several small studies, there were no obvious adverse fetal or maternal effects.^{380,381} Although phenytoin is not as effective as magnesium for prophylaxis or treatment of eclampsia,^{372,382} it can be used safely when magnesium is inappropriate, such as in women with myasthenia gravis or markedly compromised renal function. Phenytoin nonetheless does have potential severe adverse effects that may be magnified by unfamiliarity of obstetric personnel with its use.

Anticonvulsant Therapy. Magnesium is more effective than phenytoin or benzodiazepam to treat eclamptic seizures.³⁷² An initial infusion of 4 g can be administered safely intravenously over as little as 5 minutes, and intravenous $MgSO_4$ can be administered at 1 to 2 g/hr to maintain therapeutic serum magnesium levels. If a patient already receiving magnesium has an eclamptic seizure, it is safer to terminate seizures with another agent, such as 5 to 10 mg of diazepam (Valium), 4 mg of lorazepam (over 2 to 5 minutes),³⁸³ or a short-acting barbiturate, such as pentobarbital (125 mg given intravenously). If these measures fail, general anesthesia may be necessary to terminate the seizures.

TABLE 35-9 DRUGS FOR TREATMENT OF HYPERTENSIVE EMERGENCIES

Drug	Time Course of Action			Intramuscular Dosage	Intravenous Dosage	Interval between Doses	Mechanism
	Onset	Maximum	Duration				
Hydralazine	10-20 min	20-40 min	3-8 hr	10-50 mg	5-25 mg	3-6 hr	Direct dilatation of arterioles
Sodium nitroprusside	0.52-2 min	1-2 min	3-5 min	—	IV solution: 0.01 g/L; IV infusion rate: 3-4 µg/kg/min		Direct dilatation of arterioles and veins
Labetalol	1-2 min	10 min	6-16 hr	—	20-50 mg	3-6 hr	α- and β-Adrenergic blocker
Nifedipine	5-10 min	10-20 min	4-8 hr	—	10 mg orally	4-8 hr	Calcium channel blocker

Most seizures terminate spontaneously within 1 to 2 minutes. The most important measures for any seizure before pharmacologic therapy is initiated are prevention of injury and protection of the airway to prevent aspiration.

ANTIHYPERTENSIVE THERAPY

Antihypertensive agents are not administered routinely to women with preeclampsia. There is no evidence that administration of these agents has beneficial fetal effects. The suggestion that lowering blood pressure reduces the risk of seizures has not been tested. The goal of antihypertensive treatment is prevention of intracranial bleeding and stroke.

Therapy is reserved for women in whom blood pressure is elevated to more than 160 mm Hg systolic or more than 105 to 110 mm Hg diastolic, which are the levels associated with intracranial bleeding or stroke.^{384,385} The goal of blood pressure control is not to attain normal blood pressure but merely to reduce blood pressure to a level that can provide a margin of maternal safety (i.e., 135 to 145 mm Hg systolic and 95 to 100 mm Hg diastolic) without compromising adequate uterine perfusion. These patients have elevated blood pressure with reduced plasma volume. Overly aggressive treatment lowers maternal cardiac output and uterine perfusion and may result in iatrogenic fetal distress.

Several agents available for reducing blood pressure rapidly are described in Table 35-9. Not listed in this table are potent diuretic agents that lower blood pressure rapidly by depleting plasma volume, because the use of these agents in the plasma volume-depleted patient may reduce maternal cardiac output and uterine perfusion.

Hydralazine. The agent most widely used to reduce blood pressure in women with severe preeclampsia is hydralazine. As a direct vasodilator, it offers two major advantages. First, vasodilation with hydralazine results in a reflex increase in cardiac output and increased uterine blood flow as blood pressure decreases. Second, the increase in cardiac output blunts the hypotensive effect and makes it difficult to overdose the patient. The important side effects of hydralazine are headache and epigastric pain, which may be confused with worsening preeclampsia.

The pharmacokinetic profile of hydralazine is outlined in Table 35-9. The onset of action occurs in 10 to 20 minutes, and peak action occurs 20 minutes after administration, even when the agent is given intravenously. The duration of action is 3 to 8 hours. The use of continuous intravenous infusions of hydralazine is not sensible because minute-to-minute control cannot be attained. An alternative approach is to administer the drug as a bolus infusion, repeated at 20-minute intervals until the desired control is attained and then repeated as

necessary. A test dose of 1 mg is given over 1 minute, and blood pressure is determined to avoid idiosyncratic hypotensive effects; 4 mg is then infused over 2 to 4 minutes. After 20 minutes, the blood pressure is determined, and the following criteria for action are taken into account:

- If there was no effect from the first dose of hydralazine, the dose is repeated.
- If a suboptimal effect was obtained, a second, smaller dose is given.
- If diastolic blood pressure is between 90 and 100 mm Hg, therapy is not repeated until diastolic blood pressure increases to 105 mm Hg.

Other Drugs. In rare instances, hydralazine may not effectively lower blood pressure to the desired level. If blood pressure control is not adequate after the administration of 20 mg of hydralazine, other hypotensive agents must be used.

The calcium entry blocker nifedipine has been taken orally in doses of 10 mg, which may be repeated after 30 minutes if needed to lower blood pressure rapidly. For maintenance dosing, 10 to 20 mg can then be given every 3 to 6 hours as needed. It is quite effective and well tolerated; headache is the most common side effect.³⁸⁶

Labetalol, a mixed α-adrenergic and β-adrenergic antagonist, also is useful for reducing blood pressure acutely. It is given intravenously as a bolus infusion, beginning with 10 mg and followed by repeated doses that may be increased up to twofold (e.g., 20 mg, 40 mg, 80 mg), with doubling every 10 minutes as needed (up to 300 mg) for blood pressure control.³⁸⁷ The major reservation about the use of labetalol is that, unlike the vasodilators hydralazine and nifedipine, it does not reduce afterload. There are theoretical disadvantages with using labetalol for managing cardiac failure associated with the hypertension of preeclampsia.

Methyldopa (formerly designated α-methyldopa) is a safe and well-tested drug. However, its delayed onset of action (4 to 6 hours), even when administered intravenously, limits its usefulness for hypertensive emergencies. On the basis of side effects and experience, nifedipine or labetalol are preferred when hydralazine is ineffective.

MANAGEMENT OF OLIGURIA

In preeclamptic women, oliguria can have a prerenal or renal origin (see Chapters 44 and 57). Even though plasma volume is decreased in preeclamptic patients, the use of fluids is controversial. Excessive fluid infusion can lead to congestive heart failure and perhaps cerebral edema³⁸⁸; nevertheless, oliguria can be corrected in many patients by fluid infusion.

To avoid complications, the physician should not prescribe hypotonic fluids. They worsen the dilutional decreases in serum osmolality that may occur with any of the following: oliguria from renal causes, elevated antidiuretic hormone (ADH) level in response to stress, and oxytocin treatment.

Fluids must be administered with the understanding that oliguria may have a renal origin and that the patient is at risk for fluid overloading. Because acute renal failure resulting in permanent renal damage is rare in pregnancy (whereas pulmonary edema is a common event on some obstetric services), oliguria should be defined conservatively as less than 20 to 30 mL/hr for 2 hours.

If there are no clinical signs or history suggesting congestive heart failure, 1000 mL of isotonic crystalloid can safely be infused in 1 hour. If urine output increases, fluid infusion is maintained at 100 mL of isotonic crystalloid per hour. If the oliguria does not resolve, further fluid infusion should be guided by central venous or, preferably, pulmonary wedge pressures (see Chapter 57).

Relatively small amounts of intrapartum and postpartum blood loss can result in profound hypovolemia and shock in patients who already have compromised blood volumes. A large peripheral line should be in place at all times in case rapid replacement of blood volume becomes necessary.

MANAGEMENT OF LESS COMMON PROBLEMS

Disseminated Intravascular Coagulation. Evidence of DIC is an important indicator of severity and progression of preeclampsia. DIC is measurable by the usual clinical tests in 20% of severely preeclamptic and eclamptic women and is sufficient to cause coagulation problems in less than 10%.

Definitive therapy for DIC is removal of the inciting factor. In preeclampsia, whether the cause of the coagulation disorder is endothelial cell damage, release of thromboplastic materials, vasospasm with attendant microangiopathic changes, or local consumption of procoagulants in the choriodecidual space, the inciting factor is pregnancy related, and definitive therapy is termination of the pregnancy. The long-range follow-up of women with preeclampsia indicates that all organ system functions return to normal. It is unlikely that occlusion of the microvasculature by thrombi in mild forms of DIC causes permanent damage.

Evidence of early DIC is not by itself an absolute indication for immediate delivery. With rapidly deteriorating renal or hepatic function or DIC complicated by spontaneous hemorrhage, however, delivery should be expeditious.

The experience with heparin anticoagulation, which has been used to maintain pregnancies in women with symptomatic DIC or as a prophylactic measure to prevent DIC, indicates that these approaches are not effective.³⁸⁹ The use of heparin during labor in women in whom DIC necessitates delivery has not been studied extensively. The experiences already cited, however, indicate that the approach may be dangerous.

If procoagulants decrease to a level associated with spontaneous hemorrhage, appropriate procoagulant therapy should be given before delivery. This should be done whether the anticipated mode of delivery is vaginal or cesarean (see Chapter 40).

Pulmonary Edema. Pulmonary edema occurs in a small number of women with preeclampsia. In the past, this complication was associated with high rates of maternal mortality. The pathogenesis of pulmonary edema often is iatrogenic fluid overload, but it can be cardiogenic or involve transudation of fluid into alveoli. The noncardiogenic variety results from decreased colloid oncotic pressure or a pulmonary vascular leakage, and it can occur in the antepartum, intra-

partum, or postpartum period. Delayed onset of pulmonary edema requires special awareness because the edema usually occurs during postpartum diuresis, when most concerns about the complications of preeclampsia are diminishing.

Management of pulmonary edema requires intensive monitoring, with the capability to assess pulmonary and cardiac function accurately and to perform mechanical ventilation as needed (see Chapter 57). With accurate assessment of cardiopulmonary function and aggressive treatment, the mortality resulting from pulmonary edema in preeclampsia has been greatly reduced.³⁹⁰

Postpartum Management in Preeclampsia

Delivery does not immediately reverse the pathophysiologic changes of preeclampsia, and it is necessary to continue palliative therapy for various periods. Some of the constraints on therapy, however, are eliminated by delivery of the fetus. Approximately one third of convulsions occur in the postpartum period, most within 24 hours and virtually all within 48 hours, although there are rare exceptions. Most physicians advocate continuing anticonvulsant therapy for 24 hours after delivery. For simplicity, magnesium sulfate therapy is usually continued, but because there is no need to consider fetal effects, any safe anticonvulsant regimen is reasonable at this time.

Anticonvulsant efficacy rather than sedation is the goal, and barbiturate anticonvulsants in usual therapeutic doses require days to achieve effective levels. Similarly, phenytoin must be administered intravenously in large doses to achieve therapeutic levels within hours, with the attendant dangers of cardiac arrhythmia. Serum magnesium concentrations decrease with increased urinary output, and with puerperal diuresis, it is extremely unlikely that the serum magnesium concentration is therapeutic at usual doses. Despite this drawback, convulsions rarely occur in the postpartum period, suggesting that rapid diuresis indicates resolution of the preeclamptic process and that therapy may no longer be required.

On the basis of these considerations, it appears reasonable to discontinue magnesium sulfate therapy when diuresis occurs before 24 hours after delivery. Some investigators recommend continuing magnesium sulfate administration for longer than 24 hours in selected patients, but it is difficult to determine the basis on which this selection can be made. In one randomized trial limited to women with mild preeclampsia, there was no difference in seizure risk when magnesium was discontinued after only 12 hours.³⁹¹ Unfortunately, this study was limited by a relatively small sample, and it is likely that any future studies will be similarly underpowered because of the rarity of the outcome.

Hypertension may take considerably longer than 24 to 48 hours to resolve. Women who are hypertensive 6 weeks after delivery may be normotensive at long-term follow-up.⁷⁴ The indications for therapy are similar to those for the antepartum period. The patient with blood pressure greater than 160 mm Hg systolic or 105 mm Hg diastolic after delivery should be treated; the fetus no longer influences therapeutic choices. If rapid blood pressure control is necessary, sodium nitropruside is more effective and better tolerated than hydralazine. Diuretics and conventional oral antihypertensive agents can be started to achieve smooth control. The woman who remains hypertensive (>100 mm Hg diastolic pressure) should be sent home with continued antihypertensive therapy.

Patients with lesser elevations require no therapy. The choice of drugs is based on the usual step method of antihypertensive therapy. The patient sent home with a therapeutic regimen must be warned about symptoms of hypotension, and she must be seen at weekly

intervals, because the need for therapy diminishes rapidly in some cases.

Therapies No Longer Recommended

Strict sodium restriction and diuretic therapy have no role in the prevention or treatment of preeclampsia. In women with marked sodium retention as manifested by significant edema, modest sodium restriction may not alter the course of the disease but can reduce discomfort. Diuretics should not be given because plasma volume is already decreased, and further volume depletion can affect the fetus adversely. Attempts to modify the progression of the disease by volume expansion have not been conclusively shown to be helpful and require more thorough evaluation before being used in routine management of preeclampsia.³⁹²

Sodium nitroprusside is a potent, short-acting, direct vasodilator that allows excellent moment-to-moment blood pressure control. However, because elevated fetal concentrations of serum cyanide, sometimes to toxic levels, have been reported in animal studies,³⁹³ this agent is rarely used in humans.

Diazoxide is a thiazide analogue that has no diuretic effect, but it is an extremely potent antihypertensive agent, acting as a direct vasodilator. It is rarely used because of effects on maternal and fetal carbohydrate metabolism and its profound and slowly reversible effect on blood pressure.

There is little evidence that therapeutic efforts alter the underlying pathophysiology of preeclampsia. Therapeutic intervention for clinically evident preeclampsia is palliative. At best, it may slow the progression of the condition, but it is more likely to allow continuation of the pregnancy. Bed rest is a usual and reasonable recommendation for the woman with mild preeclampsia, although its efficacy is not clearly established.³⁹⁴ Prophylactic hospitalization with increased bed rest may reduce the incidence of preeclampsia for women at high risk identified by increased angiotensin sensitivity.³⁹⁵ It is unclear, however, which of the several behavioral modifications involved in hospital residence is important. Anecdotal reports of clinical improvement with bed rest must be tempered by the recognition of the unpredictable course of preeclampsia.

Follow-up Assessment for Preeclampsia

Because the early recognition and treatment of significant blood pressure elevation reduce morbidity, all women with a clinical diagnosis of preeclampsia deserve long-range follow-up. Decisions for evaluation and treatment should be deferred until 12 weeks after delivery because some women who are hypertensive at 6 weeks are normotensive years later. The woman who is normotensive 12 weeks after delivery should be advised of her increased risk for hypertension in later life⁷⁷ and should be counseled to have her blood pressure checked at least yearly. Because of the association between preeclampsia and later cardiovascular disease,⁷⁸ formal assessment of cardiovascular risk factors in such patients is prudent.

Prevention of Preeclampsia

Since the preeclamptic syndrome was first recognized, prevention has been attempted. Sodium restriction and nutrient supplements have been unsuccessful.¹⁸ Randomized, controlled trials based on several hypotheses for preventing preeclampsia have been performed. The sequence of studies for each intervention has been similar, with initial small, single-center studies suggesting benefit and subsequent larger, well-powered studies finding no significant benefit.^{36,396-398}

Aspirin trials to prevent preeclampsia are a prototype. More than 35,000 women have been included in randomized, controlled trials of various sizes and quality to determine the benefit of aspirin.³⁹⁹ Small, single-center studies suggested benefit,⁴⁰⁰⁻⁴⁰² but larger, multicenter trials showed no effect.^{36,403} One potential explanation is publication bias in favor of positive results. Results also might have varied because of the heterogeneity of preeclampsia, with benefit of therapy evident in only a subset.

A meta-analysis of trials that enrolled a large number of pregnant women found benefit for antiplatelet treatment (i.e., aspirin) to reduce the frequency of the diagnosis of preeclampsia, preterm delivery, and growth-restricted infants.^{399,404} There was a modest reduction of the incidence of preeclampsia (17%), with 72 women needing treatment to prevent one case of preeclampsia. There was a 14% reduction in the rate of fetal and neonatal deaths, with a number needed to treat of 243 to prevent one death. The investigators concluded that antiplatelet agents such as aspirin have moderate benefits when used for prevention of preeclampsia and its consequences.

Using another analytical strategy, meta-analysis of individual patient data, the Perinatal Antiplatelet Review of International Studies (PARIS) Collaborative Group attempted to differentiate the success of aspirin in subsets according to maternal diagnosis, dosage of aspirin, and time when therapy was initiated. Although the group did confirm a reduction in preterm birth and the incidence of preeclampsia by 10% with aspirin, they did not identify any particular subgroups for whom aspirin was more effective. There was no difference in perinatal death for women treated with prophylactic aspirin.⁴⁰⁵

The estimated number of women to treat to prevent one case of preterm birth in this study was 500 for low-risk pregnancies (incidence of 2%) and 50 for high-risk pregnancies when the estimated incidence of preeclampsia was 20%. Decisions about the choice of aspirin with this degree of efficacy must consider the short-term adverse effects on the mother and infant, which have not been evident in the large number of women treated, and the long-term outcome, which is largely unknown.⁴⁰⁶

Calcium supplementation to prevent preeclampsia was initiated with similar enthusiasm. Calcium was tested in a large, randomized, controlled trial in the United States³⁹⁶ based on initial studies and meta-analyses.⁴⁰⁷ The conclusion of this study was unequivocal, finding no evidence that 2 g of supplemental calcium administered to pregnant women from early gestation onward reduced the incidence of preeclampsia, altered blood pressure, or affected fetal weight. A review of published studies concluded that any benefit of calcium was related to low calcium intake before pregnancy in some women.⁴⁰⁸ Based on this rationale, the World Health Organization conducted a trial of calcium supplementation in populations with low calcium intake. Treatment did not reduce the diagnosis of preeclampsia but did reduce adverse outcomes.⁴⁰⁹ Calcium administration has therefore been proposed as useful in low calcium consuming populations.⁴¹⁰

Oxidative stress has been suggested as important in preeclampsia. The results of antioxidant therapy are similar to those with calcium and aspirin; an initial small trial of antioxidant vitamins C and E suggested benefit,⁴¹¹ but a subsequent, larger trial did not.³⁹⁷ There was concern about the safety of this therapy for the fetus because an excess of low-birth-weight infants (but not IUGR or premature infants) occurred in the antioxidant-treated group. The largest trial of low-risk women is ongoing, with results expected in 2008. This study initiated antioxidant treatment far earlier in pregnancy than the other studies (start date at 9 to 16 weeks), with 40% of women enrolled before 12 weeks, whereas the other studies began at an average of 18 weeks. This may be relevant because oxidative stress is known to accompany the

establishment of the intervillous circulation at 8 to 10 weeks' gestation.⁴¹² The primary outcome in this study is a composite outcome of maternal and fetal morbidity. Final decisions about efficacy and safety await the conclusion of this trial.⁴⁰⁸

The results of these studies of prophylaxis raise several important points:

- Randomized clinical trials of appropriate population and size to achieve sufficient power must guide clinical management. Nonetheless, the success in small trials and the failure in large, multicenter trials may be related to the heterogeneity of patients with preeclampsia.¹⁷⁴ Prophylaxis may be effective in a specific subset of women (e.g., calcium supplementation in women with low average calcium intake).
- Because the diagnosis of preeclampsia is based on signs that usually have minimal causal significance, prophylactic therapy should be aimed at the pathophysiology and judged by effects on perinatal outcome.
- The aspirin and calcium data suggest that initiation of therapy before disease is clinically evident may be successful if specific interventions can be applied to appropriately selected subjects.

Chronic Hypertension

Differentiation of chronic hypertension from preeclampsia is complex but essential. Even more important is the difficult discrimination between exacerbation of preexisting hypertension and the onset of superimposed preeclampsia. The rate of progression and the effect on the mother and fetus of these conditions are different in the two diseases. Management of hypertension in early pregnancy requires early recognition of blood pressure elevation, baseline testing to aid in the later diagnosis of superimposed preeclampsia, and meticulous maternal and fetal observation. If a decision is made to use antihypertensive therapy, antihypertensive drugs must be chosen on the basis of considerations specific to pregnancy.

Epidemiology

The prevalence of chronic hypertension increases with advancing age. In whites, the risk increases from 0.6% (18 to 29 years old) to 4.6% (30 to 39 years old). In African-American women, the risks increased to 2% and 22.3%, respectively.⁴¹³ Preeclampsia occurs in 25% of hypertensive women, compared with 4% in previously normotensive women.

Pathogenesis

Effects of Chronic Hypertension on the Mother

Blood pressure elevation during pregnancy without the superimposition of preeclampsia has the same impact as blood pressure increases in any other 10-month period. Systolic and diastolic blood pressures that exceed 160 and 105 mm Hg, respectively, increase the risk of morbidity even over this short period.

Maternal morbidity and mortality rates are greater among women with superimposed preeclampsia than among those with preeclampsia arising *de novo*. Blood pressure elevation with superimposed preeclampsia is also greater, increasing the possibility of intracranial bleeding. Two thirds of cases of eclampsia occur in first pregnancies, but two thirds of maternal deaths due to eclampsia occur in pregnan-

cies other than the first pregnancy, in which underlying hypertension is a more common predisposing factor.⁴¹⁴

One review of 28 women with preeclampsia and stroke examined blood pressures before the event. The range of systolic values ranged from 159 to 198 mm Hg, and the range for diastolic values was much greater, from 81 to 133 mm Hg (mean, 98 mm Hg). Only five women had diastolic values greater than 105 mm Hg.³⁸⁵ Morbidity is difficult to predict by blood pressure, although it seems to be significantly increased when systolic pressures exceed 160 mm Hg and may be increased when diastolic pressures exceed 100 mm Hg.³⁸⁵ The National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy has recommended initiating therapy when systolic pressures exceed 150 to 160 mm Hg and diastolic pressures exceed 100 to 110 mm Hg.

Effects of Chronic Hypertension on the Fetus

The perinatal mortality rate for infants born to hypertensive mothers increases as maternal blood pressure rises.¹⁰¹ Without antihypertensive therapy, a woman with a systolic pressure of 200 mm Hg or a diastolic pressure of 120 mm Hg had only a 50% chance of bearing a living infant. The perinatal mortality rate is strikingly higher in hypertensive women with proteinuria, indicating the impact of superimposed preeclampsia on the fetus.

The perinatal mortality rate for infants of women with superimposed preeclampsia is greater than for infants of women in whom the condition arises *de novo*.⁴¹⁵ There are two explanations for this difference.

First, the decidual vessels of women with even mild preexisting hypertension demonstrate vascular changes similar to the changes in renal arterioles seen in women with long-standing hypertension.⁴¹⁶ Decreased uteroplacental perfusion resulting from this change may be additive and perhaps synergistic with the decidual vascular changes of preeclampsia. The decidual vascular changes likely explain the higher incidence of abruptio placentae among women with superimposed preeclampsia.

Second, preeclampsia appears earlier in pregnancies of hypertensive women than in those of normotensive women. Fetal growth restriction is common in infants of hypertensive women, and it increases in frequency and severity with increasing maternal blood pressure.¹⁰¹

Some investigators suggest that hypertension without preeclampsia has no adverse effect on the fetus,^{286,417} but this observation ignores the effects of growth restriction. In a study of almost 300 pregnancies of women with chronic hypertension, perinatal death occurred only in growth-restricted infants.⁴¹⁸

Diagnosis

Chronic hypertension is defined as hypertension that is observable before pregnancy or that is diagnosed before the 20th week of gestation. Hypertension is defined as a blood pressure greater than 140/90 mm Hg. If the diagnosis of hypertension is confirmed for the first time during pregnancy and it persists beyond the 84th day after delivery, it is classified as chronic hypertension.

Pharmacologic Management of Hypertension

Antihypertensive Therapy in the Reduction of Maternal and Fetal Morbidity and Mortality

Antihypertensive therapy reduces maternal mortality as effectively during pregnancy as at any other time. Lowering of markedly elevated

blood pressure (>100 mm Hg diastolic pressure) can reduce the risk of morbid events even over 10 months, whereas the impact of such reduction on the minimal morbidity associated with less elevated pressures is unlikely. Antihypertensive therapy for women with mild to moderate hypertension can reduce the risk for severe hypertension in later pregnancy.⁴¹⁹

It has been postulated that antihypertensive therapy for the mother and fetus might reduce the incidence of superimposed preeclampsia, but there has been no evidence of that effect in large trials of antihypertensive therapy administered during pregnancy. A Cochrane review indicates no effect of antihypertensive therapy on the perinatal mortality rate, but antihypertensive therapy was begun in the first trimester in only 2 of 46 studies included in the review.⁴¹⁹ Because pathologic and pathophysiologic changes are present as early as 14 weeks' gestation, it is possible that therapy was begun too late to have any effect on preeclampsia or fetal outcomes. There is no evidence that antihypertensive therapy increased perinatal mortality rates in any of these studies.^{420,421} If therapy is indicated for maternal considerations (diastolic pressure >100 mm Hg), it is safe for the fetus if the choice of drug is appropriate.⁴²²

There is some suggestion that antihypertensive therapy may be associated with an increased risk of small infants. This increase is small and driven largely by therapy with β -blockers, specifically atenolol.⁴²³

Overview of Therapy for Hypertension in Pregnancy

Antihypertensive therapy can be used safely in pregnancy when indicated by the maternal condition. Therapy reduces the maternal risks of markedly elevated pressures, and in women with mild to moderate hypertension, it prevents severe hypertension later in pregnancy. The decision to use antihypertensive therapy is based on maternal considerations.

Antihypertensive medication is reserved for women with diastolic pressures above 90 mm Hg. Women using hypertensive therapy when they become pregnant, regardless of pretreatment blood pressure, are best served by continuation of therapy. There is no evidence that antihypertensive therapy presents a substantial risk to the fetus, and discontinuation of therapy may adversely affect long-range compliance with drug therapy, increasing the risk to the mother.

Perhaps in no other area of medicine is therapy with the potential for benefit or danger to two individuals so poorly evaluated. There is virtually no information from large, randomized, controlled trials about the fetal and maternal benefits and risks of antihypertensive therapy for mild to moderate chronic hypertension in pregnancy.

Choice of Antihypertensive Agents

EFFECT ON THE FETUS

Fetal considerations, particularly teratogenic concerns, influence the choice of antihypertensive agents (see Chapter 20). Few of the available antihypertensive agents have been associated with morphologic teratogenic effects; exceptions are the angiotensin-converting enzyme (ACE) inhibitors (discussed later). Because development does not end with gross organ development, long-term follow-up of infants and children treated in utero is needed. Such information is available only for methyl dopa. Children of mothers treated with this agent during pregnancy showed no signs of neurologic or somatic abnormalities when examined at age 7 years.⁴²⁴

Maternal drug therapy can have pharmacologic effects on the fetus. For example, maternal treatment with propranolol reduced fetal and maternal cardiac output in animal studies.⁴²⁵ Because of the potential pharmacokinetic differences between mother and fetus, appropriate

dosage for the mother may be excessive for the fetus.⁴²⁶ Drug effects of minimal importance to the mother and fetus may be of great importance to the infant.

EFFECT ON UTERINE BLOOD FLOW

Maternal medication may affect fetal well-being by altering uterine blood flow. Antihypertensive drugs act by reducing cardiac output or systemic vascular resistance, which may affect blood flow to the uterus. Optimal drug choice in pregnancy avoids agents that reduce uterine and therefore uteroplacental blood flow. Agents that reduce cardiac output are best avoided because they almost inevitably reduce uterine blood flow. Antihypertensive drugs that act on total peripheral resistance may increase, decrease, or have no effect on uterine perfusion, depending on the pattern of blood flow redistribution.

Reliable information on the effects of antihypertensive drugs on human uterine blood flow is scant. Data on the potential effects of these drugs are based on studies in pregnant animals in which it was assumed that humans and sheep respond identically or in which blood flow to the kidney—an exquisitely autoregulated organ that usually receives 10% of cardiac output—was compared with blood flow to the uterus, an organ whose perfusion increases 500-fold over several months. With these limitations, Table 35-10 outlines the available information about antihypertensive agents used in pregnancy.

USE OF DRUGS

Two common classes of antihypertensive medications—diuretics and β -adrenergic blockers—warrant comment.

Diuretics. The indiscriminate use of diuretic agents during pregnancy has appropriately been condemned and is no longer common. In an epidemiologic assessment of 8000 pregnancies, a small but significant increase in perinatal mortality rate was demonstrated in women receiving continued or intermittent diuretic therapy, especially when the drug was begun late in pregnancy.⁴²⁷ Lack of expansion of intravascular volume during pregnancy also has adverse prognostic significance.^{337,428} In women taking diuretics from early pregnancy onward, plasma volume does not expand as much as in normal pregnancy.^{429,430} Because of this, some physicians have recommended that diuretics be avoided entirely during pregnancy.^{286,431} However, diuretics are used frequently in nonpregnant patients for antihypertensive therapy, and their efficacy, safety, and infrequency of side effects are extensively documented.⁴³² The combination of diuretics with other antihypertensive drugs allows the use of lower doses of the other agents by preventing sodium retention.

Despite these theoretical concerns, when continuous diuretic therapy is begun before 24 to 30 weeks' gestation, there is no evidence of an increased perinatal mortality rate or decreased neonatal weights.^{277,279} However, diuretic therapy should never be instituted if there is any evidence of reduced uteroplacental perfusion, such as fetal growth restriction or preeclampsia. Diuretic therapy increases the serum concentration of uric acid and thereby renders uric acid determinations invalid for evaluating superimposed preeclampsia.

β -Adrenergic Antagonists. β -Adrenergic antagonists are the initial antihypertensive agents for nonpregnant patients in many settings. These agents lower blood pressure by reducing cardiac output and perhaps by interfering with renin release.

Infants born to women treated with β -blockers in pregnancy are more often growth restricted compared with infants born to women treated with placebo or other antihypertensive drugs.^{433,434} Most growth-restricted infants were born to women who received atenolol.⁴²³ β -Adrenergic antagonists vary according to their β_1 -adrenergic subtype-specific (e.g., metoprolol, atenolol) and lipid solubility. For

TABLE 35-10 ANTIHYPERTENSIVE AGENTS USED IN PREGNANCY

Agent	Mechanism	Cardiac Output	Renal Blood Flow	Side Effects	
				Maternal	Neonatal
Thiazide	Initial: decreased plasma volume and cardiac output	Decreased	Decreased	Electrolyte depletion, serum uric acid increase, thrombocytopenia, hemorrhagic pancreatitis	Thrombocytopenia
Methyldopa	Later: decreased total peripheral resistance	Unchanged	Unchanged or increased	Lethargy, fever, hepatitis, hemolytic anemia, positive Coombs test result	
	False neurotransmission, central nervous system effect	Unchanged	Unchanged		
Hydralazine	Direct peripheral vasodilation	Increased	Unchanged or increased	Flushing, headache, tachycardia, palpitations, lupus syndrome	
Prazosin	Direct vasodilator and cardiac effects	Increased or unchanged	Unchanged	Hypotension with first dose; little information on use in pregnancy	
Clonidine	Central nervous system effects	Unchanged or increased	Unchanged	Rebound hypertension; little information on use in pregnancy	
Propranolol	β -Adrenergic blockade	Decreased	Decreased	Increased uterine tone with possible decrease in placental perfusion	Depressed respiration
Labetalol	α - and β -Adrenergic blockade	Unchanged	Unchanged	Tremulousness, flushing, headache	See propranolol
Reserpine	Depletion of norepinephrine from sympathetic nerve endings	Unchanged	Unchanged	Nasal stuffiness, depression, increased sensitivity to seizures	Nasal congestion, increased respiratory tract secretions, cyanosis, anorexia
Enalapril	Angiotensin-converting enzyme inhibitor	Unchanged	Unchanged	Hyperkalemia, dry cough	Neonatal anuria
Nifedipine	Calcium channel blocker	Unchanged	Unchanged	Orthostatic hypotension, headache, tachycardia	None demonstrated in humans

example, atenolol more readily crosses the placenta compared with metoprolol. Some of the β -adrenergic antagonists, such as oxprenolol, also have β -agonist effects. The decision, both theoretical and empiric, about the safety and efficacy of these drugs requires evaluation of the pharmacologic characteristics of each drug rather than consideration of them as a class.

Labetalol. Unlike atenolol, labetalol possesses both α -adrenergic and β -adrenergic antagonist activity. It is commonly used during pregnancy for acute treatment of preeclampsia and as therapy for chronic hypertension. Although some reports have suggested potential growth restriction,⁴³³ other studies have not.^{435,436} Experience has not identified it as a teratogen (see Pharmacologic Recommendations, later).

Hydralazine. Although hydralazine seems to be an ideal antihypertensive drug for pregnant women, side effects, including headache and palpitations caused by reflex increase in cardiac output, usually prevent its use in effective dosages for chronic hypertension. Tachyphylaxis has been described with hydralazine, making its use limited to short-term blood pressure control.

Methyldopa. Methyldopa, the drug used in the largest study and the only drug whose safety for infants has been demonstrated in long-range follow-up assessments, is the benchmark of antihypertensive therapy in pregnancy. It frequently causes drowsiness, however, especially when used in the large doses necessary when diuretics are not used concomitantly, and occasionally to a degree that is incapacitating, particularly for ambulatory patients.⁴³⁷ In the original examination of

infants whose mothers received methyldopa, there was a small but statistically significant decrease in head circumference, although this effect was not found in follow-up studies.⁴²⁴

Other Drugs. Several other antihypertensive drugs are available that may offer theoretical advantages for use in pregnancy. More data are required about the efficacy and the immediate and long-range safety of these drugs in pregnancy.

One agent that is widely used in nonpregnant patients is enalapril, an ACE inhibitor. Unexplained fetal death in pregnant ewes and rabbit does treated with another ACE inhibitor, captopril, have been borne out by clinical experience. Although there are no reports of fetal death, renal agenesis and neonatal renal dysfunction have been reported.⁴³⁸ This class of drugs is now considered pregnancy category X. There is less experience with angiotensin II receptor blockers (ARBs) such as losartan and telmisartan, although case reports suggest problems similar to those with ACE inhibitors.⁴³⁹⁻⁴⁴¹ ACE inhibitors and ARBs should be discontinued before pregnancy or as soon as pregnancy is detected.⁴⁴²

Pharmacologic Recommendations

ACE inhibitors and ARBs should be discontinued during pregnancy. No other drugs are absolutely contraindicated.

The drug regimens suggested in the following paragraphs are preferred because of the available information regarding efficacy, side effects, and long-term follow-up. If a woman has established

excellent blood pressure control, however, especially after unsuccessful trials of other agents, she should continue the successful regimen on becoming pregnant. Women receiving atenolol should switch to another β -adrenergic antagonist of equivalent efficacy, such as metoprolol.

The use of diuretic therapy is associated with few acute adverse effects and potentiates other drug effects. Although the use of diuretics from early pregnancy onward appears safe,²⁷⁷⁻²⁷⁹ theoretical concerns raised by the effects of these agents on plasma volume militate against their use as initial therapy. Diuretics are also contraindicated for women with evidence of decreased uterine perfusion manifested as IUGR or preeclampsia. If the pregnancy is less than 30 weeks' gestation, these drugs appear safe despite theoretical concerns. The initial dose should be 25 mg of hydrochlorothiazide equivalent, increasing at 2- to 4-day intervals to 50 mg/day. Sodium restriction should be avoided, and dietary potassium should be supplemented when diuretics are used.

Because of its established efficacy and fetal safety, methyldopa has for many years been chosen to initiate antihypertensive therapy in pregnancy. The initial dosage is 250 mg taken at night and then 250 mg twice daily, increasing to a maximum of 1 g twice daily. If the maximal dose is not tolerated or does not control blood pressure, another agent should be added (not substituted). The addition of a diuretic usually dramatically increases the efficacy of methyldopa.

Labetalol or nifedipine is commonly added to methyldopa therapy when a second agent is required, and they are increasingly used as first-line therapy. If three drugs appear to be necessary to control blood pressure, consultation with a cardiologist or nephrologist is prudent. Used as a primary or secondary agent, labetalol is begun at 100 mg taken twice each day; it is given up to 2.4 g per day in divided doses, but the typical maximal dosage is 400 to 600 mg twice each day. Nifedipine may be given 10 to 30 mg three times each day or as 30 to 60 mg once each day in sustained-release form.

Obstetric Management of Hypertension

Obstetric management of the woman with chronic hypertension comprises the following measures:

- Recognizing superimposed preeclampsia early in the pregnancy
- Monitoring fetal well-being
- Excluding pheochromocytoma

Early in pregnancy, studies of renal function (i.e., creatinine clearance and 24-hour protein excretion), a serum urate determination, and a platelet count should be performed. These baseline studies may aid in differentiating exaggeration of the usual blood pressure changes of pregnancy from superimposed preeclampsia later in pregnancy. Because preeclampsia occurs at earlier gestational ages in hypertensive women, these patients should be seen more frequently, such as every other week at 24 to 26 weeks' gestation and weekly after 30 weeks.

Ultrasonographic evaluation of the fetus between 18 and 24 weeks' gestation allows accurate dating and provides a baseline for determining incremental growth when there is suspicion of growth restriction. Because precise knowledge of the gestational age may become critical if early delivery is needed, a first-trimester ultrasound scan to establish accurately the due date is prudent.

Most hypertensive pregnant women have essential hypertension. Thorough evaluation for most secondary forms of hypertension is best reserved for the postpartum period because of the obfuscation of many

of these forms by physiologic changes of pregnancy and because of the risks of diagnostic procedures to the mother and fetus.

Pheochromocytoma is a potentially lethal complication, especially during the intrapartum period. This condition can be simply, accurately, and inexpensively diagnosed in many individuals with fixed hypertension by determination of the serum or urinary catecholamine concentration. Hypertensive women in whom this analyte has not been measured in the past should undergo this determination in early pregnancy.

Coarctation of the aorta is a rare cause of hypertension in women of reproductive age. It can be detected readily by determination of a lag between radial and femoral pulses, which should be measured as part of the physical examination of hypertensive patients.

Extensive antenatal fetal surveillance should be employed for pregnancies with preeclampsia or growth-restricted infants.³ Because of the controversy surrounding uncomplicated hypertension and perinatal mortality and because the origin of the increased mortality is placental insufficiency, many clinicians employ some form of antenatal surveillance for uncomplicated cases in the third trimester.

Chapter 36

Clinical Aspects of Normal and Abnormal Labor

John M. Thorp, Jr., MD

Normal Labor and Its Limits

The proper management of labor and delivery depends on a thorough understanding of the biology of normal labor. Given the inherent limitations in our knowledge of human labor, the astute clinician must take care to not draw firm conclusions and be willing to change his or her practice. Moreover, effective recognition and management of labor abnormalities requires knowledge of the limits of labor and of the physiologic response of both the mother and the fetus to the stresses of labor and delivery.

Uterine contractions occur throughout normal pregnancy. These contractions are irregular in timing and intensity, discoordinate in distribution, and, for the most part, entirely painless. Such uterine activity continues in normal pregnancy until late in the third trimester, when the contractions become more frequent, of greater and more consistent intensity, and more coordinated. Also, during the latter part of the third trimester, effacement (shortening) and dilation of the cervix begin. At the end of this largely painless phase, clinical labor begins, defined as the onset of painful uterine contractions associated with effacement and dilation of the cervix.

The precise onset of this combination of events frequently cannot be ascertained, and for practical purposes clinicians must rely on the patient's best estimate of when her labor contractions began or when they became regular in consistency and intensity. The specific onset of cervical effacement and dilation can rarely be documented in cases of spontaneous onset of labor; not uncommonly, both effacement and dilation occur late in the third trimester, before the onset of regular or noticeable uterine contractions. Therefore, the precise onset of labor is difficult to determine, and much of what is written about false labor, prodromal labor, and the latent phase of labor is influenced by this uncertainty.

Hendricks and colleagues,¹ who reported the findings of serial cervical examinations of 303 patients in the third trimester, studied these prelabor changes of the cervix. Cervical dilation began earlier and was of greater magnitude in multiparas than in primiparas. Cervical effacement, on the other hand, began earlier and was of greater magnitude in primiparas. These authors introduced the concept of the "cervical coefficient," which is the product of cervical dilation (in centimeters) and the percentage of effacement. They found that, at any point in prelabor, the cervical coefficient is relatively the same for all patients regardless of parity. The mean cervical dilation during the last 3 days

before the onset of labor is 1.8 cm for nulliparas and 2.2 cm for multiparas. Their study stressed the importance of the prelabor preparation of the cervix and its influence on the duration of labor. It also pointed out the difficulty of using a specific time for onset of labor if it is defined as the beginning of cervical dilation.

Categorization of Labor Events

By convention, labor is divided into three stages:

1. *First stage:* from onset of labor to full dilation of the cervix
2. *Second stage:* from full dilation of the cervix to delivery of the infant
3. *Third stage:* from delivery of the infant to delivery of the placenta

Pritchard and MacDonald² described a fourth stage of labor, comprising the hour immediately following delivery of the placenta.

One of the most thorough evaluations of the first stage of labor was that by Friedman,³ conveniently summarized in a monograph. His graphostatistical analysis of labor in term patients^{3,4} depicted the relationship between the duration of labor and dilatation as a sigmoid curve, reflecting its exponential nature. He divided the first stage of labor into two major phases:

1. *Latent phase:* from the onset of regular uterine contractions to the beginning of the active phase
2. *Active phase:* from the time at which the rate of cervical dilation begins to change rapidly (usually at about 3 to 4 cm of dilation) to full dilation

Data from several thousand patients, in whom cervical dilation and the station of the presenting fetal part were documented throughout labor, were used to establish normal limits of labor for nulliparous and multiparous patients. A group of nulliparas and a group of multiparas were selected in whom there were no apparent complications of labor and who delivered normal infants. From these cases, the norms for "ideal" labor were determined (Table 36-1). Descent of the fetal head in relationship to the ischial spines was found to begin well before the

TABLE 36-1 CHARACTERISTICS OF LABOR IN NULLIPARAS AND MULTIPARAS*

Characteristic	Nulliparas		Multiparas	
	All Patients	Ideal Labor	All Patients	Ideal Labor
Duration of first stage (hr)				
Latent phase	6.4 ± 5.1	6.10 ± 4.0	4.80 ± 4.9	4.50 ± 4.2
Active phase	4.6 ± 3.6	3.40 ± 1.5	2.40 ± 2.2	2.10 ± 2.0
Total	11.0 ± 8.7	9.50 ± 5.5	7.20 ± 7.1	6.60 ± 6.2
Maximum rate of descent (cm/hr)	3.3 ± 2.3	3.60 ± 1.9	6.60 ± 4.0	7.00 ± 3.2
Duration of second stage (hr)	1.1 ± 0.8	0.76 ± 0.5	0.39 ± 0.3	0.32 ± 0.3

*Mean ± SD.

Data from Friedman EA: *Labor: Clinical Evaluation and Management*, 2nd ed. New York, Appleton-Century-Crofts, 1978.

second stage. The rate of descent increased late in the first stage and continued linearly into the second stage of labor until the perineal floor was reached. Data for the maximum rate of descent and the length of the second stage of labor in all patients are also given in Table 36-1.

Friedman^{3,4} formulated a series of definitions that have been incorporated into routine obstetric care. For example, he defined no cervical dilation for 2 hours as an arrest of the active phase of labor and a rate of dilation in the active phase of 1.2 cm/hr as a protracted active phase. His work has helped generations of obstetricians conceptualize progress in labor and has provided a standardized model for intervention.

Are Friedman's labor curve and definitions applicable to populations a half century later? Numerous studies done in the last decade indicate that the pattern of labor progression is different from what was observed in the 1950s⁵⁻⁹ and that the clinical cutoff points for intervention and the duration of those interventions derived from Friedman's work are no longer clinically useful.^{10,11} Zhang, Troendle, and Yancey,¹² in a landmark paper using a statistical approach based on likelihood, demonstrated how different contemporary labor progression is from that described in earlier years. Differences include the following: (1) a gradual rather than an abrupt transition from latent to active-phase labor; (2) a length of active labor of 5.5 hours, rather than the 2.5 hours described by Friedman; (3) no deceleration phase; (4) the common occurrence of at least 2 hours elapsing in the active phase without cervical dilation; and (5) the 5th percentile for rate of dilation being less than 1 cm/hr.

The findings of Zhang's group¹² appear in Table 36-2 and Figure 36-1. The figure allows comparison of Friedman's labor curves to those generated from contemporary practice. Rouse and colleagues¹¹ incorporated this finding of slower rates of progression in modern labor into a demonstration that showed that extending the minimum period of oxytocin augmentation for active-phase labor arrest, from 2 to at least 4 hours, was both effective and safe. The curves from both eras are plots of dilation against time and mimic an exponential mathematical equation. Like a compound interest curve, they begin slowly and rise more quickly as time elapses. The exponential nature of this biologic function can exasperate the patience of the laboring woman, her family, and caregivers. It lends biologic support to the age-old adage, "Patience is the virtue of the obstetrician."

Role of the Maternal Pelvis

The intelligent management of labor depends on an understanding of its mechanism as well as the norms and limits of its progress. One of the most important and helpful studies for understanding the mechanism of labor was that of Caldwell and associates.¹³ This report was

TABLE 36-2 EXPECTED TIME INTERVAL AND RATE OF CHANGE AT EACH STAGE OF CERVICAL DILATION*

Cervical Dilation (cm)		Time Interval (hr)	Rate of Cervical Dilation (cm/hr)
From	To		
2	3	3.2 (0.6, 15.0)	0.3 (0.1, 1.8)
3	4	2.7 (0.6, 10.1)	0.4 (0.1, 1.8)
4	5	1.7 (0.4, 6.6)	0.6 (0.2, 2.8)

the culmination of a study of more than 1000 radiographic examinations of the pelvis and fetal head performed before, during, or after labor, in relation to the known details of delivery and the facts ascertained by vaginal examination. Many of the findings of this and later studies by the same authors¹⁴ were incorporated in a monograph by Steer.¹⁵ Although a complete review of these important works is beyond the scope of this text, a study of their contributions will substantially increase the reader's understanding of the influence of the pelvic architecture on normal and abnormal labor. Several of the important findings of these studies are worth reemphasizing here.

With a gynecoid or android type of pelvis, the fetal head engages in the transverse position 60% to 70% of the time. The anthropoid pelvis predisposes to engagement in the occiput anterior or posterior position. After the fetal head enters the pelvis in the transverse position, it is carried downward and backward until it impinges on the sacrum low in the midpelvis. It is at this point that internal rotation begins.

Internal rotation usually occurs in the midpelvis. Anterior rotation of the fetal head is practically complete when the head makes contact with the lower aspects of the pubic rami.

The common occurrence of engagement and descent predominantly in the posterior pelvis is usually associated with a normal progress of labor and spontaneous delivery; when engagement and descent occur predominantly in the forepelvis, however, there is a higher incidence of abnormal progress of labor and a higher rate of operative delivery. If the fetal head is descending in the posterior pelvis, the cervix usually is felt posteriorly in the vagina. If the cervix is palpated in a forward position, closer to the symphysis than to the sacrum, engagement and descent in the forepelvis must be suspected.

The increasing use of the vacuum extractor and the cesarean operation for delivery after second-stage arrest of labor has contributed to the lessening of emphasis on knowledge about pelvic types and their influence on descent and rotation of the fetal head. The relationship between pelvic architecture and the position of the fetal head, however, often allows useful prediction or explanation of abnormal labor, especially in the descent phase.

A careful clinical examination frequently discloses the essential dimensions and shape of the pelvis. In general, the characteristics of the anterior segment of the inlet correspond to those of the anterior portion of the lower pelvis:

- A subpubic arch with a well-rounded apex and ample space between the ischial tuberosities is associated with a gynecoid anterior segment at the inlet.
- A subpubic arch with a narrow angle and straight rami, convergent sidewalls, and prominent spines is associated with a narrowed, android anterior segment at the inlet.
- A narrow subpubic arch with straight sidewalls is characteristic of an anthropoid anterior segment at the inlet.
- A wide subpubic arch with straight or divergent sidewalls and a wide interspinous diameter is associated with a flat anterior segment at the inlet.

The posterior segment can best be characterized by palpation of the sacrospinous ligament and the sacrosciatic notch. A narrow notch, associated with a short sacrosciatic ligament (less than 2 fingerbreadths), suggests an android posterior segment. A sacrosciatic ligament length of 2 to 3 fingerbreadths suggests a gynecoid posterior segment. If the ligament is directed backward and the spines are close together, the posterior segment of the inlet is probably anthropoid. If the ligament is directed laterally and the spines are far apart, the posterior segment of the inlet is likely to be flat.

The pelvic configuration can be assessed at the time of a pelvic examination when the patient is admitted to the labor unit, or it can be determined as part of the initial examination when the patient registers for prenatal care. The advantages of performing the assessment when the patient is hospitalized in labor are the increased relevance of the information at that time and the probability that the individual performing the examination will incorporate the results into a comprehensive assessment of the labor.

Documentation of Labor Progression

One of the most important aspects of the management of labor is accurate and thorough documentation of the progress of labor or the lack of it. Most authorities agree that a graphic display of intrapartum data that allows prompt visualization of the status and progress of cervical dilation and, in some cases, descent of the presenting part is an essential adjunct to intrapartum patient monitoring. This can be accomplished with a simple record of cervical dilation plotted against time on ruled graph paper or by a more comprehensive recording of all intrapartum data related in graphic form to the progress of cervical dilation.

If the data about effacement and dilation of the cervix and station and position of the presenting part are recorded only in narrative form, early and significant abnormalities of labor may not be recognized as soon as they would if a more visual display of labor progress were available. This is especially important if more than one attendant monitors the patient, as frequently occurs in a labor that is longer than normal or a labor that overlaps a change of shift in the hospital. Tabular and graphic displays of intrapartum data are entirely in keeping with the concept that labor and delivery are worthy of intensive surveillance, and they afford a convenient method of reviewing labor events in situations of an untoward fetal or maternal outcome.

The crucial factor in the evidence-based management of labor is the timing of interventions such as amniotomy, stimulation of contractions with oxytocin, operative delivery, or, in much of the world, transfer from home to a unit for those interventions. A World Health Organization trial performed in multiple labor units across the world, in which a graphical "partogram" was relied on to time interventions, demonstrated reductions in prolonged labors, in the frequency of emergency abdominal delivery, and in the use of oxytocin augmentation.¹⁶ Therefore, visual representation of dilation versus time can help clinicians improve the care of patients in labor.

The compulsiveness, form, and orderliness of documentation of labor events need not interfere with compassionate, family-centered care of a woman in labor. In fact, the challenge of modern obstetrics is to manage a pregnancy with the least interference and yet maintain the capability of recognizing and correcting incipient complications at the earliest possible moment.

Management of Labor Abnormalities

Abnormalities of the First Stage

In attempting to extend Friedman's work^{3,4} into contemporary practice, with its longer duration of normal labors, the modern obstetrician

TABLE 36-3 FACTORS ASSOCIATED WITH FAILURE TO PROGRESS IN THE FIRST STAGE OF LABOR

Factor	Odds Ratio	95% Confidence Interval
Premature rupture of membranes	3.8	3.2-4.5
Nulliparity	3.8	3.3-4.3
Labor induction	3.3	2.9-3.7
Maternal age >35 yr	3.0	2.6-3.6
Fetal weight >4 kg	2.2	1.8-2.7
Hypertensive disorder	2.1	1.8-2.6
Hydramnios	1.9	1.5-2.3
Fertility treatment	1.8	1.4-2.4

Modified from Sheiner E, Levy A, Feinstein O, et al: Risk factors and outcomes of failure to progress during the first stage of labor: A population-based study. *Acta Obstet Gynecol Scand* 81:224, 2002, table IV. Printed with permission from Blackwell Munksgaard.

is faced with confusing definitions, the applicability of which in the individual case cannot be certain. Other than the recommendations of Rouse and colleagues¹¹ to prolong augmentation in the face of second-stage arrest, we know of no new clinical guidelines for obstetricians to use. Moreover, Friedman's management suggestions were made without experimental verification of the hypotheses underlying his thinking. Until such desperately needed investigations are completed, however, Friedman's framework³—in which he described labor abnormalities, identified associated problems, detailed the prognosis for the mother and fetus, and recommended a course of management—remains clinically useful.

Friedman³ reported that abnormalities of the first stage of labor occurred in 8% of parturients, with a much higher incidence among primiparas than among nulliparas. Philpott and Castle¹⁷ found that 11% of primiparas experienced abnormal labor progress in the first stage and required oxytocin augmentation. In a population-based study of 92,918 women, Sheiner and associates¹⁸ found that failure to progress complicated 1.3% of all labors and resulted in abdominal deliveries. Independent risk factors are listed in Table 36-3.

Prolonged Latent Phase

On the basis of the 95th percentile limit of the distribution of latent-phase duration in the primiparous population, 20 hours is considered the definition of an abnormal latent phase. For multiparas, 14 hours is the corresponding definition of prolonged latent phase. Sometimes it is difficult to ascertain the difference between a prolonged latent phase and so-called "false" labor. Friedman³ found that prolongation of the latent phase was associated with excessive sedation, prematurely administered epidural anesthesia, unfavorable cervical status, or myometrial dysfunction.

Although early studies suggested that prolongation of the latent phase was not associated with increased perinatal mortality and was not the harbinger of other abnormalities of labor,¹⁹ subsequent studies showed otherwise. In a study of 10,979 patients in San Francisco, Chelmos and colleagues²⁰ found that prolonged latent phase of labor, defined as longer than 12 hours for nulliparous patients and longer than 6 hours for multiparous patients, was associated with an increased risk for subsequent labor abnormalities, cesarean delivery, low Apgar scores, and need for neonatal resuscitation. These risks for adverse outcomes remained significantly elevated even when the data were controlled for other labor abnormalities, prolonged rupture of mem-

branes, meconium-stained amniotic fluid, parity, and epidural use. In addition to the increased risk of cesarean delivery, these authors found that a prolonged latent phase of labor in patients who delivered vaginally was associated with an approximately twofold increased incidence of third-degree and fourth-degree lacerations, febrile morbidity, and intrapartum blood loss.

One of the major problems with evaluation and management of the latent phase of labor is knowing at what hour labor began. For this reason, some authorities have used the time of admission to the hospital as a convenient starting point for judging when to intervene in the progress of labor.^{17,21,22} Friedman,³ however, regarded the onset of regular contractions as the beginning of labor and recommended intervention when the duration of the latent phase of labor reached 20 hours in the primipara. He found that either adequate sedation ("therapeutic narcosis") or oxytocin augmentation resulted in the resumption of normal cervical dilation. Because most patients are exhausted after 20 hours of labor, Friedman preferred therapeutic narcosis over oxytocin augmentation. For narcosis, he recommended morphine sulfate, 15 to 20 mg, with 10 to 15 mg more if the first dose has not made the patient somnolent and thereby inhibited uterine contractions. The obvious advantage of this therapy is that the patient awakens rested and refreshed and prepared for the active phase of labor.

Critics of this approach, especially O'Driscoll and Meagher,²² argued that waiting out 20 hours of latent phase before considering the labor to be abnormal only promotes exhaustion and discourages the patient. They advocated a protocol for active management of labor, which has been practiced and evaluated at the National Maternity Hospital in Dublin. This involves several important features:

1. Patients are admitted to the labor unit only when they are experiencing painful uterine contractions as well as complete effacement of the cervix, ruptured membranes, or passage of blood-stained mucus.
2. Amniotomy is performed soon after admission for patients who have intact membranes.
3. Oxytocin augmentation of labor is performed if the progress of labor is less than 1 cm/hr over a 2-hour period. Oxytocin infusion is begun at 4 mU/min and is increased by 6 mU/min every 15 minutes until there are seven contractions per 15 minutes. The oxytocin infusion rate does not exceed 40 mU/min.
4. Continuous electronic fetal heart rate monitoring is used only if there is meconium-stained amniotic fluid and after fetal scalp pH has been performed to rule out fetal acidosis.
5. A nurse-midwife is in constant attendance with the patient throughout labor.
6. The patient is assured that if her labor exceeds 12 hours, cesarean delivery will probably be performed.
7. The progress of labor is documented on a simple graphic form, and the senior obstetrician in charge of the unit reviews all cases daily. A partogram, as described earlier, is used to time interventions.
8. This approach to the management of labor is confined to nulliparas.

The active management protocol, with minor modifications, has been evaluated in several obstetric services in the United States as well as in other countries. These studies have consistently demonstrated a small but significant shortening of labor associated with active management. Although most of these studies have also demonstrated a decrease in the incidence of cesarean delivery for dystocia,²³⁻²⁶ the largest prospective and best-designed controlled trial showed no dif-

ference in the incidence of cesarean delivery for dystocia²⁷ but did show shortened labor and a decreased incidence of maternal infection with the active management protocol.

Holmes and associates²⁸ clearly demonstrated that women who present to the hospital with less than 3 cm dilation are more likely to undergo cesarean section or operative vaginal delivery than women presenting with more advanced dilation. Interestingly, they found that women presenting with less than 3 cm dilation had spent less time at home (2.0 versus 4.5 hours) since the onset of painful uterine contractions. Their results imply that women who present with reduced cervical dilation could have intrinsically different labors than those who present with more advanced dilation. Murphy and coworkers²⁹ and Falzone and colleagues³⁰ made similar observations, noting that nulliparous women presenting in labor with unengaged and particularly floating (above $-3/3$ station) fetal heads had higher risks for obstetric intervention.

Protraction Disorders

Protraction disorders are those in which progress of cervical dilation and descent of the fetal head occur at a slower than normal rate in the active phase of labor. The rate of cervical dilation for nulliparas should be at least 1.2 cm/hr; for multiparas, it should be 1.5 cm/hr or faster. These criteria for minimum rates of cervical change represent the 95th percentiles for each parity category. For descent of the fetal head, the rate for nulliparas should be 1.0 cm/hr or faster; for multiparas, it should be 2.0 cm/hr.

Friedman³ found protraction disorders in primiparas to be associated frequently with cephalopelvic disproportion (CPD), use of conduction anesthesia, and fetal malposition. Whether these factors are related in a cause-and-effect manner is not known. Moreover, he found oxytocin augmentation and therapeutic narcosis to be of little value in these cases. Friedman also noted unusually high neonatal mortality and morbidity rates when this labor abnormality was terminated by mid-forceps delivery; however, the diagnosis of a primary dysfunctional labor (i.e., persisting at a cervical dilation rate of less than 1.2 cm/hr) is usually made in retrospect, after oxytocin augmentation has been used and found not to increase the dilation rate.

The experiences of Beazley and Kurjak²¹ and those of O'Driscoll and Meagher²² suggested that an early, more active use of oxytocin, as described in the active management of labor, effectively corrects most protraction disorders, although these authors did not specifically separate protraction disorders from arrest disorders. Those who advocate the active management of labor explain that the use of x-ray pelvimetry is unnecessary in the nulliparous patient, because rupture of the uterus does not occur with the recommended oxytocin augmentation. Therefore, in nulliparous patients with suboptimal progress of labor of any cause, it is safe to use a trial of oxytocin to determine whether labor will progress to completion.

Ganström and associates³¹ demonstrated significant differences in collagen content and collagen remodeling in the cervix and lower uterine segment in patients with protracted labors compared with those having normal labors. This finding may explain why some patients with protracted labor do not respond to oxytocin augmentation.

Arrest Disorders

Friedman³ defined an arrest disorder as the cessation of either cervical dilation or descent of the fetal head in the active phase of labor for longer than 2 hours. In their pure form, arrest disorders differ from protraction abnormalities in that, before the arrest of progress, the rate of cervical dilation or descent of the fetal head is normal. Arrest of progress can also complicate a protraction disorder. In either situation,

Friedman³ found that 45% of the cases of arrest disorder were associated with CPD. Philpott and Castle³² also found that patients whose labor progress crossed the "action line" (i.e., those with protraction or arrest disorders) had smaller pelvic measurements and more often required cesarean delivery for CPD.

Because of the frequent association between arrest disorders and CPD, Friedman³ recommended radiographic cephalopelvimetry followed by cesarean delivery for those with CPD and oxytocin augmentation for the remainder. He found that 80% of women with arrest disorders who did not have CPD delivered after oxytocin augmentation. Philpott and Castle³² and O'Driscoll and Meagher²² found that radiographic studies are not required, especially in primiparas, and that a trial of oxytocin augmentation is indicated in all protraction and arrest disorders. With careful monitoring of mother and fetus and discontinuation of augmentation if there is no progress after 4 to 6 hours, patients are not in danger. This is the approach of most, if not all, obstetric services in the United States; radiographic cephalopelvimetry is seldom used in the management of abnormal labor in vertex presentations.³³⁻³⁵

A notable exception is the use of the fetal-pelvic index by Thurnau and Morgan.³⁶ This technique combines ultrasound measurement of the fetal head circumference (HC) and abdominal circumference (AC) and radiographic measurement of the maternal pelvic inlet circumference (IC) and midpelvic circumference (MC). The fetal-pelvic index is the sum of the two greatest positive circumference differences (i.e., $HC - IC$, $HC - MC$, $AC - IC$, or $AC - MC$). A positive fetal-pelvic index value indicates the presence of fetal-pelvic disproportion, and a negative fetal-pelvic index value indicates the absence of fetal-pelvic disproportion. This index had a 94% positive predictive value for cesarean delivery of patients with abnormal labor patterns. These authors also found the fetal-pelvic index to be useful in predicting the success of induction of labor³⁷ and the success of women attempting vaginal birth after previous cesarean delivery.³⁸ Ferguson and colleagues³⁹ were not able to confirm the efficacy of the fetal-pelvic index, and the method is not widely used.

Using labor progression guidelines based on the slower labor curves characteristic of modern parturients, Rouse and colleagues¹⁰ demonstrated the effectiveness of a new protocol to treat arrest disorders. Their protocol had three principal elements:

- An intent to achieve a sustained uterine contraction pattern of greater than 200 Montevideo units as measured by an intrauterine pressure catheter
- A minimum of 4 hours of oxytocin-augmented labor arrest with a contraction pattern of greater than 200 Montevideo units before proceeding to abdominal delivery for active-phase arrest (more liberal than the original Friedman³ cutoff of 2 hours)
- For patients who cannot achieve a sustained uterine contraction pattern of greater than 200 Montevideo units, administration of a minimum of 6 hours of oxytocin augmentation before proceeding to cesarean delivery for active-phase labor arrest

The researchers demonstrated not only the effectiveness (92% vaginal delivery rate) but also the safety of this approach, with no serious adverse maternal or perinatal effects. The only cost of liberalization of the minimums was an increased risk of maternal infection, with the risk proportional to the time elapsed.

The recommendations of Rouse and colleagues¹⁰ raise the issue of whether intrauterine pressure catheters are useful tools for clinicians managing labor abnormalities. Lucidi and colleagues⁴⁰ reviewed the literature in 2001 and noted that there were no clinical trials testing

the utility of this device. Noteworthy is the absence of this technique from the routines of the active management protocols described heretofore. It would seem that partograms have a much stronger evidence basis than measurement of uterine contractility to guide the timing of obstetric interventions.

Several authors have evaluated the effect of ambulation on the progress of labor. Flynn and coworkers⁴¹ found that patients who ambulated had more rapid labor with fewer instances of fetal distress than a similar number of patients who labored in bed. Williams and associates,⁴² studying 48 patients who ambulated, could find no differences in duration of labor or frequency of fetal distress compared with control patients. Read and colleagues⁴³ studied 14 patients whose labors were regarded as requiring augmentation because of lack of progress attributed to inadequate contractions. In the eight patients who were randomized to an ambulation study protocol, progress of labor was as rapid as in six control patients whose labors were augmented with oxytocin.

These studies suggest that ambulation is not detrimental to the progress of labor or the well-being of the fetus. It has not been established, however, whether ambulation is clearly beneficial or whether it is a substitute for pharmacological augmentation of labor in cases of abnormal progress.

Abnormalities of the Second Stage

Abnormalities of Rotation and Descent

Textbooks of obstetrics traditionally have discussed the first and second stages of labor as if they were separate clinical and biological entities, which, in fact, they are not. Descent and rotation of the fetal head frequently occur before complete dilation of the cervix, a phenomenon that is clear to most clinicians and that was confirmed by the studies of Friedman.³ In addition to showing slower rates of cervical dilation than did Friedman, the contemporary data of Zhang, Troendle, and Yancey¹² showed a slower rate of fetal head descent. As demonstrated in Table 36-4 and Figure 36-2, it can take up to 3 hours to descend from +1/3 to +3/3 station and an additional 30 minutes for delivery. Again, there is a clear need for practice guidelines to incorporate these new data.

Arrest of descent and rotation, whether it occurs before or after complete dilation of the cervix, is a matter of concern and requires evaluation. Arbitrary limits on the duration of the second stage of labor probably resulted from the misinterpretation of the data presented by Hellman and Prystowsky.⁴⁴ In that study, patients whose second stage of labor was longer than 2 hours were at increased risk

for perinatal and maternal morbidity. This observation was interpreted by many clinicians to mean that delivery of the fetus should be accomplished, by whatever means, before 2 hours of the second stage had elapsed. This interpretation occasionally resulted in traumatic mid-forceps operations or unnecessary cesarean deliveries, not to mention overzealous use of the vacuum extractor. The reader should note that their recommendation of a 2-hour second stage limit antedates electronic fetal monitoring.

Cohen⁴⁵ demonstrated that, if patients with fetal distress or traumatic delivery are excluded, the duration of the second stage bears no relationship to perinatal outcome. If there are no serious fetal heart rate abnormalities, if the mother is well hydrated and reasonably comfortable, and if there is some progress in descent or rotation of the fetal head (regardless of how slow), there is no need for operative delivery. Similarly, Menticoglou and associates⁴⁶ confirmed that the duration of the second stage of labor is in itself not related to untoward outcomes. Hansen and coauthors,⁴⁷ in a trial of active versus passive pushing in the second stage, found that second-stage lengths of up to 4 to 9 hours had no harmful effects. Moreover, delayed pushing was better tolerated by patients and was associated with fewer fetal heart rate decelerations.

After the cervix is dilated more than 7 cm, descent or rotation of the fetal head can be expected. If this does not occur, uterine contrac-

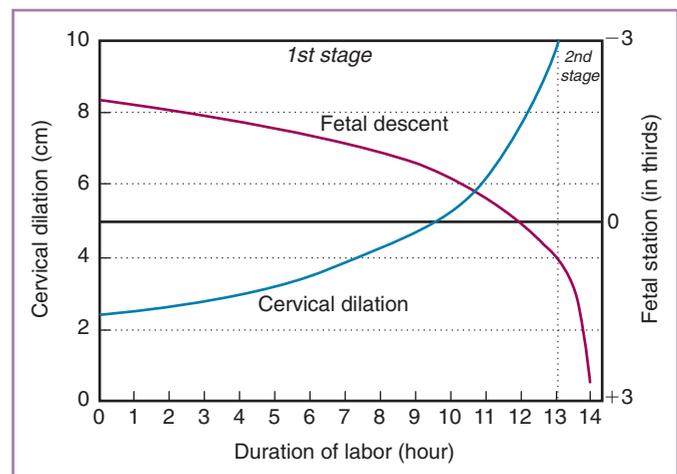

FIGURE 36-2 Patterns of cervical dilation (*left scale*) and fetal descent (*right scale*) in nulliparas. (From Zhang J, Troendle J, Yancey MK: Reassessing the labor curve in nulliparous women. *Am J Obstet Gynecol* 187:824, 2002. Printed with permission from CV Mosby.)

TABLE 36-4 EXPECTED TIME INTERVAL AND RATE OF DESCENT AT EACH STAGE OF STATION*

Station (in Thirds)		First and Second Stages		Second Stage Only	
From [†]	To	Time Interval (hr)	Rate (cm/hr) [†]	Time Interval (hr)	Rate (cm/hr)
-2	-1	7.9 (0.9, 65)	0.2 (0.03, 1.8)	—	—

tions, if they are not adequate, should be augmented with oxytocin. Manual examination to determine the position of the fetal head and the dimensions and shape of the pelvis often helps at this point. Posterior presentation, brow presentation, marked degrees of asynclitism, and very large infants are associated with longer labors, even with adequate contractions.

The Mueller-Hillis maneuver⁴⁸ also may help. The obstetrician applies pressure to the uterine fundus with one hand and detects descent of the fetal head with the examining finger in the vagina. If the fetal head descends 1 cm or more with fundal pressure, the prognosis for vaginal delivery is good; if no descent occurs, the prognosis for delivery is poor. This maneuver is not predictive of outcome if it is performed early in labor,⁴⁹ but it is helpful late in the first stage or in the second stage of labor.⁴⁸

Shoulder Dystocia

Shoulder dystocia occurs in 0.24% to 2.00% of vaginal deliveries.⁵⁰⁻⁵³ This wide range of prevalence estimates highlights the lack of a standard definition. The cause is impingement of the biacromial diameter of the fetus against the symphysis pubis anteriorly and the sacral promontory posteriorly. Why the shoulders do not descend in the oblique diameters of the pelvis is unclear, although sometimes the fetus is simply too large. Although the risk of shoulder dystocia rises with increasing birth weight, 40% to 50% of cases occur in infants whose birth weight is less than 4000 g.

Risk factors for shoulder dystocia^{50,54-56} include fetal macrosomia, diabetes, a history of shoulder dystocia in a previous birth, and prolonged second stage of labor. Other factors that have been inconsistently reported as increasing the risk^{52,53,57} include a history of macrosomia or post-term pregnancy, multiparity, obesity, and operative vaginal delivery from the midpelvis. In 50% of cases of shoulder dystocia, no risk factors are identified.

Maternal morbidity from shoulder dystocia includes postpartum hemorrhage and rectal injuries. The morbidity for the infant is attributable to asphyxia from delay in delivery or to trauma from the maneuvers used to deliver the fetus. Infant morbidity related to trauma includes brachial plexus and phrenic nerve injuries and fractures of the humerus and clavicle.⁵⁸ The most serious traumatic morbidity is brachial plexus injury (Erb palsy), which occurs in 10% to 20% of infants born after shoulder dystocia.^{52,58} If they are recognized early, 80% to 90% of brachial plexus injuries recover completely with proper physical therapy and, in some situations, neurosurgical management.⁵⁹ For this reason, permanent neurological injury is rare, occurring in 1 or 2 of every 10,000 births. This low prevalence greatly limits the ability to conduct prospective prevention studies.

Most brachial plexus injuries resulting from shoulder dystocia involve the arm and shoulder that are in the anterior pelvis at the time of delivery. The brachial plexus is believed to be injured when excessive downward traction and lateral extension of the fetal head and neck occur during the attempt to deliver the anterior shoulder⁵³; however, there are exceptions to this cause of brachial plexus injury.⁶⁰ Some infants with brachial plexus injuries were born by vaginal delivery in which there was no evidence of shoulder dystocia.⁶¹ Also, brachial plexus palsy can involve the arm that was in the posterior pelvis at the time of delivery.⁶² Furthermore, Erb palsy has occurred in infants born by cesarean delivery.^{63,64} Finally, several reports have described brachial plexus injuries in newborns in whom other physical findings and electromyographic tests confirmed that the lesions occurred before the onset of labor.^{65,66} It is postulated that these injuries resulted from chronic nerve compression due to malposition in utero.^{67,68} The presence of a permanent injury does not imply that the delivering clinician

applied excessive force despite the *res ipsa loquitur* argument seen in so many torts arising from these births.

PREVENTION OF SHOULDER DYSTOCIA

Prevention of shoulder dystocia by prophylactic induction of labor is not effective.⁶⁹ Primary cesarean delivery can prevent shoulder dystocia in a small proportion of patients when several predisposing factors are present, such as multiparity, gestational diabetes, and an estimated fetal weight in excess of 4500 g. Rouse and Owen,⁷⁰ using decision analytic techniques, concluded that prophylactic cesarean delivery for sonographically detected fetal macrosomia to prevent shoulder dystocia is a Faustian bargain. Use of either 4000 or 4500 g as the cutoff point for abdominal delivery would require more than 1000 cesarean sections to prevent one permanent injury to the brachial plexus. Also, if arrest of descent of the fetal head occurs during labor along with other risk factors for shoulder dystocia, operative vaginal delivery should be avoided.

MANAGEMENT OF SHOULDER DYSTOCIA

Conventional wisdom dictates that the most effective treatment includes prompt recognition that delivery of the shoulders will be difficult and avoidance of excessive downward traction on the fetal head when attempting to deliver the anterior shoulder. Retraction of the fetal head immediately on its delivery (turtle sign) is an early warning that delivery of the shoulders may be difficult. Studies using simulated models of the fetus and pelvis demonstrated that obstetricians frequently underestimate the amount of traction they apply to the fetal head.^{71,72}

Several maneuvers have been useful in resolving shoulder dystocia. Hyperflexion of the mother's thighs, known as the McRoberts maneuver, flattens the lumbosacral curve, thereby removing the sacral promontory as an obstruction to the inlet.^{73,74} The knee-chest position tends to accomplish the same end. Suprapubic pressure can be applied in conjunction with the McRoberts maneuver.

Rubin⁷⁵ described rotating the fetal shoulders into the oblique position by inserting the fingers of one hand vaginally behind the most accessible shoulder (usually the posterior) and pushing the shoulder toward the fetal chest. This is a substantial improvement on the commonly described Woods maneuver, which involves pushing the shoulder toward the fetal back.⁷⁶

If these maneuvers are not successful, the posterior arm of the fetus can be delivered if the obstetrician inserts one hand posteriorly, grasps the elbow, and draws the arm across the chest of the fetus.⁷⁷ This maneuver may result in fracture of the humerus or the clavicle, which is a consistently remedial injury and preferable to a brachial plexus injury of the opposite arm. Finally, replacement of the fetal head in the uterus followed by cesarean delivery—the Zavanelli maneuver—could be necessary in rare instances.⁷⁸

Although the soft tissue of the perineum does not contribute to shoulder dystocia, many protocols recommend a wide episiotomy to facilitate performing one or more of the described maneuvers.

The successful management of shoulder dystocia is a matter of considerable obstetric judgment and skill. There is an inverse relationship between the incidence of brachial plexus injuries from shoulder dystocia and the experience of the obstetrician.⁷⁹ Shoulder dystocia culminating in an injury that is permanent (1 in 10,000 births) is so rare⁸⁰ that all of the recommendations on prevention are based on accumulated wisdom and opinion rather than evidence-based medicine. Athukorala and coauthors demonstrated the paucity of evidence for interventions in their systematic review⁸¹ and pointed to the flimsy foundation underlying any obstetrician who would criti-

cize another's management of shoulder dystocia or say that any particular approach in his or her own hands would have prevented an injury.

Abnormalities of the Third Stage

Placental Separation and Control of Uterine Bleeding

The third stage of labor is defined as the time from delivery of the infant to delivery of the placenta. For all practical purposes, one should include the hour after the delivery of the placenta in the third stage of labor, because it is during this time that the patient is at greatest risk for postpartum hemorrhage.

After the infant is born, the uterus contracts, and placental separation occurs by cleavage along the plane of the decidua basalis. Placental separation usually is complete by the time two contractions have occurred, although several additional contractions may be necessary to accomplish expulsion of the placenta from the uterus. Large venous sinuses are exposed after separation of the placenta, and control of bleeding from these sinuses depends primarily on contraction of uterine muscle and only secondarily on coagulation and thrombus formation in the placental site. The average blood loss during a normal vaginal delivery is about 600 mL.⁸² In the young, healthy parturient, acute blood loss is well tolerated because of the increased blood volume of pregnancy and the decrease in vascular volume that occurs with the reduction of the uteroplacental circulation at the time of birth.

Management of the placenta in the third stage is a matter of debate among qualified obstetricians. Elective manual removal of the placenta, if performed promptly, has been associated with no increase in puerperal morbidity. Advantages include immediate identification of retained placental fragments and intrauterine extensions of cervical lacerations and shortened time of placental removal.^{83,84} Manual removal, however, is not a painless procedure in the unanesthetized patient, and it is unnecessarily invasive in most cases. Gentle massage of the uterine fundus encourages uterine contractions and helps one to detect changes in the shape of the uterus that signal placental separation. Vigorous fundal massage accomplishes nothing, is painful, and could, if combined with excessive traction on the umbilical cord of a placenta implanted in the fundus of the uterus, promote uterine inversion.

The prophylactic administration of a uterotonic medication to reduce blood loss, either immediately after delivery of the infant or after delivery of the placenta, is a generally accepted practice, and prospective trials show that it decreases blood loss and reduces the need for therapeutic oxytocics.⁸⁵ These trials also found no difference in effectiveness of ergot preparations compared with oxytocin, although there were nonsignificant trends toward an increased need for manual removal of the placenta and for blood transfusions and an increase in blood pressure associated with the use of ergot alkaloids. Intravenous oxytocin is the drug of choice on most obstetric services. Prophylactic administration of the thermostabile prostaglandin E₁ analog, misoprostol, has been used to reduce bleeding in the third stage of labor.⁸⁶⁻⁸⁹

Retained Placenta

If the placenta has not been delivered with gentle umbilical cord traction and uterine massage after 30 minutes, it should be removed manually under general anesthesia or after a tocolytic drug has been given intravenously in combination with sufficient parenteral analgesia. Nitroglycerin is particularly useful in this situation as a tocolytic.⁹⁰ It

may be given by translingual spray (400- μ g premeasured spray, 1 to 2 sprays repeated every 3 to 5 minutes for a maximum of three doses in 15 minutes) or by intravenous injection (50 to 150 μ g, repeated in 30 to 60 seconds if blood pressure is stable).

In rare instances, placental retention is caused by placenta accreta, the result of defective decidua basalis. It is characterized by the attachment and growth of chorionic villi directly into the myometrium. If the placenta cannot be removed manually and placenta accreta is suspected, hysterectomy is usually required to avoid catastrophic hemorrhage. The etiology of placenta accreta is not known, but there is a strong association with implantation of the placenta in the lower uterine segment, placenta previa, and prior cesarean delivery.

A report of 22 cases of placenta accreta by Read and coworkers⁹¹ suggested that, in cases of focal or partial placenta accreta without excessive blood loss, conservative management may be successful. The conservative approach includes curettage of the retained placenta or suturing of the bleeding site (in cases of cesarean delivery); it should be considered only if preservation of fertility is of utmost importance and with the awareness that hysterectomy will be necessary if the conservative approach does not promptly control the blood loss. Descargues and associates⁹² described the role of prophylactic, selective embolization of the uterine arteries in cases of abnormal placentation diagnosed before delivery.

The episiotomy and vaginal or cervical lacerations are also sources of blood loss in the third stage of labor. Careful inspection of the vagina and cervix immediately after delivery allows one to identify lacerations of these structures so that they can be repaired promptly. Prompt repair also facilitates the management of an unexpected hemorrhage in the immediate recovery period by allowing the obstetrician to promptly attend to uterine atony.

Postpartum Hemorrhage

In the event of an immediate postpartum hemorrhage, the patient's vital signs should be monitored frequently, adequate intravenous lines should be established promptly, adequate fluid replacement should be started with infusion of lactated Ringer solution, and preparations should be made for blood transfusion. Thereafter, a prompt review should be made seeking possible sources of hemorrhage, including uterine atony; cervical, vaginal, or uterine lacerations; coagulopathies (spontaneous or iatrogenic); adherent placenta (accreta); and uterine inversion. Real-time ultrasound scanning is helpful in identifying retained portions of placenta or residual blood clots within the uterus.

Because the usual source of hemorrhage is uterine atony, intravenous oxytocin should be given in amounts adequate to compensate for the decreased sensitivity of the postpartum uterus to this drug.⁹³ Usually, 20 to 30 units of oxytocin in 1000 mL of fluid, given at an infusion rate not to exceed 100 mU/min, suffices. Because this amount of oxytocin far exceeds the threshold for its maximum antidiuretic effect,⁹⁴ it must be recognized that fluid overloading is a potential danger in these patients. Bolus injections of oxytocin could cause hypotension and should be avoided, especially in patients who are at risk for volume depletion from hemorrhage.⁹⁵ Methylergonovine or ergonovine maleate, given in doses of 0.2 mg intramuscularly, is often effective in maintaining uterine tone, but such drugs should not be given intravenously because of the danger of hypertension, central nervous system vasospasm, and hemorrhage.⁹⁶

Increasingly, the 15-methyl analog of prostaglandin F_{2 α} (carboprost tromethamine) is being used to treat uterine atony if oxytocin infusion is not successful.⁹⁷ The recommended dose is 250 μ g intramuscularly, which can be repeated within a few minutes if the first injection does not suffice. Prostaglandin, particularly prostaglandin F_{2 α} , should be

used with great caution, if at all, in patients with cardiovascular disease or asthma.

Based on its demonstrated effectiveness as a prophylactic measure against hemorrhage when given in the third stage of labor equivalent to oxytocin and Methergine, misoprostol has been used to manage severe postpartum hemorrhage. Abdel-Aleem and colleagues⁹⁸ gave 1000 µg of misoprostol rectally, and Adekanmi and associates⁹⁹ administered 800 µg of misoprostol into the uterus transvaginally to control hemorrhage. Both authors reported successes after failure of conventional pharmacotherapy.

In some cases, uterine atony and uterine hemorrhage persist despite all measures taken to enhance uterine contractions and after other possible sources of vaginal or cervical hemorrhage have been excluded. In these situations, exploratory laparotomy is often necessary (see Chapter 57).

During preparation for laparotomy, one can take several measures that may adequately control the hemorrhage and avoid an operative procedure:

- Use of a large Foley catheter balloon as a tamponade to halt bleeding from a low placental implantation site¹⁰⁰
- Packing of the uterine cavity with sterile gauze (although no well-designed study has been undertaken to prove that packing is effective, retrospective evidence indicates that this measure can control hemorrhage resulting from atony in some cases¹⁰¹)
- For some patients, selective embolization of pelvic vessels to control hemorrhage adequately, in hospitals where the necessary facilities and personnel are available¹⁰²

If all of these procedures have been tried in vain, laparotomy is performed with one or more of the following goals: (1) to identify any sources of occult intra-abdominal bleeding, such as unexpected uterine laceration; (2) to control the bleeding by appropriate arterial ligations; (3) in the most extreme and refractory cases, to perform hysterectomy.

When laparotomy is performed for postpartum hemorrhage, the patient should be placed in semilithotomy position. Sterile drapes should be applied in such a way that one observer can, with a sterile speculum, examine the vagina and cervix to determine when the bleeding has ceased. If major uterine lacerations are not found, the uterine arteries should be ligated by the method described by O'Leary and O'Leary¹⁰³ (see Chapter 57). If this measure does not control uterine bleeding, the hypogastric arteries should be ligated. In 1997, B-Lynch and colleagues¹⁰⁴ described a "brace" suturing technique that results in closure of the uterine blood supply. Other authors have confirmed the effectiveness of this uterine-conserving technique in small case series.^{105,106} The Hayman technique is a simpler way to "brace" suture the uterus.¹⁰⁶

Burchell¹⁰⁷ described the pelvic vascular supply and demonstrated that the transient decreases in blood pressure and blood flow through regional vessels that occur at the time of internal iliac artery ligation are responsible for the control of hemorrhage. Because of the ample collateral circulation, there appear to be no long-term consequences of hypogastric artery ligation, and women have delivered normal infants in subsequent pregnancies after undergoing this procedure. Occasionally, a patient complains of mild bladder dysfunction and buttock pain in the immediate postoperative period, but these symptoms are transient.

In cases of extensive postpartum hemorrhage, the use of a central venous pressure line or a Swan-Ganz catheter facilitates more accurate monitoring of the cardiovascular status of the patient and avoids

serious errors of hydration and pulmonary edema^{108,109} (see Chapter 57).

Inversion of the Uterus

Inversion of the uterus, a rare but dramatic complication of the third stage of labor and the immediate puerperium, must be recognized and corrected promptly to avoid serious long-term morbidity.¹¹⁰ Uterine inversion is probably related to fundal implantation of the placenta, which results in thinning of the uterine wall in the area of implantation. Fundal implantation occurs in only 10% of all pregnancies but has been found in virtually all reported cases of acute puerperal uterine inversion in which the site of placental implantation was recorded.^{110,111} The thin fundal area of the myometrium invaginates as the placenta separates, whereupon the inversion proceeds, with the uterus virtually delivering itself inside out. With this scenario in mind, one can easily imagine that vigorous fundal pressure or excessive cord traction could contribute to the tendency to inversion in a uterus predisposed by fundal implantation of the placenta.

Complete uterine inversion occurs when the inverted fundus extends beyond the cervix, usually looking like a beefy-red mass at the vaginal introitus. Incomplete inversions occur when the inverted fundus has not extended beyond the external cervical os. These cases are not as obvious and may be detected only by bimanual or visual examination of the cervix. In cases of postpartum hemorrhage in which the uterine fundus cannot be palpated abdominally, incomplete uterine inversion should be suspected.

Tocolytic drugs, including magnesium sulfate,¹¹² β-mimetic compounds,¹¹³ and nitroglycerin¹¹⁴ have been used to assist in reinversion of the uterus. Because of the extensive blood loss and shock that often are associated with uterine inversion, anesthesiologist should be summoned as soon as the diagnosis is recognized so that general anesthesia can be available if reinversion using tocolysis fails.

The technique of reinversion is the same whether it is accomplished with intravenous tocolysis or general anesthesia. The uterus is reinverted with gentle but firm and persistent pressure applied on the fundus to elevate it into the vagina.¹¹⁵ In most cases, this technique, which presumably results in reinversion by indirect traction on the round ligaments when the uterus is elevated into the abdomen, is successful. Authorities disagree about whether the placenta, which is often attached to the inverted fundus, should be removed before attempts to reinvert the fundus are made. The practical matter is that the Johnson technique for reinversion¹¹⁵ is easier if the placenta is not in place.

If the diagnosis is made and reinversion is accomplished promptly, there are no long-term sequelae. If the complication is unrecognized and reinversion is delayed, tissue edema magnifies the constriction of the cervix around the inverted fundus, making reinversion difficult. Tissue necrosis and damage to the bladder or urethra could ensue.

If the Johnson method of reinversion is not successful, laparotomy should be performed. The first step is to grasp the round ligaments about 1 inch into the inverted uterus and exert traction while an assistant elevates the uterus with a hand in the vagina. This procedure, described by Huntington,¹¹⁶ may fail because the inverted fundus is too tightly trapped below the cervical ring, in which case the Haultain¹¹⁷ procedure may be performed. In the Haultain procedure, a longitudinal incision is made posteriorly through the inverted fundus, allowing ample room to reinvert the fundus. The incision is then closed, leaving the equivalent of a classic cesarean incision on the posterior surface of the uterus. If uterine inversion is recognized and treated promptly, an operative procedure is rarely necessary to accomplish reinversion.

The third stage of labor and the immediate puerperal recovery period are a crucial time for the parturient. Occasionally, uterine hem-

orrhage goes undetected or is recognized but treated inadequately. Acute tubular necrosis, pituitary necrosis, and adult respiratory distress syndrome—all recognized complications of puerperal shock and hypoxia—can be avoided by careful observation of all patients during this time and by deliberate and aggressive management of hemorrhage if it occurs.

Induction of Labor

Induction of labor is elective (i.e., performed for the convenience of the patient or professional staff) or is indicated for medical, obstetric, or fetal complications of pregnancy.

Between 1989 and 1998 in the United States, there was an increase in the incidence of induction of labor, from 9% to 19% of all births (Fig. 36-3).^{118,119} In 1998, the incidence of induction of labor varied widely from region to region, from 10.9% in Hawaii to 41.6% in Wisconsin. Also, the increase in the incidence of indicated induction was significantly smaller than the overall increase (70% to 100% increase), suggesting that the rate of elective induction increased more rapidly than did the rate of indicated induction.

Nicholson and colleagues¹²⁰ and Caughey and colleagues¹²¹ questioned the conventional wisdom that induction is a risk factor for abdominal delivery. They pointed out that comparisons between women induced at a given gestational age and those in spontaneous labor at that age overestimate the risk of cesarean section, because the real comparison group for induced women should be the entire cohort awaiting spontaneous labor. Analysis of cohorts with their novel approach indicated that induction reduces the risk of abdominal delivery compared to expectant management, which is the real choice a woman and her obstetrician face. Verification of this inversion of conventional wisdom in prospective trials would radically change the practice of contemporary obstetrics.

Elective Induction

Elective induction of labor is often justified on one or more of the following grounds:

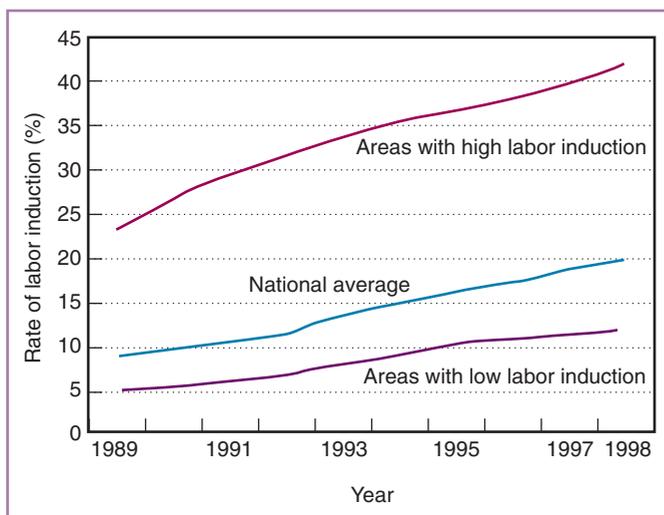

FIGURE 36-3 Rate of labor induction in the United States, 1989-1998. (From Zhang J, Yancey MK, Henderson CE: U.S. national trends in labor induction, 1989-1998. *J Reprod Med* 47:121, 2002. Printed with permission from the Journal of Reproductive Medicine.)

- To assure the patient that the physician with whom she has good rapport will be present during delivery
- To ensure that labor will occur when maximum physician, nursing, and support personnel coverage is available in case of labor complications
- To enable the patient to plan for care of her home and other children and allow her partner to make suitable arrangements to be with her during labor and delivery

The studies by Keettel at the University of Iowa between 1957 and 1966 established the safety of elective induction of labor in patients who were at term and whose cervix was partially effaced and dilated at least 2 cm.¹²² Subsequent studies confirmed this salutary experience.^{123,124} Follow-up studies of children for as long as 8 years found no evidence of neurodevelopmental abnormalities related to elective induction of labor.^{125,126}

There are two major risks of elective induction of labor: an increased risk for cesarean delivery and an increased risk for neonatal respiratory morbidity. Elective induction of labor at term is associated with a twofold increased incidence of cesarean delivery compared with spontaneous labor.^{127,128} This increase is confined almost entirely to nulliparous women and, more specifically, to those in whom the induction of labor is attempted when the cervix is not well effaced and somewhat dilated.^{129,130} This risk can be minimized by restricting elective induction of labor to patients with a favorable or ripe cervix.

An objective classification for selection of patients who are “favorable” for induction of labor¹³¹ is shown in Table 36-5. Bishop found that a pelvic score of 9 or greater, in the term multipara, was associated with no failed inductions of labor in his series and that the average duration of labor was 4 hours. Although the criteria for successful induction of labor as described by Bishop applied only to multiparous women, subsequent studies showed the usefulness of Bishop’s scoring system in nulliparous patients.¹³² There is a 50% risk of failed induction of labor in nulliparous women at term for whom the Bishop pelvic score is 5 or less. Lange and colleagues,¹³³ in a study of induction of labor in 808 patients, found that dilatation was the most important of the five components in the Bishop score and recommended that it be scored at twice the value given by Bishop. Most experienced obstetricians would agree with this. Transvaginal ultrasound examination of the cervix does not improve on the Bishop score in predicting the success of induction of labor.^{134,135} The presence of fetal fibronectin (fFN) in cervical and vaginal secretions is an additional means for predicting the success of induction of labor.^{136,137} The role that vaginal

fFN can play in selecting patients for elective induction of labor has yet to be determined.¹³⁸

Amniotomy is often successful in inducing labor in patients who have a favorable cervix, although the mechanism of action is not entirely clear. Mitchell and associates¹³⁹ showed that artificial rupture of the membranes is followed by a substantial increase in plasma prostaglandins. In one of the largest studies of elective induction of labor, Keettel¹²² found that, if the patient was at term with a vertex presentation, the fetal vertex was engaged in the pelvis, and the cervix was at least 2 cm dilated and partially effaced, only 3.4% of patients required oxytocin infusion after amniotomy to induce labor successfully. If the use of oxytocin is necessary, it should be given by intravenous infusion, preferably by constant infusion pump, with monitoring of the fetal heart rate, uterine contractions, and maternal vital signs. Whether induction is elective or indicated, adequate stimulation of uterine contractions is important in reducing the incidence of failed induction of labor. Rouse and associates¹¹ and Lin and Rouse¹⁴⁰ showed the effectiveness of requiring a minimum of 12 hours of oxytocin stimulation after membrane rupture before failed labor induction is diagnosed.

The second major risk of elective induction of labor is neonatal respiratory morbidity.^{141,142} This is caused, in part, by surfactant deficiency resulting from unexpected delivery of a premature infant. Consequently, scrupulous attention to confirmation of gestational age is necessary. The following criteria should be fulfilled before a patient is considered a candidate for induction:

1. A well-established ovulation date, which can be determined by one of the following:
 - a. A regular menstrual history prior to the last menstrual period; the last menstrual period should not be considered normal if it occurred after cessation of oral contraceptive use
 - b. Basal body temperature chart demonstrating a biphasic rise
 - c. Clomiphene induction of ovulation followed by early confirmation of ovulation in pregnancy
 - d. Artificial insemination or in vitro fertilization and embryo transfer
2. Examination of the patient by the 14th week of pregnancy in which the uterine size was consistent with estimated gestational dates
3. Sonographic estimation of fetal weight performed before 20 weeks' gestation
4. Bishop pelvic score of 6 or greater

Using these criteria, the patient should be considered for elective induction of labor at 40 weeks (280 ± 3 days) after the last menstrual period, if the menstrual interval is 28 days, or at $266 \text{ days} \pm 3$ days after the suspected ovulation date.

For some infants who develop respiratory morbidity after elective induction of labor, the cause is that birth takes place before the occurrence of the normal events associated with parturition that prepare the fetus for the transition to extrauterine life.¹⁴³ One of the critical transition phenomena is a decrease in fetal lung fluid associated with the spontaneous onset of labor.^{144,145} If this does not occur, the most common manifestation in the newborn is "wet lung syndrome," which clears spontaneously in a few hours. In some infants, the respiratory morbidity is more serious, involving persistence of the fetal circulation and requiring mechanical ventilation.¹⁴⁶

Waiting until the pregnancy is at 40 weeks' gestation and the cervix is well effaced and partially dilated before induction of labor can minimize the risks of cesarean delivery and neonatal respiratory morbidity.

If an obstetrics service concludes that elective induction of labor is permissible, the professional staff, including physicians and nurses from labor and delivery and the nursery, should collectively agree on criteria for patient selection and draw up a protocol for the labor induction procedure. After such guidelines of care are established, elective induction of labor should undergo periodic review to determine the degree of compliance with the guidelines and to identify any related maternal or perinatal morbidity.

Indicated Induction

Induction of labor is indicated if prolongation of pregnancy is dangerous for either the mother or the fetus and there are no contraindications to amniotomy or the augmentation of uterine contractions. Maternal indications include the following:

- Severe pregnancy-induced hypertension
- Fetal death
- Chorioamnionitis

Fetal indications for pregnancy termination include any condition in which a variety of fetal tests demonstrate significant fetal jeopardy in any of the following settings:

- Diabetes mellitus
- Post-term pregnancy, especially in association with oligohydramnios
- Hypertensive complications of pregnancy
- Intrauterine growth restriction
- Isoimmunization
- Chorioamnionitis
- Premature rupture of the membranes with established fetal maturity

Induction of labor is contraindicated any time that spontaneous labor and delivery would be more dangerous for the mother or fetus than abdominal delivery. Such conditions include

- Acute severe fetal distress
- Shoulder presentation
- Floating fetal presenting part
- Uncontrolled hemorrhage
- Placenta previa
- Previous uterine incision that would preclude a trial of labor

The following are relative contraindications to induction of labor:

- Grand multiparity (five or more previous pregnancies beyond 20 weeks' gestation)
- Multiple pregnancy
- Suspected CPD
- Breech presentation
- Inability to adequately monitor the fetal heart rate throughout labor

The relative contraindications are all controversial, and there are mitigating circumstances under which induction of labor might be attempted in any of them.

If the cervical status is favorable and the vertex is well engaged (Bishop pelvic score ≥ 6), the preferred method of labor induction is amniotomy, followed, if necessary, by a closely monitored oxytocin infusion. If the cervical status is not favorable, as is common when

delivery is indicated for maternal or fetal complications, several methods may improve cervical effacement and dilatation.

Danforth¹⁴⁷ was among the first to study the effect of pregnancy on the cervix and to describe the histology of cervical softening and effacement. The cervix is composed largely of connective tissue, including types I, III, and IV collagen, and only 10% to 15% smooth muscle.¹⁴⁸ Before the onset of labor, the collagen content of the cervix decreases by 30% to 50% as the content of water and noncollagen and nonelastin proteins increases. The process of cervical ripening involves the production of cytokines (tumor necrosis factor α , interleukin 1β [IL- 1β], IL-6, IL-8) and the extravasation of neutrophils into the cervical stroma. Degranulation of the neutrophils releases proteases that are involved in the modification of cervical collagen.¹⁴⁹ The proteolytic enzymes are responsible for degrading cross-linked, newly synthesized collagen and thereby contribute to the rearrangement of collagen cells that is a hallmark of cervical softening. Apoptosis of smooth muscle cells in the cervix may also contribute to cervical ripening.¹⁵⁰ That this process is a genetically determined, timed event may explain the length of gestation. Although the specific endocrine and biomolecular mechanisms of cervical ripening (including the role of prostaglandins) are not fully understood, the result of this phenomenon is softening, thinning, and early dilation of the cervix.

Multiple drugs and devices have been used to enhance cervical ripening: oxytocin, estrogen, corticosteroids, hyaluronidase, breast stimulation, sexual intercourse, relaxin, castor oil, prostaglandin E₁ (PGE₁) and E₂ (PGE₂), mifepristone, hydrophilic cervical inserts, balloon catheters, and extra-amniotic saline infusion. Systematic reviews of the studies of most of these methods are included in the Cochrane Database. Table 36-6 lists methods that have been found to be ineffective or unsafe or for other reasons not commonly used. Table 36-7 summarizes the findings of the systematic reviews in the Cochrane Database regarding methods of cervical ripening that are presently in common use and for which there is some evidence of both efficacy and safety. The end points of the studies on cervical ripening included changes in effacement and dilatation of the cervix, time of delivery after the medication or device was applied, and incidence of cesarean delivery. Vaginal applications of PGE₂, which are available in the United States as dinoprostone (Prepidil and Cervidil), have been shown to be effective in promoting cervical ripening.¹⁵¹

Misoprostol (PGE₁), originally approved for use in preventing gastric ulcers induced by nonsteroidal anti-inflammatory drugs, has proved to be an effective cervical ripening agent when applied intravaginally in doses of 25 or 50 μ g. A meta-analysis by Hofmeyr and Gulmezoglu¹⁵² found that misoprostol was more effective in cervical

ripening and induction of labor than intravaginal or intracervical PGE₂. Although intravaginal misoprostol in doses of 25 µg compared with 50 µg results in greater need for oxytocin augmentation, there is less uterine hyperstimulation; therefore, the most commonly recommended regimen is 25 µg repeated every 4 hours. In April 2002, the manufacturer of misoprostol (Cytotec) revised the drug labeling information to acknowledge use of the medication for cervical ripening and induction of labor, although the U.S. Food and Drug Administration has not formally approved the drug for this use.

A systematic review of the studies of various cervical inserts, including laminaria tents and balloon catheters, found that these devices (compared with intravaginal PGE₂) achieved a lower rate of delivery within 24 hours, resulted in no difference in cesarean delivery rate, and were less likely to cause uterine hyperstimulation.¹⁵³ Small studies found that the use of the Foley catheter compared favorably with intravaginal PGE₁ (misoprostol) for cervical ripening,¹⁵⁴ but larger prospective trials are needed to confirm this impression.

Although randomized trials have shown that prostaglandins in general, and misoprostol specifically, result in cervical ripening as manifest in a significant increase in the Bishop pelvic score, they have not demonstrated a significant decrease in the incidence of failed induction of labor or a decrease in the risk of cesarean delivery after induction of labor in nulliparous patients. This suggests that failed induction of labor could be the result of several incomplete mechanisms of parturition, of which cervical ripening is but one manifestation.

Abnormal Presentations

Breech Presentation

Breech presentation occurs in approximately 3% to 4% of all deliveries. Its incidence decreases with advancing gestation. Weisman,¹⁵⁵ using periodic radiographic examination throughout pregnancy, found that 24% of fetuses were in breech presentation at 18-22 weeks of gestation, 8% at 28 to 30 weeks, 7% at 34 weeks, and 2.8% at 38 to 40 weeks. It is generally agreed that higher rates of neonatal morbidity and mortality are associated with breech presentation than with cephalic presentation at all gestational ages and birth weights.¹⁵⁶ There is less agreement about what can be done to eliminate the risk for the infant in breech presentation at the time of delivery.

Part of the problem could be inherent in the etiology of breech presentation itself. Term breech presentation is associated with fundal-cornual implantation of the placenta, which occurs in only 7% of all pregnancies.¹⁵⁷ This association suggests that breech presentation often is related to a space problem in the uterus: Given the fundal-placental implantation, an otherwise normal fetus finds it more comfortable to assume a breech position. Other studies have suggested that breech presentation could result from abnormal motor ability or diminished muscle tone in the fetus.

Braun and colleagues,¹⁵⁸ reporting from a dysmorphology clinic, showed that the expected incidence of breech presentation (corrected for gestational age) was higher in fetuses with a variety of congenital disorders. Specifically, infants with neuromuscular disorders had an inordinately high rate of breech presentation at delivery.^{159,160} Furthermore, McBride and associates¹⁶¹ found that 100 children delivered in a breech presentation at term and studied at 5 years of age scored less well on motor skills than children delivered in cephalic presentations, regardless of the method by which the breech delivery was accomplished. These results suggested that, at least in some cases, the fetus remains in a breech position because it is less capable of movement within the uterus. If these concepts are accurate, the outcome for the fetus in a breech presentation could depend to a great extent on the reason for the breech position rather than the eventual mode of delivery.

Risks to the fetus inherent in breech presentation during labor and delivery include the following:

- Prolapse of the umbilical cord (especially in the footling breech)
- Trapping of the after-coming head by the incompletely dilated cervix (particularly in preterm infants weighing less than 1500 g and in CPD)
- Trauma resulting from extension of the head or nuchal position of the arms

Wright¹⁶² was the first to suggest that a policy of cesarean delivery for all breech presentations would result in the lowest possible perinatal morbidity and mortality rates. Nevertheless, most patients with a term breech presentation were delivered vaginally until the mid-1970s, when the cesarean delivery rate began to increase as a result of the concern for fetal well-being. At one university center, the rate of cesarean delivery for term breech presentation abruptly increased, from 13% in the years 1970 to 1975 to 54% in 1976 to 1977.¹⁶³ In that study,

a detailed analysis of the eight perinatal deaths that occurred among patients with a term breech presentation who delivered vaginally after having documented criteria for safe vaginal delivery found that six of the deaths would have been prevented by planned cesarean delivery. After 1975, the rate of cesarean delivery for breech presentation increased among most obstetric services in the United States. Data combined largely from retrospective cohort studies comparing vaginal with cesarean birth for patients with term breech presentations showed a small but statistically significant increase in risk of perinatal mortality and morbidity in patients who had vaginal deliveries.¹⁶⁴⁻¹⁶⁶

In 2000, Hannah and colleagues¹⁶⁷ published the results of a large multicenter, randomized, controlled trial comparing planned vaginal delivery with planned cesarean delivery in patients with a breech presentation at term. This study of 2088 subjects was terminated when an independent data monitoring committee found statistically significant evidence that perinatal morbidity and mortality were greater with planned vaginal delivery, without any significant differences in maternal mortality or serious morbidity. There were several limitations to this study: (1) fewer than 10% of women underwent x-ray pelvimetry (thought by many authorities to be essential in screening patients for safe vaginal delivery); (2) the frequency and use of oxytocin for induction or augmentation of labor were not controlled for in the regression analyses; and (3) most importantly, 22% of patients who delivered vaginally were not attended by an obstetrician, whereas this was true for only one of the patients delivered by cesarean section.¹⁶⁸⁻¹⁷⁰ These and other limitations notwithstanding, the results of this study confirmed the mounting evidence from most of the retrospective studies that even with careful screening of patients with a breech presentation for a trial of labor, the risk of perinatal death and serious morbidity is slightly but significantly greater for planned vaginal delivery than for planned cesarean delivery.

In light of these findings, the ACOG¹⁷¹ recommended that, if external version is not successful in a woman with a breech presentation at term, the patient should be advised to undergo a planned cesarean delivery. This recommendation does not apply to patients with breech presentation of a second twin.

Long-term developmental outcome (5 years) of surviving infants delivered vaginally in a breech presentation does not differ significantly from that of infants delivered by cesarean section because of breech presentation.^{161,172,173}

Breech Vaginal Delivery

Some authorities still take the position that, in the presence of a qualified obstetrician, a patient who fulfills criteria for safe vaginal delivery of a breech presentation can be offered this option.^{168,174,175} Because of the declining frequency of breech delivery, however, fewer obstetricians are acquiring the requisite skills to safely allow a trial of labor and vaginal delivery for patients with breech presentations. Criteria for allowing a trial of labor in a breech presentation are as follows:

- Frank or complete breech presentation
- Estimated fetal weight of 2000 to 3800 g
- Normal gynecoid pelvis with adequate measurements
- Flexed fetal head

Safe vaginal delivery of a breech presentation depends, to a great extent, on the experience, judgment, and skill of the obstetrician. If an obstetrician is unsure about his or her skills for vaginal delivery with a breech presentation, cesarean delivery is preferred.

Most authorities agree that radiographic pelvimetry has a place in selecting patients for a trial of labor when there is a breech presenta-

tion. Potter and coworkers¹⁷⁶ studied 13 term infants without congenital defects who died from intracranial injury as a result of vaginal breech delivery. In 7 of the 13 mothers, pelvic radiographs (five of which were obtained in the puerperium) revealed diminished pelvic capacity. In the remaining six patients, radiographs were not obtained.

Beischer¹⁷⁷ reviewed the outcome of term breech radiographs. Thirteen patients were delivered by cesarean section; all infants survived. Among the 51 infants delivered vaginally, there were 4 deaths, 3 of which were the result of tentorial tears. That study, together with the report of Todd and Steer¹⁷⁸ of 1006 term breech deliveries, suggested that vaginal delivery is not safe with radiographic pelvic measurements of less than the following:

- Anteroposterior diameter of the inlet, 11 cm
- Widest transverse of the inlet, 12 cm
- Interspinous diameter, 9 cm

Any other encroachment on the space below the inlet also contraindicates vaginal delivery. Pelvimetry performed with computed tomography exposes the fetus to substantially less radiation and is performed with greater facility in most hospitals than conventional x-ray pelvimetry.^{179,180} Also, pelvimetry by magnetic resonance imaging has been used for breech presentation, but the cost and the greater time required for this procedure make it less practical than pelvimetry via computed tomography.¹⁸¹

Not uncommonly, patients are found to be in labor with an unexpected breech presentation. This will continue to occur despite the increasing practice of planned cesarean delivery for all patients with a term breech presentation. In a study by Zatuchni and Andros,¹⁸² clinical screening of patients with breech presentations at term identified mothers who safely accomplished a vaginal delivery. Screening criteria did not include radiographic pelvimetry. On admission to the hospital in labor, patients were evaluated according to a “diagnostic index” (Table 36-8). In a prospective study of 139 patients with term breech presentations, which excluded patients with a prolapsed umbilical cord, severe congenital anomaly, or uterine bleeding, the authors found that perinatal mortality and morbidity occurred only in patients with an index of 3 or lower and that cesarean delivery of all patients with such an index would have resulted in an abdominal delivery rate of 21.5%.

The method of pain control for a vaginal breech delivery is another controversial issue. Conduction anesthesia has been used with good results,¹⁸³ and a case can be made that it prevents the mother from pushing uncontrollably in the second stage and allows for an easier and more comfortable application of the Piper forceps to the after-coming head. In a study of 643 singleton term breech presentations, however, epidural analgesia was associated with longer duration of labor, increased need for augmentation of labor with oxytocin, and a significantly higher rate of cesarean delivery in the second stage of labor.¹⁸⁴ An anesthesiologist can be of great assistance if there is difficulty in the delivery of nuchal arms or the after-coming head.

Fetal monitoring is essential during labor with a breech presentation. Because the fetal abdomen and the insertion of the umbilical cord are in the lower uterine segment during the late first stage and the second stage of labor, significant variable decelerations are more likely to be encountered than with cephalic presentation. For this reason, membranes should be left intact as long as possible, to provide some hydraulic protection against umbilical cord compression. Vaginal breech deliveries are more often associated with significant fetal acidosis than cephalic presentations.¹⁸⁵ Therefore, one must exercise careful

TABLE 36-8 PROGNOSTIC INDEX FOR VAGINAL BREECH DELIVERY*

Factor	Points Assigned		
	0	1	2
Parity	0	>1	—
Gestational age (wk)	39	38	37
Estimated fetal weight	>8 lb (3630 g)	7 lb 1 oz to 7 lb 15 oz (3176–3629 g)	<7 lb (3175 g)
Previous breech deliveries (birth weight >2500 g)	0	1	2
Dilation (cm)	2	3	4
Station	–3 or higher	–2	–1 or lower

*The index is obtained by adding the points scored for each factor.

Adapted from Zatuchni GI, Andros GJ: Prognostic index for vaginal delivery in breech presentation at term: Prospective study. *Am J Obstet Gynecol* 98:854, 1967.

judgment as to when to intervene for “fetal distress.” Fetal blood samples can be obtained from the buttock if there is a suspected or ominous fetal heart rate pattern; if the pH obtained between contractions is lower than 7.20 early in the second stage, abdominal delivery should be considered.

The use of oxytocin for induction of labor or augmentation of abnormal labor in a breech presentation is controversial. In the randomized, controlled trial by Hannah and associates,¹⁶⁷ a disproportionate number (64%) of the perinatal deaths in the intended vaginal delivery arm occurred in labors that were induced or augmented with oxytocin. If oxytocin is used, it must be administered with extraordinary caution.

Skillful, atraumatic delivery, regardless of the route of birth, is essential in keeping infant morbidity to a minimum. Milner¹⁸⁶ showed that application of forceps to the after-coming head was associated with a reduced rate of neonatal mortality from breech delivery. The well-illustrated publication by Piper and Bachman,¹⁸⁷ describing the use of the forceps designed by Piper and presenting in detail the method of breech delivery, should be standard reading for all physicians planning to assist in the vaginal delivery of a breech presentation. Even when the delivery is cesarean, forceps should be available (use of Piper forceps is not necessary), and they should be applied through the uterine incision to the after-coming head if there is any difficulty with its extraction. Calvert¹⁸⁸ found that infants in breech presentation born by cesarean section had a higher incidence of birth asphyxia than a comparable group of infants in cephalic presentation born by cesarean. A uterine incision does not ensure an atraumatic delivery of an infant, especially one in a breech presentation.

External Version

External version substantially reduces the incidence of term breech presentation.^{189,190} If the procedure is performed at 36 weeks' gestation, the success rate is approximately 65%. Complications that require immediate delivery, including placental separation and umbilical cord compression, occur in 1% to 2% of patients. The procedure is performed late in gestation and with cesarean delivery capability available, so that prompt delivery can be accomplished if persistent umbilical cord compression or premature separation of the placenta occurs. Tocolytic medications have been used in most series to prevent uterine contractions during the procedure, and the evidence shows that their use improves the success rate of external version.¹⁹¹ Some have found that the use of epidural analgesia, either with the initial attempt or after a first attempt has failed, improves the success rate of external version, but the extant studies are not large enough to determine the safety of this practice or its cost-effectiveness.¹⁹²⁻¹⁹⁴

Overall, for patients who undergo external version of a breech presentation at 36 weeks' gestation, the risk of cesarean delivery is reduced by 50%. In addition to a reduced morbidity risk for mother and infant, cost savings are substantial.¹⁹⁵ Chan and coauthors¹⁹⁶ compared delivery outcomes in pregnancies that had undergone successful external cephalic version for breech presentation with singleton vertex presentations without external version. After successful external version, patients had significantly higher rates of instrumental delivery and emergency cesarean delivery. The higher risk of operative delivery was the result of an increase in several major indications: fetal heart rate abnormalities, failure of labor to progress, and failed induction of labor. It is apparent that external cephalic version, even when successful, does not eliminate all of the risks inherent in breech presentation.

Contraindications to external version include the following:

- Uterine anomalies
- Third-trimester bleeding
- Multiple gestation
- Oligohydramnios
- Evidence of uteroplacental insufficiency
- A nuchal cord as identified by ultrasonography
- Previous cesarean delivery or other significant uterine surgery
- Obvious CPD

Primiparity, maternal obesity, advanced gestation, anterior implantation of the placenta, and excessive fetal weight have been associated with decreased success of external version but are not in themselves contraindications.

The procedure should be performed in a hospital in which cesarean delivery can be accomplished if unrelenting fetal distress occurs. A real-time ultrasonographic scan is performed to confirm the breech presentation; to detect multiple gestation, oligohydramnios, or fetal abnormalities; and to measure fetal dimensions.

Following a reactive nonstress test, a tocolytic drug is administered (terbutaline sulfate, 0.25 mg subcutaneously). (Some obstetricians prefer to first attempt version without tocolysis, proceeding with external version under tocolysis if this is unsuccessful.) After the uterus relaxes, the version is attempted. One person can elevate and laterally displace the breech while a second person manipulates the fetal head in the opposite direction. Mineral oil on the abdomen facilitates movement of the hands during the procedure. A forward roll is attempted; if this is unsuccessful, a backward roll is tried. The fetal heart rate should be monitored intermittently with Doppler or real-time scanning. Fetal bradycardia occurs in about 20% of cases but almost always

subsides after the manipulation ceases. External fetal heart rate monitoring is continued for 1 hour, after which the patient is discharged. Patients who are Rh-negative and who have a negative antibody titer should be given 1 unit (300 µg) of Rh immune globulin because of the risk of fetal-maternal transfusion associated with version (6% to 28%).^{197,198}

Transverse Lie (Shoulder Presentation)

Transverse lie occurs in approximately 1 of every 300 deliveries.¹⁹⁹ Cruikshank and White,²⁰⁰ reporting on 118 shoulder presentations, found that prematurity (38%) and high parity (87% of patients had already borne three or more infants) were the two most frequently associated conditions. Premature rupture of membranes (30%) and placenta previa (10%) are also more common in transverse lie than in longitudinal presentation. The high perinatal mortality rates (3.9% to 24%) associated with transverse lie¹⁹⁹ are almost surely a result of the high prevalence of low-birth-weight infants in shoulder presentations, although prolapse of the umbilical cord occasionally results in perinatal death of a term infant in transverse lie. These accidents typically happen unexpectedly, when spontaneous rupture of the membranes occurs outside the hospital setting. In such cases, the patient is usually admitted to the hospital with a severely asphyxiated or dead fetus.

The diagnosis can usually be made by palpation of the abdomen. Not infrequently, the patient notes that the fetus is in an unusual position and draws this fact to the physician's attention. The fetal position can be confirmed by real-time ultrasonography.

Management of the patient with a confirmed diagnosis of transverse lie depends on the length of gestation, the size of the fetus, the position of the placenta, and whether the membranes have ruptured. If the patient is in labor with a transverse lie and the expected fetal weight and gestational age are below those compatible with a reasonable (10%) chance of survival, no intervention is necessary beyond attempts to stop labor in the interest of increasing fetal weight and maturity before delivery. A fetus of this size (usually <600 g) eventually is delivered vaginally in shoulder presentation (*conduplicato corpore*) without undue trauma to the mother. If the gestational age or expected fetal weight is such that the chance for neonatal survival, in the absence of severe asphyxia or trauma, is greater than 10%, cesarean delivery is usually necessary, especially if the membranes are ruptured or placenta previa is present.

The role of external version in the management of transverse lie is highly controversial. Before 36 to 37 weeks' gestation in patients who are not in labor, external version should not be attempted because of the danger of cord entanglement or placental trauma and the difficulty of maintaining the normal axial lie after version. Moreover, there is the possibility that spontaneous version to a longitudinal lie will occur with additional growth and maturity of the fetus or with the onset of contractions. However, if a transverse lie is identified at or beyond 36 to 37 weeks' gestation in a patient with intact membranes, and CPD and placenta previa are not present, external version often results in a longitudinal lie and a normal vaginal delivery.

Edwards and Nicholson²⁰¹ demonstrated the benefits of a policy of admitting to the hospital all patients beyond 37 weeks' gestation in whom "unstable lie" is diagnosed. Their protocol in such patients was to search for etiologic factors and then, provided CPD and placenta previa were excluded, to perform external version followed by induction of labor after 38 weeks' gestation. In 102 cases so managed, 86 patients delivered vaginally, with only 1 case of cord prolapse and no perinatal deaths. In contrast, in 50 cases of unstable lie at or beyond

37 weeks' gestation in which the onset of spontaneous labor was awaited, there were 10 cases of prolapsed cord and 4 perinatal deaths. This experience suggests that, when a transverse or oblique lie is identified at or beyond 37 weeks' gestation, thorough etiologic evaluation and admission to the hospital should be considered.

If fetal mobility is restricted by well-advanced labor or the absence of amniotic fluid, or if placenta previa or CPD is detected, abdominal delivery in transverse lie is mandatory. Most authorities advise a low vertical or classic uterine incision in such cases, although Cruikshank and White²⁰⁰ found an extraordinarily high maternal morbidity rate (severe intraperitoneal infection, 21%; maternal death, 8.3%) associated with classic incisions for delivery in shoulder presentations. The low transverse incision often suffices in cases of a back-up transverse lie, and the high transverse incision described by Durfee²⁰² can be used in cases of a back-down shoulder presentation.

Finally, a technique of intra-abdominal version to allow the use of a low transverse incision has been described.²⁰³ Use of a transverse rather than a vertical incision decreases the overall maternal morbidity of cesarean delivery by reducing acute puerperal complications associated with vertical incisions and by allowing the option of managing subsequent pregnancies with a trial of labor and vaginal delivery. However, uterine incision should always be chosen with the primary purpose of abdominal delivery in mind (i.e., to avoid fetal trauma and asphyxia).

Deflection Abnormalities

Brow and face presentations are manifestations of different degrees of deflection of a cephalic presentation and therefore can be considered together. Seeds and Cefalo¹⁹⁹ reviewed the literature regarding brow and face presentations. Each occurs with a frequency of about 1 in 500 deliveries, although the incidence probably would be higher if all fetal presentations were assessed carefully early in labor. About 50% of such diagnoses are not made until the second stage of labor; many of the deflection problems detected early in labor correct themselves spontaneously as labor progresses.

With the exception of anencephaly, which almost always results in a face presentation, fetal anomalies do not seem to account for deflection problems in labor. Commonly reported etiologic factors in brow and face presentations include

- CPD
- Increased parity
- Prematurity
- Premature rupture of membranes

Apart from prematurity and anencephaly, the major problem associated with deflection presentations is dysfunctional labor in brow presentations. Friedman³ found that face presentation, contrary to generally held clinical impressions, did not appear to affect the course of labor significantly in either nulliparas or multiparas.
