Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

CONTRIBUTORS

Vikki M. Abrahams, PhD

Assistant Professor, Department of Obstetrics, Gynecology, and Reproductive Sciences, Yale University School of Medicine, New Haven, Connecticut

- **The Immunology of Pregnancy**

Michael J. Aminoff, MD, DSc, FRCP

Professor of Neurology, University of California, San Francisco, School of Medicine, Attending Physician, University of California Medical Center, San Francisco, California

- **Neurologic Disorders**

Marie H. Beall, MD

Professor of Obstetrics and Gynecology, Geffen School of Medicine at the University of California, Los Angeles; Vice Chair, Department of Obstetrics and Gynecology, Harbor–University of California, Los Angeles, Medical Center, Torrance, California

- **Amniotic Fluid Dynamics**

Kurt Benirschke, MD

Professor Emeritus, Reproductive Medicine and Pathology, University of California, San Diego, California

- **Normal Early Development**
- **Multiple Gestation: The Biology of Twinning**

Daniel G. Blanchard, MD, FACC

Professor of Medicine, Director, Cardiology Fellowship Program, University of California, San Diego, School of Medicine, La Jolla, California; Chief of Clinical Cardiology, Thornton Hospital, University of California, San Diego, Medical Center, San Diego, California

- **Cardiac Diseases**

Kristie Blum, MD

Assistant Professor of Medicine, Division of Hematology/Oncology, The Arthur G. James Cancer Hospital, The Ohio State University, Columbus, Ohio

- **Malignancy and Pregnancy**

Patrick Catalano, MD

Professor, Reproductive Biology, Case Western Reserve University; Chairman, Obstetrics and Gynecology, MetroHealth Medical Center, Cleveland, Ohio

- **Diabetes in Pregnancy**

Christina Chambers, PhD, MPH

Associate Professor, Departments of Pediatrics and Family and Preventive Medicine, University of California, San Diego, School of Medicine, La Jolla, California

- **Teratogenesis and Environmental Exposure**

Ronald Clyman, MD

Professor of Pediatrics, Investigator, Cardiovascular Research Institute, University of California, San Francisco

- **Fetal Cardiovascular Physiology**

David Cohn, MD

Donald and Patsy Jones Professor of Obstetrics and Gynecology, Division of Gynecologic Oncology, Arthur G. James Cancer Hospital and Richard J. Solove Research Institute, The Ohio State University College of Medicine, Columbus, Ohio

- **Malignancy and Pregnancy**

Robert K. Creasy, MD

Professor Emeritus, Department of Obstetrics, Gynecology, and Reproductive Sciences, University of Texas School of Medicine at Houston, Houston, Texas; Corte Madera, California

- **Preterm Labor and Birth**
- **Intrauterine Growth Restriction**

Mary E. D'Alton, MD, FACOG

Professor and Chair, Department of Obstetrics and Gynecology, Columbia University College of Physicians and Surgeons, New York, New York; Chair, Department of Obstetrics and Gynecology, Columbia University Medical Center, New York, New York

- **Multiple Gestation: Clinical Characteristics and Management**

John M. Davison, MD, FRCOG

Emeritus Professor of Obstetric Medicine, Institute of Cellular Medicine Medical School, Newcastle University; Consultant Obstetrician, Directorate of Women's Services, Royal Victoria Infirmary Newcastle upon Tyne, United Kingdom

- **Renal Disorders**

Jan A. Deprest, MD, PhD

Professor of Obstetrics and Gynecology, Division of Woman and Child, University Hospitals, Katholieke Universiteit Leuven, Leuven, Belgium

- **Invasive Fetal Therapy**

Mitchell P. Dombrowski, MD

Professor, Wayne State University, School of Medicine; Chief, Department of Obstetrics and Gynecology, St. John Hospital and Medical Center, Detroit, Michigan

- **Respiratory Diseases in Pregnancy**

Edward F. Donovan, MD

Emeritus, Professor of Pediatrics, University of Cincinnati College of Medicine; Medical Director, Child Policy Research Center, Cincinnati Children's Hospital Research Foundation, Cincinnati, Ohio

PREFACE

With this new edition, we welcome Dr. Charles J. Lockwood and Dr. Thomas R. Moore as editors of this textbook. Their previous contributions have been of unique importance to the success of our efforts, and we look forward to a long and productive relationship.

The 6th edition brings many innovations, most prominent of which is that it will also be available as an Expert Consult title, www.expertconsult.com. The online version will be fully searchable, with all text, tables, and images included. Additional content that could not be included in print form will be presented in the Web edition. In recognition of how rapidly the field of maternal-fetal medicine is advancing, we will initiate quarterly updates with this edition as well. The text includes several new chapters: “Pathogenesis of Spontaneous Preterm Labor,” “Benign Gynecologic Conditions in Pregnancy,” “Developmental Origins of Health and Disease,” and “Neonatal Morbidities of Prenatal and Perinatal Origin.” All chapters have been extensively rewritten and updated, and we are, as always, deeply appreciative of the contributions of our many new and returning authors.

We also wish to express our appreciation and gratitude to our marvelous editors at Elsevier, particularly Kristina Oberle, our Developmental Editor, for her organizational skills and for always being available for counsel. We are also indebted to Rebecca Schmidt Gaertner for her overall supervision of the project and to Rachel Miller for moving the project through final production.

Finally, we are indebted to our families for their patience and support, because every hour spent producing this text was an hour spent away from them.

The Editors

Chapter 1

Basic Genetics and Patterns of Inheritance

Bruce A. Hamilton, PhD, and Anthony Wynshaw-Boris, MD, PhD

Impact of Genetics and the Human Genome Project on Medicine in the 21st Century

For most of the 20th century, geneticists were considered to be outside the everyday clinical practice of medicine. The exceptions were those medical geneticists who studied rare chromosomal abnormalities and rare causes of birth defects and metabolic disorders. As recently as 20 years ago, genetics was generally not taught as part of the medical school curriculum, and most physicians' understanding of genetics was derived from undergraduate studies.¹ How things have changed in the 21st century! Genetics is now recognized as a contributing factor to virtually all human illnesses. In addition, the widespread reporting of genetic discoveries in the lay press and the plethora of genetic information available via the Internet has led to a great increase in the sophistication of patients and their families as medical consumers regarding genetics.

The importance of genetics in medical practice has grown as a consequence of the immense progress made in genetics and molecular biology during the 20th century. In the first year of that century, Mendel's laws were rediscovered and applied to many fields, including human disease. In 1953, Watson and Crick published the structure of DNA and ushered in the era of molecular biology. At nearly the same time, the era of cytogenetics began with the determination of the correct number of human chromosomes (46). In the 1970s, Sanger and Gilbert independently published techniques for determining the sequence of DNA. These findings, combined with automation of the Sanger method in the 1980s, led several prominent scientists to propose and initiate the Human Genome Project, with the goal of obtaining the complete human DNA sequence. At the time, it was hard to imagine that this goal could be achieved, but in the first year of the 21st century, a draft of the human genome was published simultaneously by the publicly funded Human Genome Project² and a private company, Celera.³ Since then, additional public consortia and private companies have made systematic efforts to catalog DNA sequence variations that may predict or contribute to human disease. These include both single nucleotide polymorphisms (SNPs)⁴ and copy number variations (CNVs)⁵ of large blocks of sequence. Most of these data are available in public databases, and disease-related discoveries based on them are being reported at a rapid pace. The concepts, tools, and techniques of

modern genetics and molecular biology have already had a profound impact on biomedical research and will continue to revolutionize our approach to human disease risk management, diagnosis, and treatment over the next decade and beyond.

Genetics plays an important role in the day-to-day practice of obstetrics and gynecology, perhaps more so than in any other specialty of medicine. In obstetric practice, genetic issues often arise before, during, and after pregnancy. Amniocentesis or chorionic villus sampling may detect potential chromosomal defects in the fetus. Fetuses examined during pregnancy by ultrasound may have possible birth defects. Specific prenatal diagnostic tests for genetic diseases may be requested by couples attempting to conceive who have a family history of that disorder. Infertile couples often require a workup for genetic causes of their infertility. In gynecology, genetics is particularly important in disorders of sexual development and gynecologic malignancies.

What Is a Gene?

Genes are the fundamental unit of heredity. As a concise description, a gene includes all the structural and regulatory information required to express a heritable quality, usually through production of an encoded protein or an RNA product. In addition to the more familiar genes encoding proteins (through messenger or mRNA) and RNAs that function in RNA processing (small nuclear or snRNA), ribosome assembly (small nucleolar or snoRNA), and protein translation (transfer or tRNA and ribosomal or rRNA), there are more recently appreciated classes of regulatory RNAs that function in control of gene expression, including microRNAs (miRNA), piwiRNAs (piRNAs), and other noncoding RNAs (ncRNA). Structural segments of the genome that do not encode an RNA or a protein may also be considered genes if their mutation produces observable effects. Humans are now thought to have 20,000 to 25,000 distinct protein-coding genes, although this number has fluctuated with improved methods for identifying genes. We shall now outline the chemical nature of genes, the biochemistry of gene function, and the classes and consequences of genetic mutations.

Chemical Nature of Genes

Human genes are composed of deoxyribonucleic acid (DNA) (Fig. 1-1). DNA is a negatively charged polymer of nucleotides. Each nucleotide is composed of a "base" attached to a 5-carbon deoxyribose sugar.

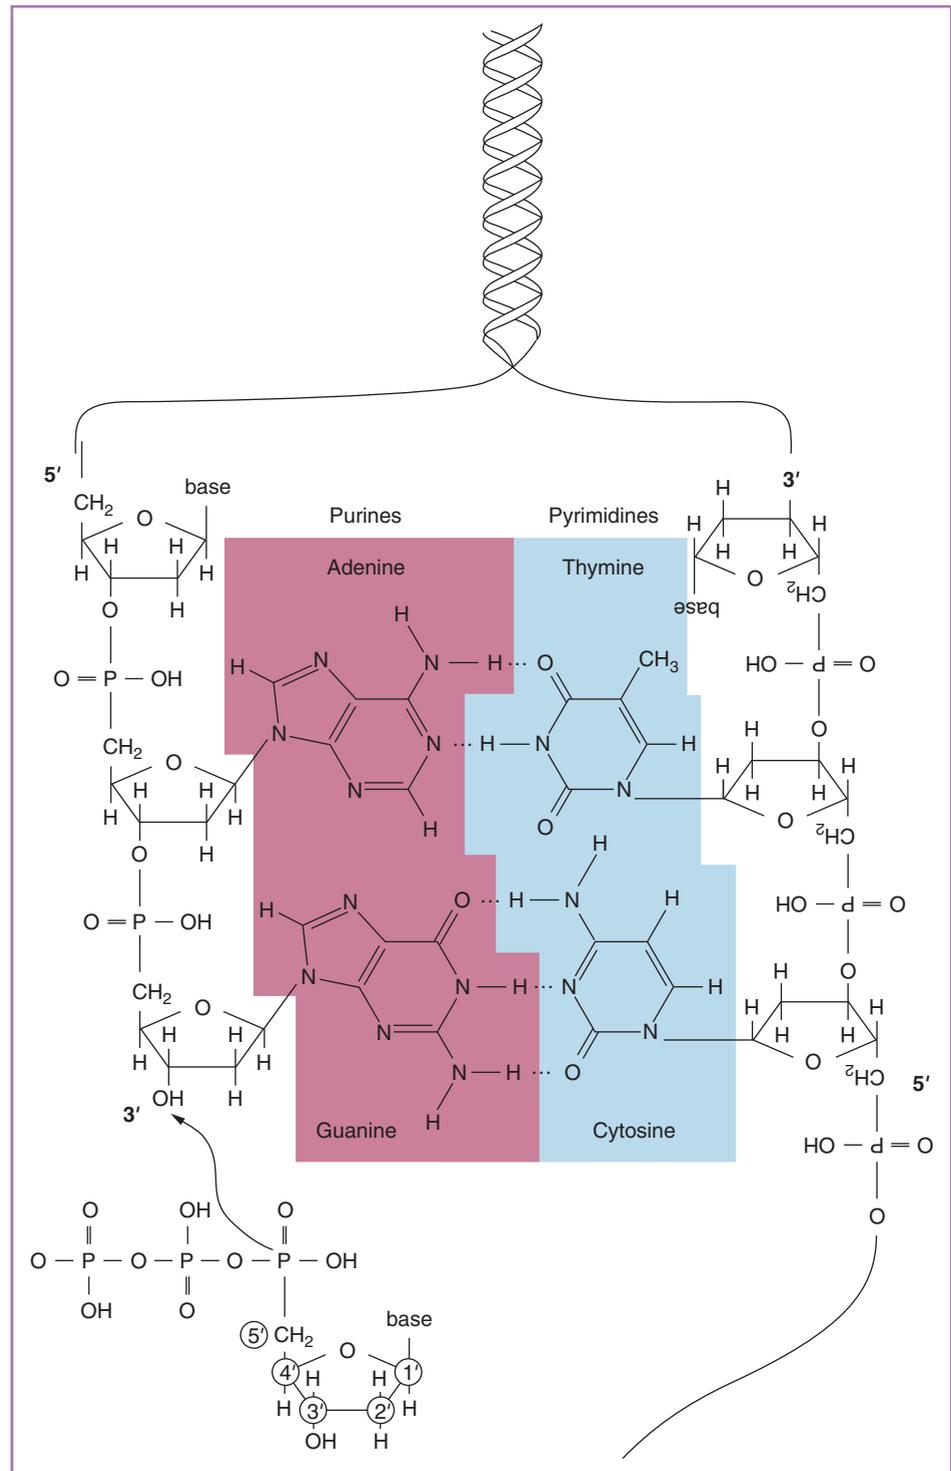

FIGURE 1-1 Schematic diagram of DNA structure. Each strand of the double helix is a polymer of deoxyribonucleotides. Hydrogen bonds (shown here as dots [...]) between base pairs hold the strands together. Each base pair includes one purine base (adenine or guanine) and its complementary pyrimidine base (thymine or cytosine). Two hydrogen bonds form between A:T pairs and three between G:C pairs. The two polymer strands run antiparallel to each other according to the polarity of their sugar backbone. As shown at the bottom, DNA synthesis proceeds in the 5'-to-3' direction by addition of new nucleoside triphosphates. Energy stored in the triphosphate bond is used for the polymerization reaction. The numbering system for carbon atoms in the deoxyribose sugar is indicated.

Four bases are used in cellular DNA: two purines, adenine (A) and guanine (G), and two pyrimidines, cytosine (C) and thymine (T). The polymer is formed through phosphodiester bonds that connect the 5' carbon atom of one sugar to the 3' carbon of the next, which imparts directionality to the polymer.

Cellular DNA is a double-stranded helix. The two strands run antiparallel; that is, the 5' to 3' orientation of one strand runs in the opposite direction along the helix from its complementary strand. The

bases in the two strands are paired: A with T, and G with C. Hydrogen bonds between the base pairs hold the strands together: two hydrogen bonds for A:T pairs and three for G:C pairs. Each base thus has a complementary base, and the sequence of bases on one strand implies the complementary sequence of the opposite strand. DNA is replicated in the 5' to 3' direction using the sequence of the complementary strand as a template. Nucleotide precursors used in DNA synthesis have 5' triphosphate groups. Polymerase enzymes use the energy

of this triphosphate to catalyze formation of a phosphoester bond with the hydroxyl group attached to the 3' carbon of the extending strand.

Chemical attributes of DNA are the basis for clinical and forensic molecular diagnostic tests. Because nucleic acids form double-stranded duplexes, synthetic DNA and RNA molecules can be used to probe the integrity and composition of specific genes from patient samples. Non-complementary base pairs formed by hybridization of DNA from a subject carrying a sequence variant relative to a reference sample are often detected by physicochemical properties such as reduced thermal stability of short (oligonucleotide) hybrids. In vitro DNA synthesis with recombinant polymerase enzymes are the basis for polymerase chain reaction (PCR) amplification of specific gene sequences. Increasingly, DNA sequencing methods are being used to detect small, nucleotide-level variations, and hybridization-based methods are used to discriminate between some known allelic differences and to assess structural variations such as variations in gene copy number.

Biochemistry of Gene Function

Information Transfer

DNA is an information molecule. The central dogma of molecular biology is that information in DNA is *transcribed* to make RNA, and information in messenger RNA (mRNA) is *translated* to make protein. DNA is also the template for its own replication. In some instances, such as in retroviruses, RNA is reverse-transcribed into DNA. Although proteins are used to catalyze the synthesis of DNA, RNA, and proteins, proteins do not convey information back to genes. The sequence of RNA nucleotides (A, C, G, and uracil [U] bases coupled to ribose) is the same as the *coding* or *sense strand* of DNA (except that U replaces T), and the complementary antisense strand of DNA is the template for synthesis. The sequence of amino acids in a protein is determined by a three-letter code of nucleotides in its mRNA (Fig. 1-2). The phase of the reading frame for these three-letter codons is set from the first codon, usually an AUG, encoding the initial methionine.

Quality Control in Gene Expression

Several mechanisms protect the specificity and fidelity of gene expression in cells. *Promoter* and *enhancer* sequences are binding sites on DNA for proteins that direct transcription of RNA. Promoter sequences are typically adjacent and 5' to the start of mRNA encoding sequences (although some promoter elements are also found downstream of the start site, particularly in introns), whereas enhancers may act at a considerable distance, from either the 5' or 3' direction. The combinations of binding sites present determine under what conditions the gene is transcribed.

Newly transcribed RNA is generally processed before it is used by a cell. Many processing steps occur cotranscriptionally, on the elongated RNA as it is synthesized. Pre-mRNAs generally receive a 5' "cap" structure and a poly-adenylated 3' tail. Protein-coding genes typically contain exons that remain in the processed RNA, and one or more introns that must be removed by *splicing* (Fig. 1-3). Nucleotide sequences in the RNA that are recognized by protein and RNA splicing factors determine where splicing occurs. Many RNAs can be spliced in more than one way to encode a related series of products, greatly increasing the complexity of products that can be encoded by a finite number of genes. For most genes, only spliced RNA is exported from the nucleus. Spliced RNAs that retain premature stop codons are rapidly degraded. Mutations in genes involved in these quality control steps appear in the clinic as early and severe genetic disorders, includ-

FIGURE 1-2 The genetic code. The letters U, C, A, and G correspond to the nucleotide bases. In this diagram, U (uracil) is substituted for T (thymidine) to reflect the genetic code as it appears in messenger RNA. Three distinct triplets (codons)—UAA, UAG, and UGA—are "nonsense" codons and result in termination of messenger RNA translation into a polypeptide chain. All amino acids except methionine and tryptophan have more than one codon; thus the genetic code is degenerate. This is the primary reason that many single base-change mutations are "silent." For example, changing the terminal U in a UUU codon to a terminal C (UUC) still codes for phenylalanine. In contrast, an A to T (U) change (GAG to GUG) in the β -globin gene results in substitution of valine for glutamic acid at position 6 in the β -globin amino acid sequence, thus yielding "sickle cell" globin.

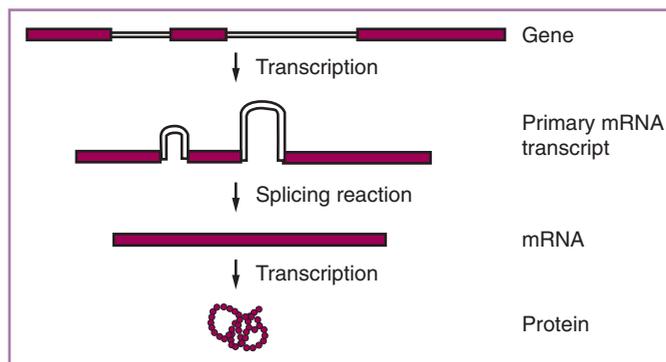

FIGURE 1-3 Transcription of DNA to RNA and translation of RNA to protein. Introns (*light sections*) are spliced out of the primary messenger RNA (mRNA) transcript and exons (*dark sections*) are joined together to form mature mRNA.

ing spinal muscular atrophy (caused by mutations in *SMN1*, which encodes a splicing accessory factor) and fragile X syndrome (mutations in *FMRI*, which encodes an RNA-binding protein). Protein synthesis is also highly regulated. Translation, folding, modification, transport, and sometimes cleavage to create an active form of the protein are all regulated steps in the expression of protein-coding genes.

Mutations

Changes in the nucleotide sequence of a gene may occur through environmental damage to DNA, through errors in DNA replication, or

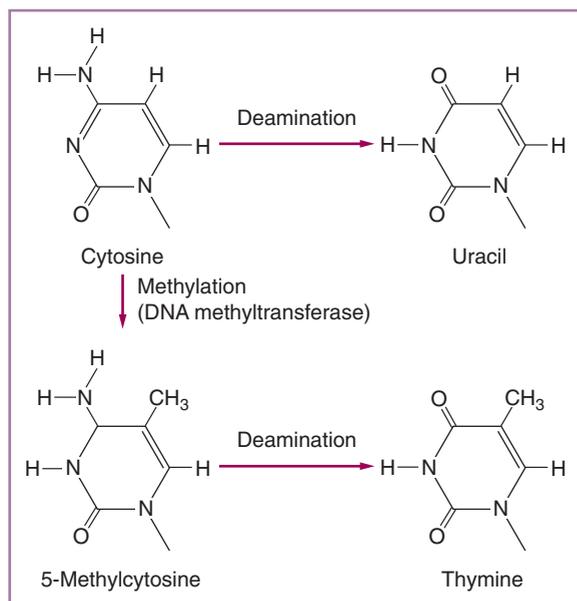

FIGURE 1-4 Deamination of cytosine. Deamination of cytosine or of its 5-methyl derivative produces a pyrimidine capable of pairing with adenine rather than guanine. Repair enzymes may remove the mispaired base before replication, but replication before repair (or repair of the wrong strand) results in the change becoming permanent. Spontaneous deamination of cytosine is a major mechanism of mutation in humans. Deamination of cytosine is also accelerated by some mutagenic chemicals, such as hydrazine.

through unequal partitioning during meiosis. Ultraviolet light, ionizing radiation, and chemicals that intercalate, bind to, or covalently modify DNA are examples of mutation-causing agents. Replication errors often involve changes in the number of a repeated sequence; for example, changes in the number of (CAG)_n repeats encoding polyglutamine in the *Huntintin* gene can result in alleles prone to Huntington disease. Replication also plays a crucial role in other mutations. Cells generally respond to high levels of DNA damage by blocking DNA replication and inducing a variety of DNA repair pathways. However, for any one site of DNA damage, replication may occur before repair. A frequent source of human mutation is spontaneous deamination of cytosine (Fig. 1-4). The modified base can be interpreted as a thymine if replication occurs before repair of the G:T mismatch pair. Ultraviolet light causes photochemical dimerization of adjacent thymine residues that may then be altered during repair or replication; in humans, this is more relevant to somatic mutations in exposed skin cells than to germline mutations. Ionizing radiation, by contrast, penetrates tissues and can cause both base changes and double-strand breaks in DNA. Errors in repair of double-strand breaks result in deletion, inversion, or translocation of large regions of DNA. Many chemicals, including alkylating agents and epoxides, can form chemical adducts with the bases of DNA. If the adduct is not recognized during the next round of DNA replication, the wrong base may be incorporated into the opposite strand. In addition, the human genome includes hundreds of thousands of endogenous retroviruses, retrotransposons, and other potentially mobile DNA elements. Movement of such elements or recombination between them is a source of spontaneous insertions and deletions, respectively.

Changes in the DNA sequence of a gene create distinct alleles of that gene. Alleles can be classified based on how they affect the function of that gene. An *amorphic* (or null) allele is a complete loss of function,

hypomorphic is a partial loss of function, *hypermorphic* is a gain of normal function, *neomorphic* is a gain of novel function not encoded by the normal gene, and an *antimorphic* or dominant negative allele antagonizes normal function. A practical impact of allele classes is that distinct clinical syndromes may be caused by different alleles of the same gene. For example, different allelic mutations in the androgen receptor gene have been tied to partial or complete androgen insensitivity⁶ (including hypospadias and Reifenstein syndrome), prostate cancer susceptibility, and spinal and bulbar muscular atrophy.⁷ Similarly, mutations in the *CFTR* chloride channel cause cystic fibrosis, but some alleles are associated with pancreatitis or other less severe symptoms; mutations in the *DTDST* sulfate transporter cause diastrophic dysplasia, atelosteogenesis, or achondrogenesis, depending on the type of mutation present.

A small fraction of changes in genomic DNA affect gene function. Approximately 2% to 5% of the human genome encodes protein or confers regulatory specificity. Even within the protein coding sequences, many base changes do not alter the encoded amino acid, and these are called *silent substitutions*. Changes in DNA sequence that occurred long ago and do not alter gene function or whose impact is modest or uncertain are often referred to as *polymorphisms*, whereas *mutation* is reserved for newly created changes and changes that have significant impacts on gene function, such as in disease-causing alleles of disease-associated genes. Mutations that do affect gene function may occur in coding sequences or in sequences required for transcription, processing, or stability of the RNA. The rate of spontaneous mutation in humans can vary tremendously depending on the size and structural constraints of the gene involved, but estimates range from 10⁻⁴ per generation for large genes such as *NF1* down to 10⁻⁶ or 10⁻⁷ for smaller genes. Given current estimates of 20,000 to 25,000 human genes,^{2,3} and given that more than 6 billion humans inhabit the earth, one may expect that each human is mutant for some gene and each gene is mutated in some humans. Several public databases that curate information about human genes and mutations are now available online (Table 1-1).

Chromosomes in Humans

Most genes reside in the nucleus and are packaged on the *chromosomes*. In the human, there are 46 chromosomes in a normal cell: 22 pairs of

autosomes, and the X and Y sex chromosomes (see later). The autosomes are numbered from the largest (1) to the smallest (21 and 22). Each chromosome contains a *centromere*, a constricted region that forms the attachments to the mitotic spindle and governs chromosome movements during mitosis. The *chromosomal arms* radiate on each side of the centromere, terminating in the *telomere*, or end of each arm. Each chromosome contains a distinct set of genetic information. Each pair of autosomes is homologous and has an identical set of genes. Normal females have two X chromosomes, whereas normal males have one X and one Y chromosome. In addition to the nuclear chromosomes, the mitochondrial genome contains approximately 37 genes on a single chromosome that resides in this organelle.

Each chromosome is a continuous DNA double-helical strand, packaged into *chromatin*, which consists of protein and DNA. The protein moiety consists of basic *histone* and acidic *nonhistone* proteins. Five major groups of histones are important for proper packing of chromatin, whereas the heterogeneous nonhistone proteins are required for normal gene expression and higher-order chromosome packaging. Two each of the four core histones (H2A, H2B, H3, and H4) form a histone octamer nucleosome core that binds with DNA in a fashion that permits tight supercoiling and packaging of DNA in the chromosome-like thread on a spool. The fifth histone, H1, binds to DNA at the edge of each nucleosome in the spacer region. A single nucleosome core and spacer consists of about 200 base pairs of DNA. The nucleosome “beads” are further condensed into higher-order structures called solenoids, which can be packed into loops of chromatin that are attached to nonhistone matrix proteins. The orderly packaging of DNA into chromatin performs several functions, not the least of which is the packing of an enormous amount of DNA into the small volume of the nucleus. This orderly packing allows each chromosome to be faithfully wound and unwound during replication and cell division. Additionally, chromatin organization plays an important role in the control of gene expression.

Cell Cycle, Mitosis, and Meiosis

Cell Cycle

In replicating somatic cells, the complete diploid set of chromosomes is duplicated and the cell divides into two identical daughter cells, each with chromosomes and genes identical to those of the parent cell. The process of cell division is called *mitosis*, and the period between divisions is called *interphase*. Interphase can be divided into G_1 , S, and G_2 phases, and a typical cell cycle is depicted in Figure 1-5. During the G_1 phase, synthesis of RNA and proteins occurs. In addition, the cell prepares for DNA replication. *S phase* ushers in the period of DNA replication. Not all chromosomes are replicated at the same time, and within a chromosome DNA is not synchronously replicated. Rather, DNA synthesis is initiated at thousands of origins of replication scattered along each chromosome. Between replication and division, called the G_2 phase, chromosome regions may be repaired and the cell is made ready for mitosis. In the G_1 phase, DNA of every chromosome of the diploid set ($2n$) is present once. Between the S and G_2 phases, every chromosome doubles to become two identical polynucleotides, referred to as *sister chromatids*. Thus, all DNA is now present twice ($2 \times 2n = 4n$).

Mitosis

The process of mitosis ensures that each daughter cell contains an identical and complete set of genetic information from the parent cell; this process is diagrammed in Figure 1-6. Mitosis is a continuous

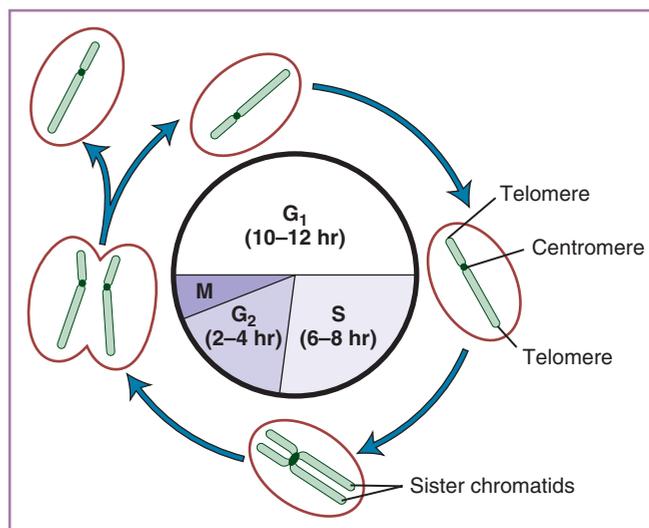

FIGURE 1-5 Cell cycle of a dividing mammalian cell, with approximate times in each phase of the cycle. In the G_1 phase, the diploid chromosome set ($2n$) is present once. After DNA synthesis (S phase), the diploid chromosome set is present in duplicate ($4n$). After mitosis (M), the DNA content returns to $2n$. The telomeres, centromere, and sister chromatids are indicated. (From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's Genetics in Medicine, 6th ed. Philadelphia, WB Saunders, 2001.)

process that can be artificially divided into four stages based on the morphology of the chromosomes and the mitotic apparatus. The beginning of mitosis is characterized by swelling of chromatin, which becomes visible under the light microscope by the end of *prophase*. Only 2 of the 46 chromosomes are shown in Figure 1-6. In *prophase*, the two sister chromatids (chromosomes) lie closely adjacent. The nuclear membrane disappears, the nucleolus vanishes, and the spindle fibers begin to form from the microtubule-organizing centers, or *centrosomes*, that take positions perpendicular to the eventual plane of cleavage of the cell. A protein called *tubulin* forms the microtubules of

the spindle and connects with the centromeric region of each chromosome. The chromosomes condense and move to the middle of the spindle at the eventual point of cleavage.

After prophase, the cell is in *metaphase*, when the chromosomes are maximally condensed. The chromosomes line up with the centromeres located on an equatorial plane between the spindle poles. This is the important phase for cytogenetic technology. When a cell is in metaphase, virtually all clinical methods of examining chromosomes cause arrest of further steps in mitosis. Thus, we see all sister chromatids ($4n$) in a standard clinical karyotype.

Anaphase begins as the two chromatids of each chromosome separate, connected at first only at the centromere region (*early anaphase*). Once the centromeres separate, the sister chromatids of each chromosome are drawn to the opposite poles by the spindle fibers. During telophase, chromosomes lose their visibility under the microscope, spindle fibers are degraded, tubulin is stored away for the next division, and a new nucleolus and nuclear membrane develop. The cytoplasm also divides along the same plane as the equatorial plate in a process called *cytokinesis*. Cytokinesis occurs once the segregating chromosomes approach the spindle poles. Thus, the elaborate process of mitosis and cytokinesis of a single cell results in the segregation of an equal complete set of chromosomes and genetic material in each of the resulting daughter cells.

Meiosis and the Meiotic Cell Cycle

In mitotic cell division, the number of chromosomes remains constant for each daughter cell. In contrast, a property of meiotic cell division is the reduction in the number of chromosomes from the diploid number in the germline to the haploid number in gametes (from 46 to 23 in humans). To accomplish this reduction, two successive rounds of meiotic division occur. The first division is a reduction division in which the chromosome number is reduced by one half, and it is accomplished by the pairing of homologous chromosomes. The second meiotic division is similar to most mitotic divisions, except the total number of chromosomes is haploid rather than diploid. The haploid number is found only in the germline; thus, after fertilization the diploid chromosome number is restored. The selection of chromosomes from each homologous pair in the haploid cell is completely random, thereby ensuring genetic variability in each germ cell. In addition, recombination occurs during the initial stages of chromosome pairing during the first phase of meiosis, providing an additional layer of genetic diversity in each of the gametes.

STAGES OF MEIOSIS

Figure 1-7 depicts the stages of meiosis. DNA synthesis has already occurred before the first meiotic division and does not occur again during the two stages of meiotic division. A major feature of *meiotic*

FIGURE 1-7 The stages of meiosis. Paternal chromosomes are *green*; maternal chromosomes are *white*. **A**, Condensed chromosomes in mitosis. **B**, Leptotene. **C**, Zygotene. **D**, Diplotene with crossing over. **E**, Diakinesis, anaphase I. **F**, Anaphase I. **G**, Telophase I. **H₁** and **H₂**, Metaphase II. **I**, Resolution of telophase II produces two haploid gametes. (From Vogel F, Motulsky AG: Human Genetics: Problems and Approaches. New York, Springer-Verlag, 1979.)

division I is the pairing of homologous chromosomes at homologous regions during prophase I; this is a complex stage in which many tasks are accomplished, and it can be subdivided into substages based on morphology of meiotic chromosomes. These stages are termed *leptonema*, *zygonema*, *pachynema*, *diplonema*, and *diakinesis*. Condensation and pairing occur during leptonema and zygonema (see Fig. 1-7C,D). The paired homologous chromosome regions are connected at a double-structured region, the *synaptonemal complex*, during pachynema. In diplonema, four chromatids of each kind are seen in close approximation side by side (see Fig. 1-7D). Nonsister chromatids become separated, whereas the sister chromatids remain paired; the chromatid crossings (*chiasmata*) between nonsister chromatids can be seen (see Fig. 1-7D). The chiasmata are believed to be sites of recombination. The chromosomes separate at diakinesis (see Fig. 1-7E). The chromosomes now enter meiotic metaphase I and telophase I (see Fig. 1-7F,G).

Meiotic division II is essentially a mitotic division of a fully copied set of haploid chromosomes. From each meiotic metaphase II, two daughter cells are formed (see Fig. 1-7H₁ and H₂), and a random assortment of DNA along the chromosome is accomplished at division (see Fig. 1-7I). After meiosis II, the genetic material is distributed to four cells as haploid chromosomes (23 in each cell). In addition to random crossing over, there is also random distribution of nonhomologous chromosomes to each of the final four haploid daughter cells. For these 23 chromosomes, the number of possible combinations in a single germ cell is 2^{23} , or 8,388,608. Thus $2^{23} \times 2^{23}$ equals the number of possible genotypes in the children of any particular combination of parents. This impressive number of variable genotypes is further enhanced by crossing over during prophase I of meiosis. Chiasma formation occurs during pairing and may be essential to this process, because there appears to be at least one chiasma per chromosome arm. A chiasma appears to be a point of crossover between two nonsister chromatids that occurs through breakage and reunion of nonsister chromatids at homologous points (Fig. 1-8).

SEX DIFFERENCES IN MEIOSIS

There are crucial distinctions between the two sexes in meiosis.

Males. In the male, meiosis is continuous in spermatocytes from puberty through adult life. After meiosis II, sperm cells acquire the ability to move effectively. The primordial fetal germ cells that produce oogonia in the female give rise to gonocytes at the same time in the male fetus. In these gonocytes, the tubules produce Ad (dark) spermatogonia (Fig. 1-9). During the middle of the second decade of life in males, spermatogenesis is fully established. At this point, the number of Ad spermatogonia is approximately 4.3 to 6.4×10^8 per testis. Ad spermatogonia undergo continuous divisions. During a given division, one cell may produce two Ad cells, whereas another produces two Ap (pale) cells. These Ap cells develop into B spermatogonia and hence into spermatocytes that undergo meiosis (see Fig. 1-9). Primary spermatocytes are in meiosis I, whereas secondary spermatocytes are in meiosis II. Vogel and Rathenberg⁸ calculated approximations of the number of cell divisions according to age. On the basis of these approximations, it can be estimated further that from embryonic age to 28 years, the number of cell divisions of human sperm is approximately 15 times greater than the number of cell divisions in the life history of an oocyte.

Females. In the primitive gonad destined to become female, the number of ovarian stem cells increases rapidly by mitotic cell division. Between the 2nd and 3rd months of fetal life, oocytes begin to enter meiosis (Fig. 1-10). By the time of birth, mitosis in the female germ cells is finished and only the two meiotic divisions remain to be fulfilled.

Rights were not granted to include this figure in electronic media.
Please refer to the printed publication.

FIGURE 1-8 Crossing over and chiasma formation.

A, Homologous chromatids are attached to each other. **B**, Crossing over with chiasma occurs. **C**, Chromatid separation occurs. (From Vogel F, Motulsky AG: Human Genetics: Problems and Approaches. New York, Springer-Verlag, 1979.)

After birth, all oogonia are either transformed into oocytes or they degenerate. Fetal germ cells increase from 6×10^5 at 2 months' gestation to 6.8×10^6 during the 5th month. Decline begins at this time, to about 2×10^6 at birth. Meiosis remains arrested in the viable oocytes until puberty. At puberty, some oocytes start the division process again. An individual follicle matures at the time of ovulation. At the completion of meiosis I, one of the cells becomes the secondary oocyte, accumulating most of the cytoplasm and organelles, whereas the other cell becomes the first polar body. The maturing secondary oocyte completes meiotic metaphase II at the time of ovulation. If fertilization occurs, meiosis II in the oocyte is completed, with the formation of the second polar body. Only about 400 oocytes eventually mature during the reproductive lifetime of a woman, whereas the rest degenerate. In the female, only one of the four meiotic products develops into a mature oocyte; the other three become polar bodies that usually are not fertilized.

There are, then, three basic differences in meiosis between males and females:

1. In females, one division product becomes a mature germ cell and three become polar bodies. In the male, all four meiotic products become mature germ cells.

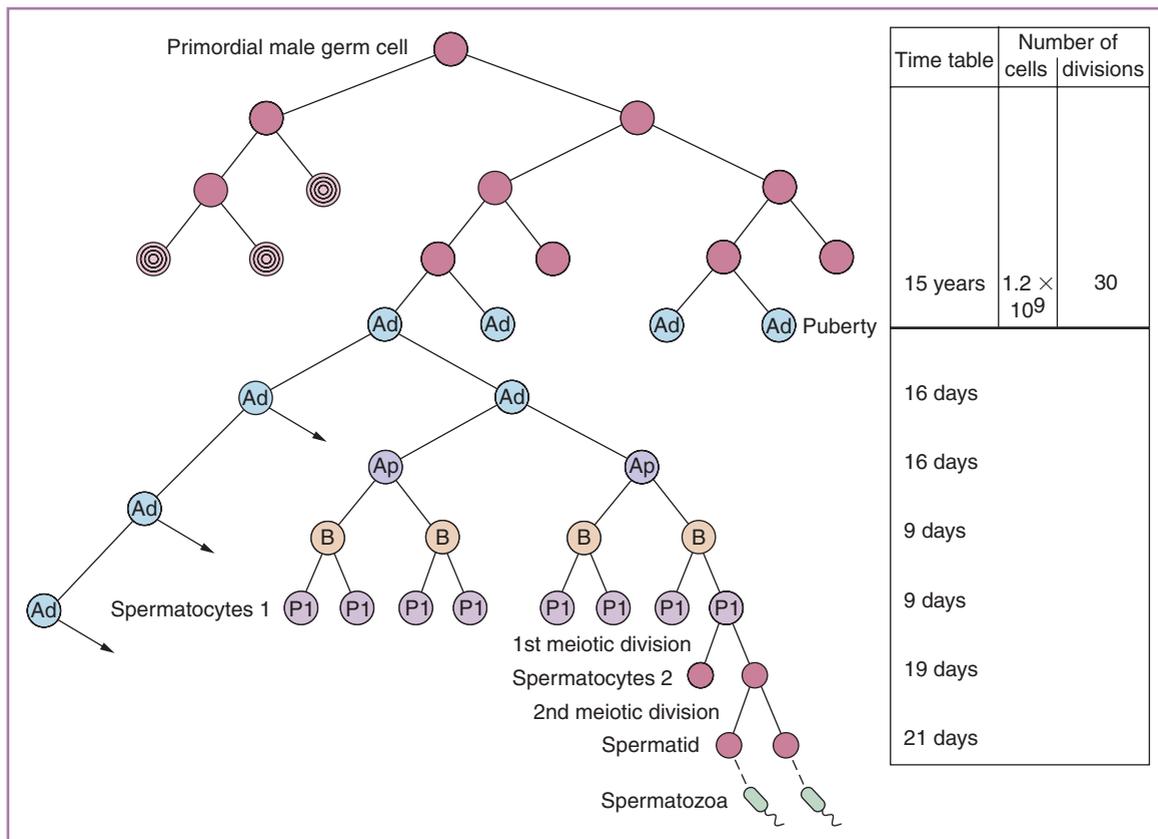

FIGURE 1-9 Cell divisions during spermatogenesis. The overall number of cell divisions is much higher than in oogenesis. It increases with advancing age. Ad, dark spermatogonia; Ap, pale spermatogonia; B, spermatogonia; P1, spermatocytes. Concentric circles indicate cell atrophy. (From Vogel F, Motulsky AG: Human Genetics: Problems and Approaches. New York, Springer-Verlag, 1979.)

- In females, a low number of embryonic mitotic cell divisions occurs very early, followed by early embryonic meiotic cell division that continues to occur up to around the 9th month of gestation; division is then arrested for many years, commences again at puberty, and is completed only after fertilization. In the male, there is a much longer period of mitotic cell division, followed immediately by meiosis at puberty; meiosis is completed when spermatids develop into mature sperm.
- In females, very few gametes are produced, and only one at a time, whereas in males, a large number of gametes are produced virtually continuously.

FERTILIZATION

The chromosomes of the egg and sperm are segregated after fertilization into the pronuclei, and each is surrounded by a nuclear membrane. The DNA of the diploid zygote replicates soon after fertilization, and after division two diploid daughter cells are formed, initiating embryonic development.

CLINICAL SIGNIFICANCE OF MITOSIS AND MEIOSIS

The proper segregation of chromosomes during meiosis and mitosis ensures that the progeny cells contain the appropriate genetic instructions. When errors occur in either process, the result is that an individual or cell lineage contains an abnormal number of chromosomes and an unbalanced genetic complement. Meiotic non-

disjunction, occurring primarily during oogenesis, is responsible for chromosomally abnormal fetuses in several percent of recognized pregnancies. Mitotic nondisjunction can occur during tumor formation. In addition, if it occurs early after fertilization, it may result in chromosomally unbalanced embryos or mosaicism that may result in birth defects and mental retardation.

Analysis of Human Chromosomes

The era of clinical human cytogenetics began just about 50 years ago with the discovery that somatic cells in humans contain 46 chromosomes. The use of a simple procedure—hypotonic treatment for spreading the chromosomes of individual cells—enabled medical scientists and physicians to microscopically examine and study chromosomes in single cells rather than in tissue sections. Between 1956 and 1959, it was recognized that visible changes in the number or structure of chromosomes could result in a number of birth defects, such as Down syndrome (trisomy 21), Turner syndrome (45,XO), and Klinefelter syndrome (47,XXY). Chromosome disorders represent a large proportion of fetal loss, congenital defects, and mental retardation. In the practice of obstetrics and gynecology, clinical indications for chromosome analysis include abnormal phenotype in a newborn infant, unexplained first-trimester spontaneous abortion with no fetal karyotype, pregnancy resulting in stillborn or neonatal death, fertility problems, and pregnancy in women of advanced age.^{9,10}

FIGURE 1-10 Meiosis in the human female. Meiosis starts after 3 months of development. During childhood, the cytoplasm of oocytes increases in volume, but the nucleus remains unchanged. About 90% of all oocytes degenerate at the onset of puberty. During the first half of every month, the luteinizing hormone of the pituitary stimulates meiosis, which is now almost completed (end of the prophase that began during embryonic stage; metaphase I, anaphase I, telophase I, and—within a few minutes—prophase II and metaphase II). Then meiosis stops again. A few hours after metaphase I is reached, ovulation is induced by luteinizing hormone. Fertilization occurs in the fallopian tube, and then the second meiotic division is complete. Nuclear membranes are formed around the maternal and paternal chromosomes. After some hours, the two “pronuclei” fuse and the first cleavage division begins. (From Bresch C, Haussmann R: *Klassische und Molekulare Genetik*, 3rd ed. Berlin, Springer-Verlag, 1972.)

Preparation of Human Metaphase Chromosomes

Metaphase chromosomes can be prepared from any cell undergoing mitosis. Clinical and research cytogenetic laboratories routinely perform chromosome analysis on cells derived from peripheral blood, bone marrow, amniotic fluid, skin, or other tissues in situ and in tissue culture. For clinical cytogenetic diagnosis in living nonleukemic individuals, it is easiest to obtain metaphase cells from peripheral blood samples. To obtain adequate numbers of metaphase cells from peripheral blood, mitosis must be induced artificially, and in most procedures, *phytohemagglutinin*, a mitogen, is used for this purpose.

Specifically, T-cell lymphocytes are induced to undergo mitosis; thus, almost all chromosome analyses of human peripheral blood samples produce karyotypes of T lymphocytes. In general descriptive terms, a suspension of peripheral blood cells is incubated at 37°C in tissue culture media with mitogen for 72 hours to produce an actively dividing population of cells. The cells are then incubated for 1 to 3 hours in a dilute solution of a mitotic spindle poison such as colchicine to stop the cells in metaphase when chromosomes are condensed. Next, the nuclei containing the chromosomes are made fragile by swelling in a short treatment (10 to 30 minutes) in a hypotonic salt solution. The chromosomes are fixed in a mixture of alcohol

and acetic acid and then gently spread on a glass slide for drying and staining.

Most cytogenetic laboratories use one or more staining procedures that stain each chromosome with variable intensity at specific regions, thereby providing “bands” along the chromosome; hence, the term *banding patterns* is used to identify chromosomes. All procedures are effective and provide different types of morphologic information about individual chromosomes. For convenience in descriptive terminology, various banding patterns have been named for the methods by which they were revealed. Some of the more commonly used methods are as follows:

1. *G bands* are revealed by Giemsa staining in association with various other secondary steps. This is probably the most widely used banding technique.
2. Quinacrine mustard and similar fluorochromes provide fluorescent staining for *Q bands*. The banding patterns are identical to those in G bands, but a fluorescence microscope is required. Q banding is particularly useful for identifying the Y chromosomes in both metaphase and interphase cells.
3. *R bands* are the result of “reverse” banding. They are produced by controlled denaturation, usually with heat. The pattern in R banding is opposite to that in G and Q banding; light bands produced on G and Q banding are dark on R banding, and dark bands on G and Q banding are light on R banding.
4. *T bands* are the result of specific staining of the telomeric regions of the chromosome.
5. *C bands* reflect constitutive heterochromatin and are located primarily on the pericentric regions of the chromosome.

Modifications and new procedures of band staining are constantly being developed. For example, a silver stain can be used to identify specifically the nucleolus organizer regions that were functionally active during the previous interphase. Other techniques enhance underlying chromosome instability and are useful in identifying certain aberrations associated with malignancies. Recent modifications of the basic culture-staining procedures have resulted in more elongated chromosomes, prophase-like in appearance, with more readily identifiable banding patterns.

Figure 1-11 depicts an ideogram of G banding in two normal chromosomes. Starting from the centromeric region, each chromosome is organized into two regions: the p region (*short arm*) and the q region (*long arm*). Within each region, the area is further subdivided numerically. These numerical band designations greatly facilitate the descriptive identification of specific chromosomes. A complete male karyogram is depicted in Figure 1-12. A female karyogram would have two X chromosomes.

Molecular Cytogenetics: Fluorescence In Situ Hybridization and Multicolor Karyotyping

Besides routine karyotyping methods, more specific and sophisticated techniques have been developed that make use of fluorescence techniques and specific DNA sequences isolated by molecular biologic techniques. These techniques allow the evaluation of a chromosomal preparation for gain or loss of specific genes or chromosome regions and for the presence of translocations. In fluorescence in situ hybridization (FISH), DNA probes representing specific genes, chromosomal regions, and even whole chromosomes can be labeled with fluorescently tagged nucleotides. After hybridization to metaphase or interphase preparations of chromosomes (or both), these probes will specifically bind to the gene, region, or chromosome of interest (Fig.

FIGURE 1-11 An ideogram of two representative chromosomes. Chromosome 8 and chromosome 15 represent arbitrary examples of schematic high-resolution mid-metaphase Giemsa banding. At the level of resolution demonstrated in this figure, a haploid set of 23 chromosomes has a combined total of approximately 550 bands. Light red areas represent the centromere, and the blue and white areas represent regions of variable size and staining intensity. The green area at the end of chromosome 15 is satellite DNA. A detailed ideogram of the entire human haploid set of chromosomes was published by the Standing Committee on Human Cytogenetic Nomenclature. (ISCN: Report of the Standing Committee on Human Cytogenetic Nomenclature. Basel, Karger, 1995.)

1-13). This technique facilitates the detection of fine details of chromosome structure. For example, any single-copy gene is normally present in two copies in a diploid cell, one copy on each homologous chromosome. If one of the genes is missing in certain disease states, then only one copy will be detected by FISH with a probe specific for that gene. If the gene is present in numerous copies, as often occurs with certain oncogenes in tumors, multiple copies will be detected.

Similarly, entire chromosomes can be isolated by flow cytometry and probes prepared by labeling the entire chromosomal DNA complement (called a *chromosome paint probe*). When hybridized under appropriate conditions to metaphase or interphase preparations of chromosomes (or both), these probes will specifically detect the chromosome of interest. A translocation that occurs between two chromosomes can be easily detected with a chromosomal paint probe to one

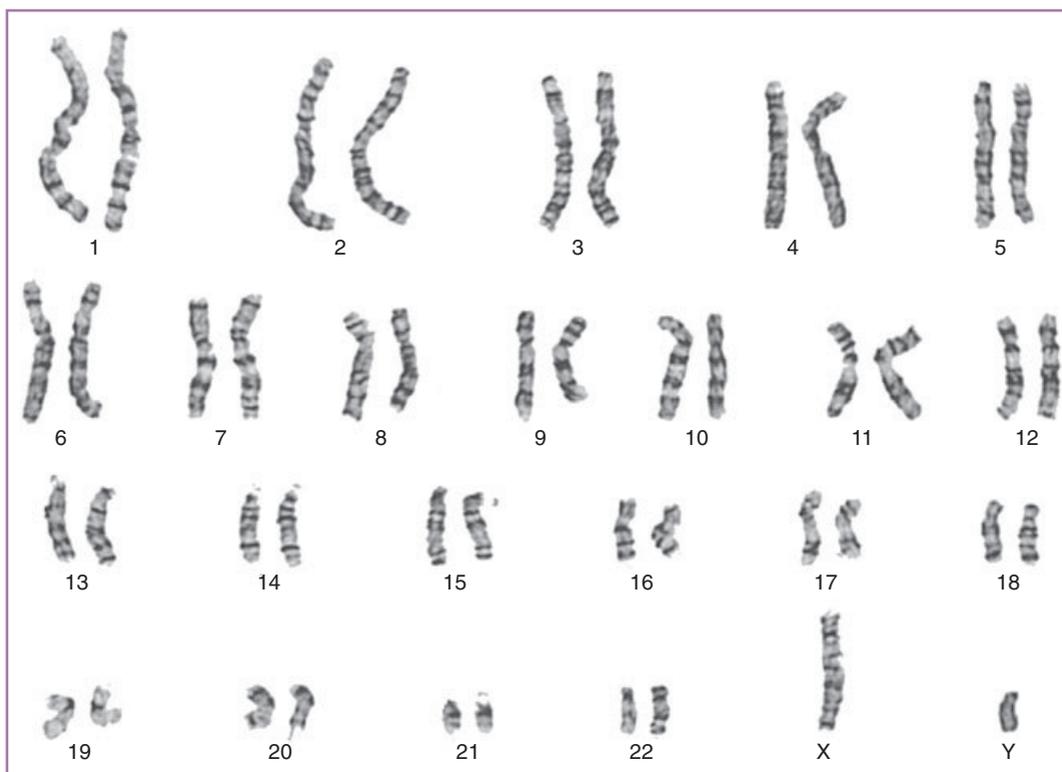

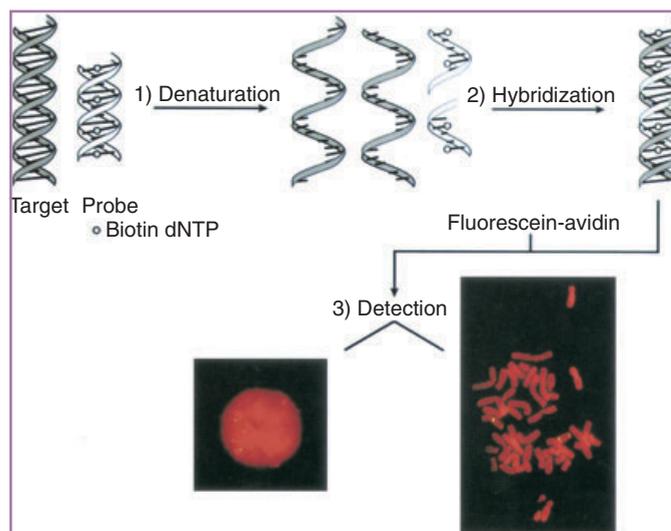

FIGURE 1-12 A standard G-banded karyogram. There is a total of approximately 550 bands in one haploid set of chromosomes in this karyogram. The sex karyotype is XY (male). A female karyogram would show two X chromosomes.

FIGURE 1-13 A schematic representation of fluorescence in situ hybridization. The DNA target (chromosome) and a short DNA fragment “probe” containing a nucleotide (e.g., deoxyribonucleotide triphosphate [dNTP]) labeled with biotin are denatured. The probe is specific for a chromosomal region containing the gene or genes of interest. During renaturation, some of the DNA molecules containing the region of interest hybridize with complementary nucleotide sequences in the probe, and with subsequent binding to a fluorochrome marker (fluorescein-avidin) a signal (*yellow-green*) is produced. The two lower panels demonstrate a metaphase cell and an interphase cell. The probe used is specific for chromosome 7. A control probe for band q36 on the long arm establishes the presence of two number 7 chromosomes. The second probe is specific for the Williams syndrome region at band 7q11.23. This signal is more intense and demonstrates no deletion at region 7q11.23 and essentially excludes the diagnosis of Williams syndrome. The signals are easily visible in both the metaphase and interphase cells.

of the translocation partners. Normally, this probe would identify two diploid chromosomes, and the entire length of each chromosome will be fluorescent. In contrast, the paint probe will identify a normal completely labeled chromosome and two new incompletely labeled chromosomes, representing the translocated fragments.

Recently, an extension of this methodology has been developed that is useful for the fluorescent detection and analysis of all chromosomes simultaneously. One such method is called *spectral karyotyping* (Fig. 1-14). A large number of fluorescent tags are available that can be used individually or in combination to prepare labeled chromosomes. It is

possible to individually label each chromosome with unique combinations of these tags so that each one will emit a unique fluorescent signal when hybridized to chromosomal preparations. If all uniquely labeled chromosomal paint probes are mixed and hybridized to metaphase preparations simultaneously, each chromosome will emit a unique wavelength of light. These different wavelengths can be detected by a microscope-mounted spectrophotometer linked to a high-resolution camera. Sophisticated image analysis programs can then distinguish individual chromosomes, and a metaphase spread will appear as a multicolored array (see Fig. 1-14). With knowledge of the expected

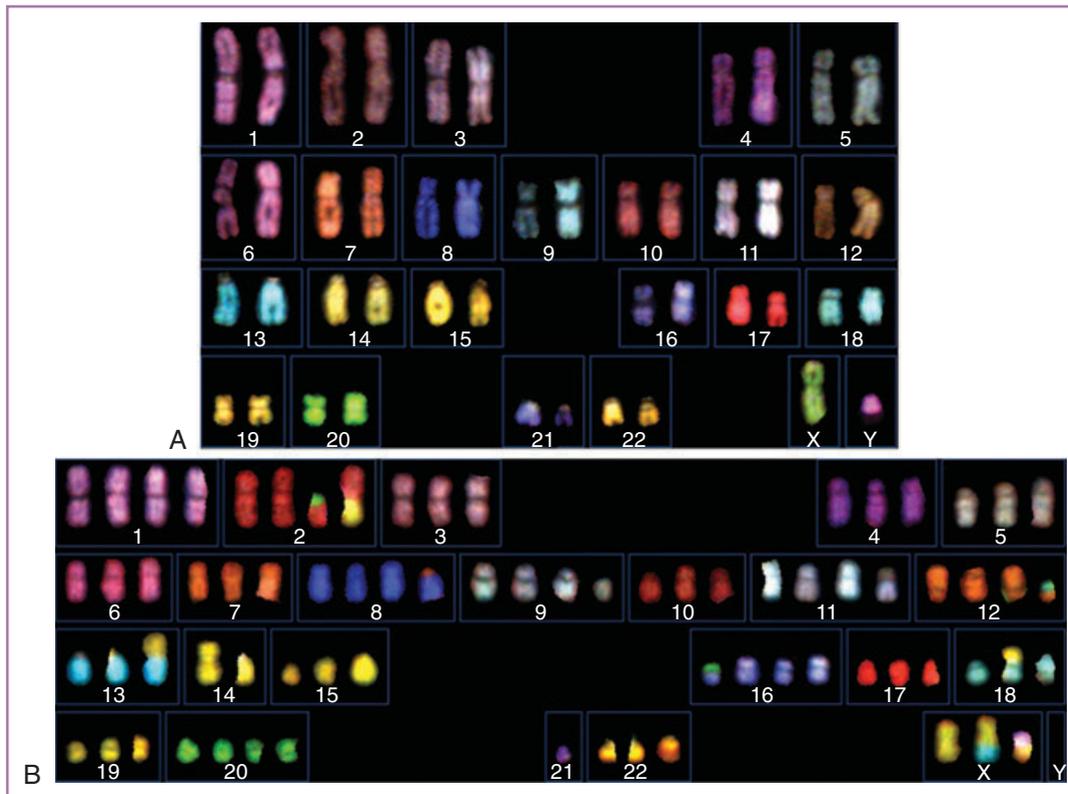

FIGURE 1-14 Spectral karyotyping (SKY). **A**, A normal human karyotype after SKY analysis, showing the presence of two copies of each chromosome, each pair with a different color. In addition, the X and Y chromosomes are different colors. **B**, SKY analysis of a tumor cell line, displaying extra copies of nearly all chromosomes, as well as translocations. These can be appreciated as chromosomes consisting of two colors. (Photos courtesy of Dr. Karen Arden, Ludwig Cancer Institute, UCSD School of Medicine.)

emission from each chromosome, the signal from each chromosome can be specifically identified, and the entire metaphase can be displayed as a karyogram. This method is particularly useful for the identification of translocations between chromosomes.

Copy Number Variation and High-Resolution Comparative Genomic Hybridization

Once the human genome was sequenced, producing an “average” human genome, the next phase of analysis was to find genome variations in individuals and in populations. One of the most remarkable findings was that individuals differ in the number of copies they have of pieces of DNA scattered throughout their genome.⁵ Copy number variation (CNV) is the most prevalent type of structural variation in the human genome, and it contributes significantly to genetic heterogeneity. CNVs can be detected by whole-genome-array technologies, often referred to as *high-resolution comparative genomic hybridization* (hCGH), and careful measurement of intensities of hybridization to these arrays can provide a measure of regional duplication and deletion. Some of these CNVs are common in populations, but the extent of common CNVs has been difficult to estimate. Several array platforms were used in the early studies, making it difficult to compare one study with another. Also, more population studies and reference databases for control populations and populations with certain diseases are needed to determine the association between CNV frequency and disease. Some CNVs can contribute to human phenotype, including rare genomic disorders and mendelian diseases. Other CNVs are likely to be found to influence human phenotypic diversity

and disease susceptibility. This is an active area of research that will very likely lead to findings with clinical importance in the near future.

Characteristics of the More Common Chromosome Aberrations in Humans

Abnormalities in Chromosome Number

Alteration of the number of chromosomes is called *heteroploidy*. A heteroploid individual is *euploid* if the number of chromosomes is a multiple of the haploid number of 23, and *aneuploid* if there is any other number of chromosomes. Abnormalities of single chromosomes are usually caused by nondisjunction or anaphase lag, whereas whole-genome abnormalities are referred to as *polyploidization*.

ANEUPLOIDY

Aneuploidy is the most frequently seen chromosome abnormality in clinical cytogenetics, occurring in 3% to 4% of clinically recognized pregnancies. Aneuploidy occurs during both meiosis and mitosis. The most significant cause of aneuploidy is *nondisjunction*, which may occur in both mitosis and meiosis but is observed more frequently in meiosis. One pair of chromosomes fails to separate (disjoin) and is transferred in anaphase to one pole. Meiotic nondisjunction can occur in meiosis I or II. The result is that one product will have both members of the pair and one will have neither of that pair (Fig. 1-15). After fertilization, the embryo will either contain an extra third chro-

Please refer to the printed publication.

FIGURE 1-15 Nondisjunction of the X chromosome in the first and second meiotic divisions in a female. Fertilization is by a Y-bearing sperm. An XXY genotype and phenotype can result from both first and second meiotic division nondisjunction. (From Vogel F, Motulsky AG: Human Genetics: Problems and Approaches. New York, Springer-Verlag, 1979.)

mosome (trisomy) or have only one of the normal chromosome pair (monosomy).

Anaphase lag is another event that can lead to abnormalities in chromosome number. In this process, one chromosome of a pair does not move as rapidly during the anaphase process as its sister chromosome and is lost. Often this loss leads to a mosaic cell population, one euploid and one monosomic (e.g., 45,XO/46,XX mosaicism).

POLYPLOIDY

In affected fetuses that are polyploid, the whole genome is present more than once in every cell. When the increase is by a factor of one for each cell, the result is *triploidy*, with 69 chromosomes per cell. Triploidy is most often caused by fertilization of a single egg with two sperm, but rarely it results from the duplication of chromosomes during meiosis without division.

Alterations of Chromosome Structure

Structural alterations in chromosomes constitute the other major group of cytogenetic abnormalities. Such defects are seen less frequently in newborns than numerical defects and occur in about 0.0025% of newborns. However, chromosome rearrangements are a common occurrence in malignancies. Structural rearrangements are balanced if there is no net loss or gain of chromosomal material, or unbalanced if there is an abnormal genetic complement.

DELETIONS AND DUPLICATIONS

Deletions refer to the loss of a chromosome segment. Deletions may occur on the terminal segment of the short or long arm. Alternatively, an interstitial deletion may occur anywhere on the chromosome.

Deletions can result from chromosomal breakage and when loss of the deleted fragment lacks a centromere (Fig. 1-16), or from unequal crossover between homologous chromosomes. One of the chromosomes carries a deletion, whereas the other reciprocal event is a duplication. A *ring chromosome* results from terminal deletions on both the short and long arms of the same chromosome (Fig. 1-17).

Autosomal Deletion and Duplication Syndromes

Autosomal deletions and duplications are often associated with clinically evident birth defects or milder dysmorphisms. Often the chromosomal defect is unique to that individual, and it is difficult to provide prognostic information to the family. In a few cases, a number of patients with similar phenotypic abnormalities were found to display similar cytogenetic defects. Some of these are cytogenetically detectable, whereas others are smaller and require molecular cytogenetic techniques. These are termed microdeletion and microduplication syndromes and merely reflect the size of the deletion or duplication. Table 1-2 summarizes some of the deletion and duplication syndromes that have been described and for which commercial FISH probes are available.

INSERTIONS

In the process of insertion, an interstitial deleted segment is inserted into a nonhomologous chromosome (Fig. 1-18).

INVERSIONS

Inversions more often involve the centromere (*pericentric*) rather than noncentromeric areas (*paracentric*). Figure 1-19 is a diagram-

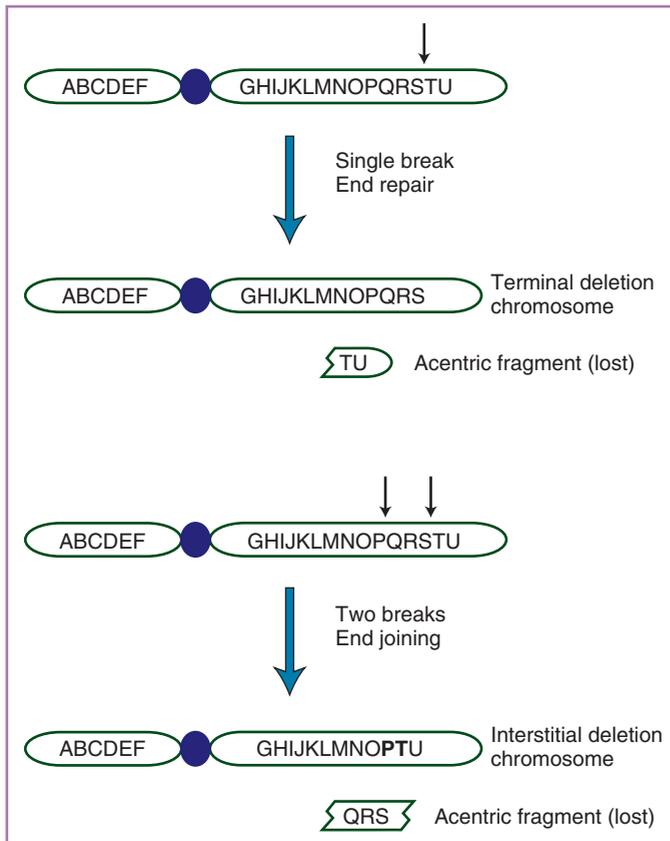

FIGURE 1-16 Schematic representation of two kinds of deletion events. A single double-strand break (*small black arrow*) may produce a terminal deletion if the end is repaired to retain telomere function. The telomeric fragment lacks a centromere (indicated by the *filled oval* in the intact chromosome) and will generally be lost in the next cell division. A chromosome with two double-strand breaks (*pair of black arrows*) may suffer an interstitial deletion if the break is repaired by end joining of the centromeric and telomeric fragments.

matic representation of a pericentric inversion. Inversions reduce pairing between homologous chromosomes, and crossing over may be suppressed within inverted heterozygote chromosomes. For homologous chromosomes to pair, one must form a loop in the region of the inversion (Fig. 1-20). If the inversion is pericentric, the centromere lies within the loop. When crossing over occurs, each of the two chromatids within the crossover has both a duplication and a deletion. If gametes are formed with the abnormal chromosomes, the fetus will be monosomic for one portion of the chromosome and trisomic for another portion. One result of abnormal chromosome recombinants might be increased fetal demise from duplication or deficiency of a chromosomal region.

When pericentric inversion occurs as a new mutation, usually the result is a phenotypically normal individual. However, when a carrier of a pericentric inversion reproduces, the pairing events just described may occur. If fertilization involves the abnormal gametes, there is a risk for abnormal progeny. When pericentric inversion is observed in a phenotypically abnormal child, parental karyotyping is indicated.

An exception to this rule involves a pericentric inversion in chromosome 9, the most common inversion noted in humans. The frequency of this inversion has been observed to be approximately 5% in 14,000 amniotic fluid cultures. In the 30 or so instances in which

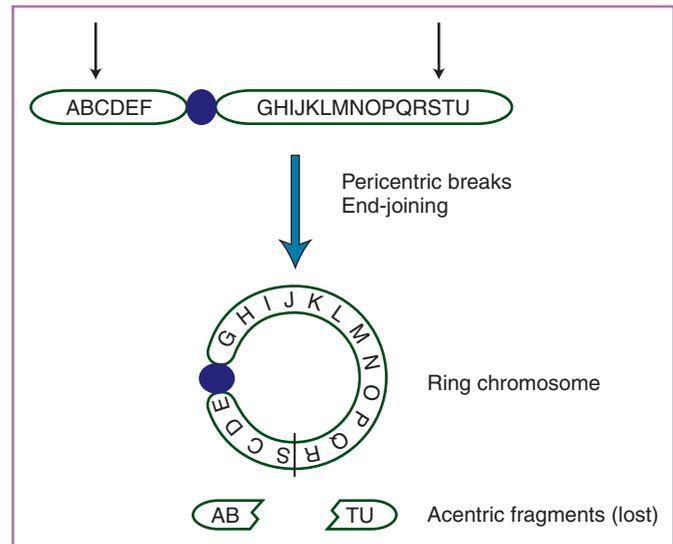

FIGURE 1-17 Ring chromosome formation. A chromosome with a double-strand break on each side of its centromere (*filled oval*) can result in terminal deletions (see Fig. 1-16), pericentric inversion, or formation of a ring chromosome by joining the two centromeric ends from the breaks. In the case of ring chromosome formation, the acentric fragments would be lost in the next cell division.

TABLE 1-2 DIAGNOSIS OF MICRODELETION SYNDROMES

Syndrome	Chromosome Band	Chromosome Defect
Alagille	20p12.1-p11.23	Deletion
Angelman	15q11-q13	Deletion (maternal genes)
Cri du chat	5p15.2-p15.3	Deletion
DiGeorge*	22q11.21-q11.23	Deletion
Miller-Dieker	17p13.3	Deletion
Prader-Willi	15q11-q13	Deletion (paternal genes)
Rubenstein-Taybi	16p13.3	Deletion
Smith-Magenis	17p11.2	Deletion
WAGR	11p13	Deletion
Williams	7q11.23	Deletion
Wolf-Hirschhorn	4p16.3	Deletion

*Patients with velocardiofacial (Shprintzen [catch 22] syndrome) also have deletions at 22q11.21-q11.23.

WAGR, Wilms tumor, aniridia, genital anomalies, growth retardation.

parental karyotyping was performed, invariably one or the other parent carried a pericentric inversion on one number 9 chromosome. One explanation for the apparently benign status of pericentric inversion in this chromosome is that the pericentric region on chromosome 9 contains many highly repetitive or genetically silent regions in the nucleotide sequence, so that inversion in this region is of no clinical consequence. Another explanation could be that inversions involving relatively short DNA sequences may not be involved in crossing over.

TRANSLOCATIONS

A translocation is the most common form of chromosome structural rearrangement in humans. There are two types: *reciprocal* (Fig. 1-21) and *robertsonian* (Fig. 1-22).

Reciprocal Translocation. If a reciprocal translocation is balanced, phenotypic abnormalities are uncommon. Unbalanced trans-

locations result in miscarriage, stillbirth, or live birth with multiple malformations, developmental delay, and mental retardation. Reciprocal translocations nearly always involve nonhomologous chromosomes among any of the 23 chromosome pairs, including chromosomes X and Y.

Gametogenesis in heterozygous carriers of translocations is especially significant because of the increased risk for chromosome segregation that produces gametes with unbalanced chromosomes in the diploid set (see Fig. 1-21). In a reciprocal translocation, there will be four chromosomes with segments in common (see Fig. 1-21). During meiosis, homologous segments must match for crossing over, so that in a translocation set of four, a *quadrivalent* is formed. During meiosis I, the four chromosomes may segregate randomly in two daughter cells with several results.

In 2:2 alternate segregation (see Fig. 1-21), one centromere segregates to one daughter cell and the next centromere segregates to the other daughter cell. This is the only mode that leads to a normal or balanced normal karyotype. Adjacent segregation and 3:1 nondisjunction segregation all produce unbalanced gametes.

If a gamete is chromosomally unbalanced, the odds are increased for spontaneous abortion. In familial translocations, the risk of unbal-

anced progeny seems to depend on the method of ascertainment. For example, if a familial reciprocal translocation is ascertained by a chromosomally unbalanced live birth or stillbirth, the risk for subsequent chromosomally unbalanced children is approximately 15% and the risk for spontaneous abortion or stillbirth is approximately 25%. In contrast, if the ascertainment is unbiased, risk for chromosomally unbalanced live birth is 1% to 2%, but the risk for miscarriage or stillbirth remains at 25%.

There appears to be a parental sex influence on the risk for chromosomally unbalanced progeny associated with certain types of segregants. In general, the risk for unbalanced progeny is higher if the female parent carries the translocation than it is with the paternal carrier. In addition, a viable conceptus is influenced by the type of configuration produced during meiosis by the translocated chromosomes. In general, larger translocated fragments and more asymmetrical pairing are associated with a greater likelihood for abnormal outcome of pregnancy.

Robertsonian Translocation. Robertsonian translocations involve only the *acrocentric* chromosome pairs 13, 14, 15, 21, and 22. They are joined end to end at the centromere and may be homologous (e.g., t21;21) or nonhomologous (e.g., t13;14). Robertsonian translocation is named for an insect cytogeneticist, W. R. B. Robertson, who in 1916 was the first to describe a translocation involving two acrocentric chromosomes. The robertsonian translocation is unique because the fusion of two acrocentric chromosomes usually involves the centromere (see Fig. 1-22) or regions close to the centromere. However, reciprocal translocations may also include acrocentric chromosomes.

Robertsonian translocations are nearly always nonhomologous. Most homologous robertsonian translocations produce nonviable conceptuses. For example, translocation 14;14 would result in either trisomy 14 or monosomy 14, and both are nonviable.

The most common nonhomologous robertsonian translocation in humans is 13;14. Approximately 80% of all nonhomologous robertsonian translocations involve chromosomes 13, 14, and 15. The next most common are translocations involving one chromosome from pairs 13, 14, and 15 and one chromosome from pairs 21 and 22.

Figure 1-23 illustrates gametogenesis in a nonhomologous 14;21 robertsonian translocation carrier and also represents the model for segregation during gametogenesis with any robertsonian translocation. Translocation carriers theoretically produce six types of gametes in equal proportions. Monosomic gametes are generally nonviable, as are many trisomies (e.g., trisomy 14 or 15). As illustrated, three gametes may result in viable conceptuses and one (B_1) may produce a liveborn abnormal infant.

Robertsonian translocation 14;21 is the most medically significant in terms of incidence and genetic risk. In contrast, the most

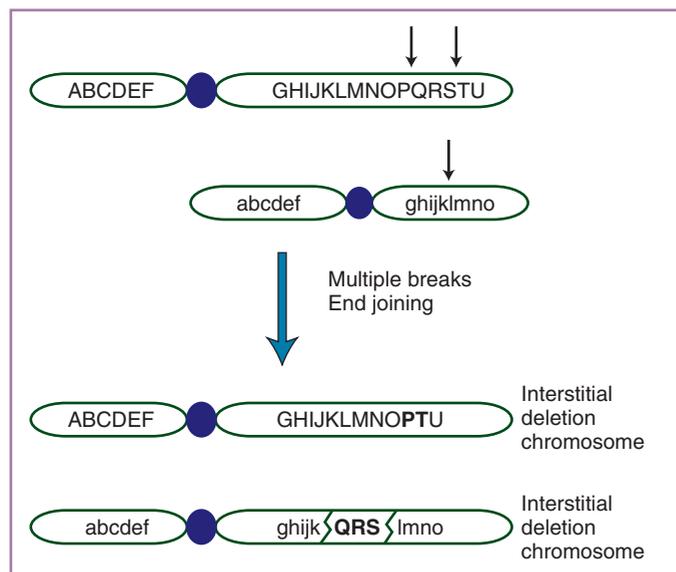

FIGURE 1-18 Interstitial translocations. Interstitial translocations can result from repair by end joining of fragments from nonhomologous chromosomes. In the example illustrated, a fragment QRS is liberated from one chromosome and inserted at a break between k and l in the recipient chromosome.

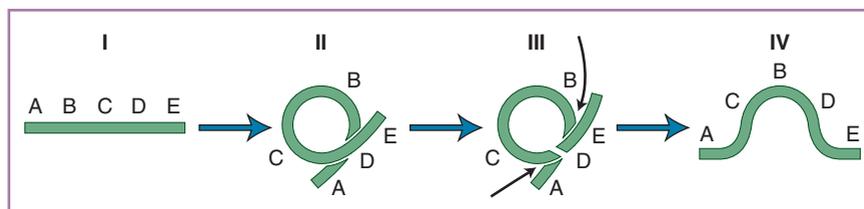

FIGURE 1-19 An example of a possible mechanism for development of a pericentric inversion. **I**, Normal sequence of coded information on the chromosome. **II**, Formation of a loop involving a chromosome region. **III**, Breakage and reunion at the *arrows*, where the chromosome loop intersects itself. **IV**, Formation of the inverted information sequence after reunion.

FIGURE 1-20 Inversions. Crossing over within the inversion loop of an inversion heterozygote results in aberrant chromatids with duplications or deficiencies. (From Srb AM, Owen RD, Edgar RS: General Genetics, 2nd ed. San Francisco, WH Freeman, 1965.)

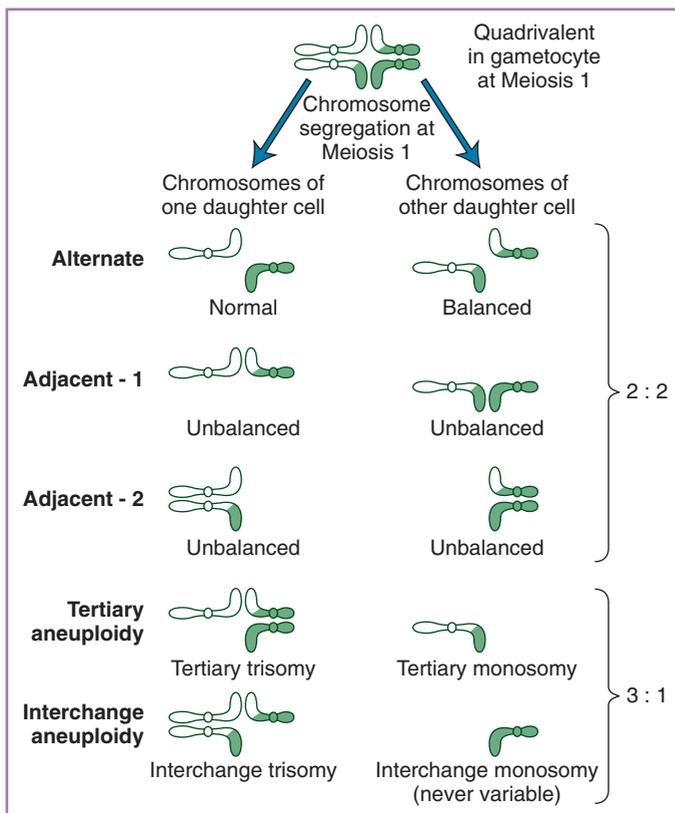

FIGURE 1-21 Chromosome segregation during meiosis in a reciprocal translocation heterozygote. (Modified from Gardner RJM, Sutherland GR: Chromosome Abnormalities and Genetic Counseling. New York, Oxford University Press, 1989.)

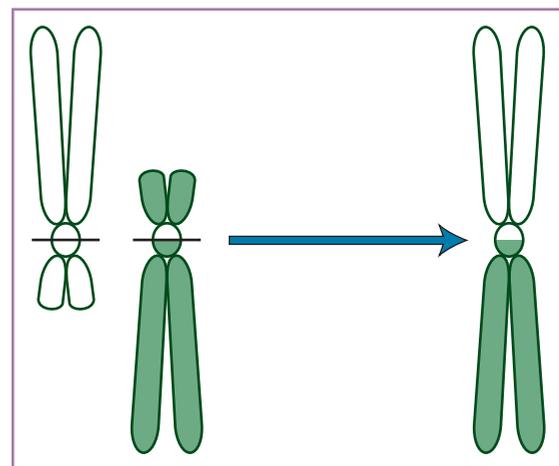

FIGURE 1-22 Formation of a centric fusion (monocentric) robertsonian translocation. Robertsonian translocations involve only the acrocentric chromosomes.

frequent robertsonian translocation, 13;14, rarely produces chromosomally unbalanced progeny. Nonetheless, genetic counseling and at least consideration of prenatal diagnosis is recommended for all families with a robertsonian or reciprocal chromosome translocation.

ISOCHROMOSOMES

An isochromosome is a structural rearrangement in which one arm of a chromosome is lost and the other arm is duplicated. The resulting chromosome is a mirror image of itself. Isochromosomes often involve the long arm of the X chromosome.

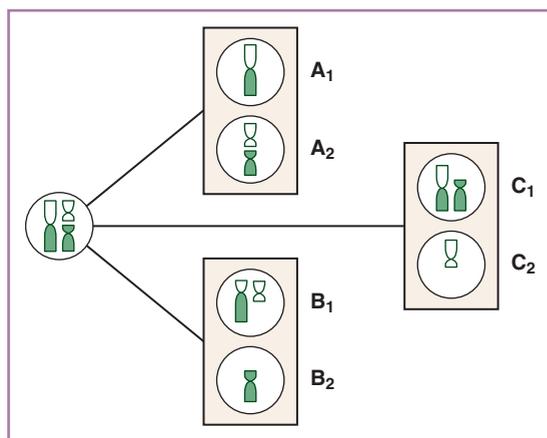

FIGURE 1-23 Gametogenesis for robertsonian translocation. A_1 is balanced with 22 chromosomes, including $t(14q21q)$. A_2 is normal with 22 chromosomes. B_1 is abnormal with 23 chromosomes, including $t(14q21q)$ and 21. This gamete would produce an infant with Down syndrome. B_2 is abnormal with 22 chromosomes and monosomy for chromosome 21. C_1 is abnormal with 23 chromosomes, including $t(14q21q)$ and 14. C_2 is abnormal with 22 chromosomes and no chromosome 14.

Clinical and Biologic Considerations of the Sex Chromosomes

The X and Y chromosomes merit separate discussions. They have distinct patterns of inheritance and are structurally different. However, they pair in male meiosis because of the presence of the pseudoautosomal region at the ends of the short arms of the X and Y chromosomes. The pseudoautosomal region is the only region of homology between the X and Y chromosomes, and both pairing and recombination occur in this region.

The primitive gonad is undifferentiated, and phenotypic sex in humans is determined by the presence or absence of the Y chromosome. This is the case for two reasons. First, in the absence of the Y chromosome, the primitive gonad will differentiate into an ovary, and female genitalia will form. Thus, the female sex is the default sex. Second, the *SRY* gene, present on the Y chromosome, is necessary and sufficient for testis formation and for male external genitalia.

The X chromosome is present in two copies in females but only one copy in males. To equalize dosage (copy number) differences in critical genes on the X chromosomes between the two sexes, one of the X chromosomes is randomly inactivated in somatic cells of the female.¹¹ In addition, in cells with more than two X chromosomes, all but one of them are inactivated. This ensures that in any diploid cell, regardless of sex, only a single active X chromosome is present. X inactivation results in the complete inactivation of about 90% of the genes on the X chromosome. This is noteworthy because 10% of genes on the X chromosome escape *X inactivation*. Many of these are clustered on the short arm of X, so aneuploidies involving this region may have greater clinical significance than those on the long arm. X chromosome inactivation occurs because of the presence of an X inactivation center on Xq13 that contains a gene called *XIST* that is expressed on the allele of the inactive X chromosome. At the moment, the mechanism of action of *XIST* in X chromosome inactivation is unclear.

Although X inactivation is random in normal somatic cells, structural abnormalities of the X chromosome often result in nonrandom X inactivation. In general, when a structural abnormality involves only

one X chromosome (i.e., deletion, isochromosome, ring chromosome), the abnormal X chromosome always appears to be the one inactivated.¹⁰ If the structural abnormality is a translocation between part of one X chromosome and an autosome, the “normal” X seems to be the one genetically inactive. Although this pattern is not proven, it is assumed that if the X chromosome translocated to an autosome is genetically inactivated, part or all of that autosome might also become inactive, rendering that cell functionally monosomic for the autosome and thus nonviable. This phenomenon helps to explain why some females heterozygous for X-linked recessive biochemical disorders, such as Duchenne muscular dystrophy, have phenotypic expression of that disorder. In this instance, if the mutant X chromosome is the one involved in the X autosome translocation and the normal allele is inactive by virtue of being on the normal inactive X chromosome, it is likely that the female will express the disease.

Abnormalities of the sex chromosomes or genes on the sex chromosomes may affect any of the stages of sexual and reproductive development. Although an increased number of either the X or the Y chromosome enhances the likelihood of mental retardation and other anatomic anomalies, irrespective of the sex phenotype, aneuploidy of the sex chromosome does not alter prenatal fetal development nearly as much as aneuploidy of an autosome. Of note, many mutations or deletions in the X chromosome do result in X-linked mental retardation. Numeric and structural sex chromosome aneuploidies are summarized in Table 1-3, and we briefly describe only a few of the more common sex chromosome aberrations.

Turner Syndrome

Although Turner syndrome occurs in approximately 1 per 10,000 live-born females, it is one of the chromosome abnormalities most commonly observed in studies of spontaneous abortuses. It is unknown why the same chromosomal defect usually results in spontaneous fetal loss but is also compatible with survival. It is often detected prenatally through ascertainment of a cystic hygroma by fetal ultrasound examination during the first or second trimester. Although there is wide variability in the phenotypic expression of Turner syndrome, it is one sex chromosome abnormality that should be identifiable by physical examination of the newborn.

Turner syndrome is associated with a 45,XO karyotype. Sex chromosome mosaics (such as 46,XX/45,XO) and structurally abnormal karyotypes (such as 46,X/delX and 46,X/isoX) are all phenotypic females like those with 45,XO Turner syndrome, but they have fewer of the typical manifestations associated with the 45,XO phenotype. The paternally derived X chromosome is more often missing in the 45,XO karyotype.

Some of the common features of the 45,XO phenotype and the frequencies with which they are seen are listed in Table 1-4. Mental retardation is not normally seen in this syndrome unless a small ring X chromosome is present. Although there is inadequate information at present to permit assessment of longevity and cause of death in adult life, the general health prognosis is good for childhood and young adult life with this phenotype. Renal anomalies, when present, rarely cause significant health problems, and when congenital heart disease is part of the phenotype, surgery is generally effective. The congenital lymphedema usually disappears during infancy, and when webbing of the neck poses a cosmetic problem, it can be corrected by plastic surgery. Short stature is a persistent problem. If a diagnosis is achieved early, height increase and external sexual development may be achieved with the collaboration of a knowledgeable endocrinologist. In particular, growth hormone therapy is standard and results in significant increases in adult height. Affected patients are nearly always sterile, and the

From Vogel F, Motulsky AG: *Human Genetics: Problems and Approaches*. New York, Springer-Verlag, 1979.

TABLE 1-4 45,XO PHENOTYPE: MAJOR FEATURES AND THEIR INCIDENCE

Feature	Incidence (%)
Small stature, often noted at birth	100
Ovarian dysgenesis with variable degree of hypoplasia of germinal elements	90+
Transient congenital lymphedema, especially notable over the dorsum of the hands and feet	80+
Shieldlike, broad chest with widely spaced, inverted, and/or hypoplastic nipples	80+
Prominent auricles	80+
Low posterior hairline, giving the appearance of a short neck	80+
Webbing of posterior neck	50
Anomalies of elbow, including cubitus valgus	70
Short metacarpal and/or metatarsal	50
Narrow, hyperconvex, and/or deepset nails	70
Renal anomalies	60+
Cardiac anomalies (coarctation of the aorta in 70% of cases)	20+
Perceptive hearing loss	50

emotional adjustment to this issue should be part of any medical management of gonadal dysgenesis.

When the diagnosis of 45,XO karyotype or a variant is missed during infancy or childhood, a complaint of persisting short stature or amenorrhea finally brings the patient to the physician. Often this delay precludes any specific therapy for the short stature. In rare variants of Turner syndrome, some cells may carry a Y chromosome, suggesting that such an individual was initially an X,Y male but the Y chromosome was lost. Occasionally, the Y chromosome line is found only in the germ cells, and the clinical manifestation in the individual may be virilization during adolescence or an unexplained growth spurt. In these cases, it is imperative to perform a gonadal biopsy for histologic and chromosome analysis. If a Y chromosome cell line is demonstrated in gonadal tissue, extirpation is indicated to prevent subsequent malignant transformation in gonadal cells.

Klinefelter Syndrome

Klinefelter syndrome, which occurs in approximately 1 per 700 to 1000 liveborn males, is associated with a 47,XXY karyotype. Major physical features of Klinefelter syndrome are as follows:

1. Relatively tall and slim body type, with relatively long limbs (especially the legs) is seen beginning in childhood.
2. Hypogonadism is seen at puberty, with small, soft testes and usually a small penis. Infertility is the rule. Gynecomastia is frequent, and cryptorchidism or hypospadias may be seen. Lack of virilization at puberty is common; indeed, it is often the reason for the patient to seek medical attention.
3. There is a tendency toward lower verbal comprehension and poorer performance on intelligence quotient tests, with learning disabilities a common feature. There is a higher incidence of behavioral and social problems, often requiring professional help.

There are several karyotypic variants of Klinefelter syndrome with more than two X chromosomes (such as the karyotype 48,XXXY). As the number of X chromosomes increases, there is a corresponding increase in the severity of the phenotype, with a greater incidence of mental retardation and with more physical abnormalities than in the typical syndrome. Approximately 15% of individuals with some of the Klinefelter phenotype have 47,XXY/46,XY mosaicism. Such mosaic individuals have more variable phenotypes and have a somewhat better prognosis for testicular function. In general, chromosome aneuploidies that include the Y chromosome are less likely to be diagnosed clinically during infancy or childhood. In fact, individuals are often first diagnosed during evaluation for infertility.

Prevalence of Chromosome Disorders in Humans

Identifiable abnormalities in the human karyotype occur more frequently than mutations, leading to mendelian hereditary disease. Table 1-5 summarizes studies on the incidence of sex chromosome and autosomal chromosomal abnormalities.⁹

TABLE 1-5 INCIDENCE OF CHROMOSOMAL ABNORMALITIES IN SURVEYS OF NEWBORNS

Rights were not granted to include this table in electronic media. Please refer to the printed publication.

From Hsu LYF: Prenatal diagnosis of chromosomal abnormalities through amniocentesis. In Milunsky A (ed): *Genetic Disorders and the Fetus*, 4th ed. Baltimore, Johns Hopkins University Press, 1998, p 179.

The most common autosomal numerical disorders in liveborn humans are trisomy 21, trisomy 18, and trisomy 13. Numerous studies have shown that trisomy 21 is the most common aneuploidy among liveborn humans. On the other hand, balanced reciprocal translocations occur almost as frequently. Trisomy 13 occurs at a much lower frequency than trisomy 18 or trisomy 21, possibly because of increased fetal demise with this mutation.⁹ Among sex chromosomes, aneuploidies 45,X, 47,XYY, and 47,XXY are seen in liveborn infants.

It is noteworthy that the incidence of common chromosome abnormalities such as trisomy 21 is nearly 10 times greater than the incidence of genetic diseases such as achondroplasia, hemophilia A, and Duchenne muscular dystrophy. The cumulative data on chromosome abnormalities reveal an unanticipated finding. Chromosome analysis in newborns from several worldwide population samples shows the overall incidence of chromosome abnormalities to be 0.5% to 0.6%. In a large study series of nearly 55,000 infants, more than two thirds had no significant physical abnormality in association with these chromosomal defects, and of the one third with significant phenotype abnormalities, nearly 66% had trisomy 21.⁹

Chromosome Abnormalities in Abortuses and Stillbirths

About 15% of pregnancies terminate in spontaneous abortions, and at least 80% of those do so in the first trimester. The incidence of chro-

TABLE 1-6 FREQUENCY OF CHROMOSOME ABNORMALITIES IN SPONTANEOUS ABORTIONS WITH ABNORMAL KARYOTYPES

Type	Approximate Proportion of Abnormal Karyotypes
Aneuploidy	
Autosomal trisomy	0.52
Autosomal monosomy	<0.01
45,X	0.19
Triploidy	0.16
Tetraploidy	0.06
Other	0.07

Based on analysis of 8841 unselected spontaneous abortions, as summarized by Hsu LYF: Prenatal diagnosis of chromosomal abnormalities through amniocentesis. In Milunsky A (ed): *Genetic Disorders and the Fetus*, 4th ed. Baltimore, Johns Hopkins University Press, 1998, p 179.

mosome abnormalities in spontaneous abortuses during the first trimester has been reported to be as high as 61.5%.¹² Table 1-6 summarizes the karyotype incidence in chromosomally abnormal abortuses.⁹ For comparison, note the incidence of chromosome abnormalities in liveborn infants (see Table 1-5). At an incidence of 19%, 45,XO is the most common chromosome abnormality found in first-trimester spontaneous abortions. Comparison with the relatively low incidence of 45,XO in liveborn infants suggests that most conceptuses with this karyotype are aborted spontaneously. Trisomic embryos are seen for all autosomes except chromosomes 1, 5, 11, 12, 17, and 19.

The studies of Creasy and colleagues¹³ and Hassold¹⁴ offer a comparison between karyotypic abnormalities in live births and in spontaneous abortions (Table 1-7). Triploidy or tetraploidy, and trisomy 16 are the most common autosomal abnormalities in spontaneous abortuses but are never seen in live births. Comparison of the overall incidence of about 1 per 830 live births for trisomy 21 with the incidence in abortuses suggests that approximately 78% of trisomy 21 conceptuses are aborted spontaneously.

Summary of Maternal-Fetal Indications for Chromosome Analysis

Among all genetic aspects of maternal-fetal medicine, chromosome mutations and clinical syndromes associated with a dysmorphic phenotype constitute the category that most often requires the physician's attention. It is worthwhile, therefore, to review indications for the consideration, at least, of chromosome analysis as part of the evaluation of fetus, infant, or parents. The following situations would justify chromosome analysis.

Abnormal Phenotype in a Newborn Infant

Most abnormal phenotypes in the newborn resulting from chromosome abnormalities reflect abnormal autosomes. The important findings that should prompt karyotyping include (1) low birth weight or early evidence of failure to thrive; (2) any indication of developmental delay, in particular mental retardation; (3) abnormal (dysmorphic) features of the head and face, such as microcephaly, micrognathia, and abnormalities of eyes, ears, and mouth; (4) abnormalities of the hands and feet; and (5) congenital defects of various internal organs.

Other	39	37	95	2
Total abnormal	800	750	94	50

A single isolated malformation or a mental retardation without an associated physical malformation significantly reduces the likelihood of a chromosome abnormality. Disorders of the sex chromosomes are more likely to be associated with phenotypic ambiguity of the external genitalia and perhaps slight abnormality in growth pattern. Certainly, any newborn manifesting sexual ambiguity should undergo a chromosome analysis. In addition to helping to exclude the possibility of a life-threatening genetic disorder (e.g., adrenogenital syndrome), the identification of sex genotype by chromosome analysis will assist attending physicians in their decisions about therapy and counseling for the parents. For the infant suspected of having autosome abnormalities, in whom the chromosomal genotype is urgently needed for making decisions about the infant's care, rapid chromosome analysis can be obtained by culture of bone marrow aspirate. When a familial chromosome mutation, such as unbalanced translocation, is detected in the infant, karyotyping of other kindred is indicated.

Unexplained First-Trimester Spontaneous Abortion with No Fetal Karyotype

Usually, couples seek medical help because of recurrent first-trimester abortions, and there is no previous karyotype for aborted tissue. Many genetic centers now recommend parental karyotyping after several (usually two or three) spontaneous abortions have occurred. The likelihood of a parental genome mutation is probably greatest if the couple has already produced a child with birth defects. When a parental chromosome structural abnormality is identified, genetic counseling and prenatal fetal monitoring in all subsequent pregnancies are advised.

Stillbirth or Neonatal Death

Unless an explanation is obvious, any evaluation of a stillborn infant or a child dying in the neonatal period should include chromosome analysis. There is an approximately 10% incidence of chromosomal abnormalities in such individuals, compared with less than 1% for liveborn infants surviving the neonatal period. The likelihood of finding a chromosome mutation is increased significantly if intrauterine growth retardation or phenotypic birth defects are present.

Fertility Problems

In women presenting with amenorrhea and couples presenting with a history of infertility or spontaneous abortion, the incidence of chromosomal defects is between 3% and 6%.

In men presenting with infertility, deletions in the human Y chromosome have been found.¹⁵ Among other disorders, these men can present with spermatogenic failure, or the absence of, or very low levels of, sperm production. It is known that the Y chromosome contains more than 100 testis-specific transcripts. Several deletions that remove some of these transcripts have been found that appear to cause spermatogenic failure. Screening for such deletions in infertile men is now a standard part of clinical evaluation. In addition, many other Y-chromosome structural variants have been described using techniques such as high-resolution comparative genomic hybridization (described earlier). Some of these structural variants affect gene copy number, although additional research is necessary to address the phenotypic effect of many of these structural variants.

Neoplasia

All patients with cancer present with some element of genomic instability, and specific chromosomal defects are often pathognomonic of certain specific cancers, especially hematologic malignancies.

Pregnancy in a Woman of Advanced Age

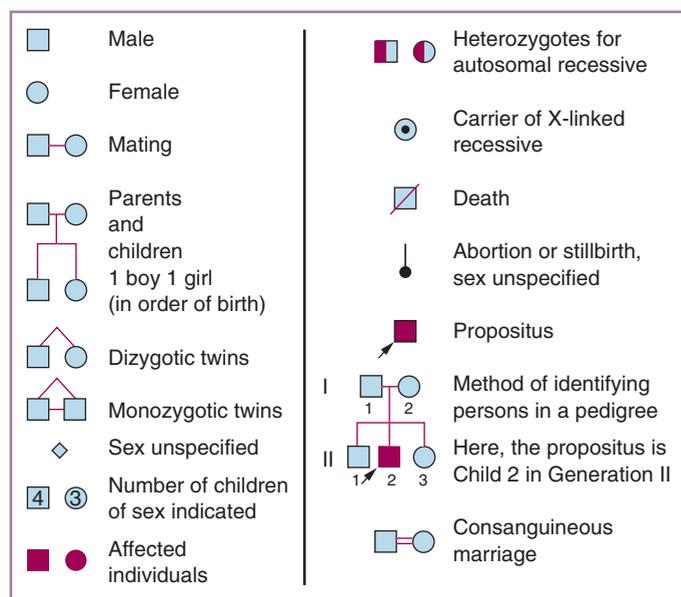

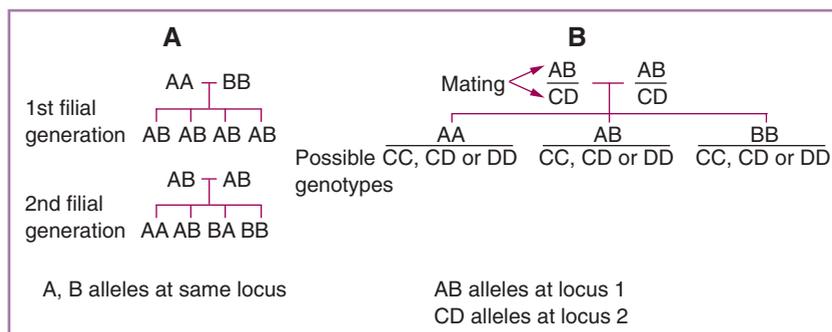

There is an increased risk of chromosomal abnormalities in fetuses conceived in women older than 30 to 35 years.¹⁶ A karyotypic analysis of the fetus can be part of routine care in such pregnancies, or such women can be offered noninvasive screening.

Patterns of Inheritance

Single-gene traits are those inherited from a single locus. They segregate on the basis of two fundamental laws of genetics in diploid organisms established by Gregor Mendel using garden peas in 1857. These two laws are *segregation* (Fig. 1-24A) and *independent assortment* (see Fig. 1-24B). In medical genetics, the term *mendelian disorders* refers to single-gene phenotypes that segregate distinctly within families and generally occur in the proportions noted by Mendel in his experiments. Specific phenotypic or genotypic traits are inherited in distinct fashions, depending on whether the responsible gene is on the X chromosome or an autosome, and whether one or two copies of a gene are necessary for a phenotype. A phenotype is *dominant* if it is expressed when present on only one chromosome of a pair, whereas *recessive* traits are expressed only when present on both chromosomes. A purely dominant trait has the same phenotype when present on either one or

FIGURE 1-24 Mendel's first and second laws.

A, With A and B representing alleles at the same locus, a mating of homozygous A and homozygous B individuals results in heterozygotes for A and B in each offspring. Mating of heterozygotes A,B results in the 1-2-1 segregation ratio in offspring. **B**, The segregation of genotypes for A and B at locus 1 is independent of the segregation of alleles C and D at locus 2. (From Kelly TE: Clinical Genetics and Genetic Counseling. Chicago, Year Book Medical, 1980.)

**FIGURE 1-25** Symbols commonly used in pedigree charts. (From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's Genetics in Medicine, 6th ed. Philadelphia, WB Saunders, 2001.)

two chromosome pairs. However, if a phenotype is expressed when present as a single copy but is expressed more strongly when present on two chromosomes, the trait is *codominant*. Victor McKusick's catalog of single-gene phenotypes and mendelian disorders¹⁷ is now available online¹⁸ (see Table 1-1) and is an indispensable reference for human genetic traits and disorders.

Familial studies for genetic evaluation require development of a pedigree or a graphic representation of family history data. Figure 1-25 illustrates some of the symbols useful in this process. This aspect of data gathering serves several functions:

1. It assists the determination of transmission for the gene expression in question (recessive, dominant, sex-linked, or autosomal).
2. There is a greater likelihood that all possible genetic issues will be included in the data gathering when a formal pedigree chart is assembled.
3. When consanguinity is present, the pedigree chart helps to relate the consanguinity to individuals in subsequent generations who are expressing the phenotype of a particular inheritable disorder.

Autosomal Dominant Mode of Inheritance

In autosomal dominant inheritance, the disease is expressed in the heterozygote, and the probability of transmitting the gene to progeny is 50% with each pregnancy. The pedigree in Figure 1-26 demonstrates the features of inheritance of an autosomal dominant disease: gene expression in each generation, approximately half of the offspring affected (both males and females), and father-to-son transmission.

Criteria for Autosomal Dominant Inheritance

The criteria for autosomal dominant inheritance may be summarized as follows:

1. Expression of the gene rarely skips a generation.
2. Affected individuals, if reproductively fit, transmit the gene expression to progeny with a probability of 50%.
3. The sexes are affected equally, and there is father-to-son transmission.
4. A person in the kindred at risk who is not affected will not transmit the gene to progeny.

Other Characteristics

Other characteristics, although not exclusive properties of autosomal dominant disease, seem to be associated with this group of diseases more frequently.

VARIABLE EXPRESSIVITY

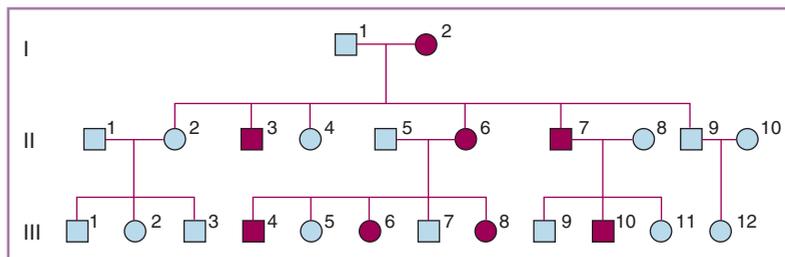

Variable expressivity refers to the degree of severity of expression of a trait and is commonly seen in kindreds with autosomal dominant traits. In neurofibromatosis, for example, a kindred may have a range of phenotypic expression in affected individuals, from some café au lait spots with a few tumors to extensive café au lait spots with massive neurofibromata.

PENETRANCE

Penetrance refers to whether there is any recognition of phenotypic expression of a particular mutant allele. If a gene is fully penetrant, it is always expressed as part of the genome of that individual. On the other hand, if a gene displays incomplete penetrance, not all individuals with that gene display any recognizable phenotype. For example, in the autosomal dominant form of retinoblastoma, the mutant gene is only 80% penetrant. This means that a person who receives the gene for retinoblastoma from a parent has a 20% chance that the disease phenotype will not be expressed.

Penetrance may also be influenced by the means available to detect expression of the gene. For example, in autosomal dominant hyper-

FIGURE 1-26 Stereotypical pedigree of autosomal dominant inheritance. Half the offspring of affected persons (7 of 14) are affected. The condition is transmitted only by affected family members, never by unaffected ones. Equal numbers of males and females are affected. Male-to-male transmission is seen. (From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's Genetics in Medicine, 6th ed. Philadelphia, WB Saunders, 2001.)

cholesterolemia, a myocardial infarction (a manifestation of gene expression and penetrance) may not appear until well into adult life. In this disorder, there is a laboratory test for expression, namely the serum cholesterol level, which becomes elevated quite early in life, well before the first chest pain of angina pectoris.

NEW MUTATIONS

It is not uncommon for an autosomal dominant disorder to manifest for the first time in a kindred as a new mutation. New mutations are also seen with sex-linked recessive disorders. For example, in a form of autosomal dominant dwarfism called achondroplasia, nearly 80% of individuals represent new mutations. When this phenomenon can be identified with certainty, parents may be reassured that the recurrence risk is probably no greater than that for the general population. The recurrence risk for offspring of the affected individual is 50%. New mutations for autosomal dominant diseases appear to be related to paternal age.

Autosomal Recessive Mode of Inheritance

For autosomal recessive diseases, mutant genes are expressed only in homozygous individuals. Consanguinity is often a clue for autosomal inheritance when the specific gene mutation has not been identified. A pedigree consistent with autosomal recessive inheritance is shown in Figure 1-27. Primary features consistent with autosomal recessive inheritance may be summarized as follows:

1. Both males and females are affected.
2. Unless consanguinity or random selection of heterozygous matings in each generation occurs, mutant gene expression may appear to skip generations, in contrast to autosomal dominant inheritance, which rarely skips generations.
3. Parents are usually unaffected, but unaffected sibs of affected homozygotes may be heterozygous carriers. Affected individuals rarely have affected children.
4. Subsequent to identification of a propositus, the recurrence risk for homozygous affected progeny in each subsequent pregnancy is one chance in four.
5. If the incidence of the disorder is rare, consanguineous parentage is often seen.

Sex-Linked Mode of Inheritance

In this discussion, sex-linked refers to inheritance from the X chromosome. For this group of genetic diseases, the male is considered to be hemizygous in relation to X-linked genes, whereas females are almost always heterozygous. However, because of patterns of X inactivation, females of some X-linked disorders may be more mildly affected than males with the same disorder.

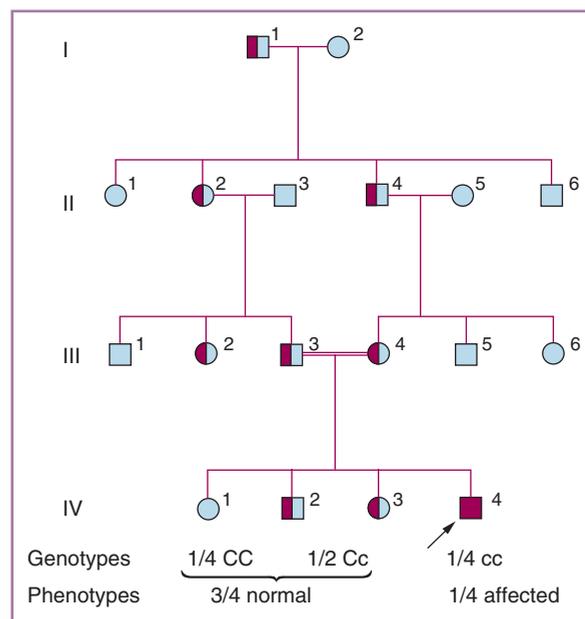

FIGURE 1-27 Stereotypical pedigree of autosomal recessive inheritance, including a cousin marriage. A gene from a common ancestor I-1 has been transmitted down two lines of descent to “meet itself” in IV-4 (arrow). (From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's Genetics in Medicine, 6th ed. Philadelphia, WB Saunders, 2001.)

Hemophilia A is among the best-known X-linked recessive diseases. For illustrative purposes, we shall use the symbol X_h to represent the recessive allele for hemophilia A on the X chromosome and X_H to represent the normal or dominant allele. The diagrams in Figure 1-28 demonstrate progeny genotypes in matings between affected males and normal females as well as matings between normal males and heterozygous phenotypically normal females. When the father is affected, all sons will be normal and all daughters will be heterozygous carriers and phenotypically normal (see Fig. 1-28A). In the other mating cross, each daughter will have a 50% chance of being normal and a 50% chance of being a heterozygous carrier who is phenotypically normal (see Fig. 1-28B). Each son will have a 50% chance of being normal and a 50% chance of being affected.

Characteristics of X-linked recessive inheritance may be summarized as follows:

1. A higher incidence of the disorder is noted in males than in females.
2. The mutant gene expression is never transmitted directly from father to son.

		OVA

FIGURE 1-28 Sex-linked recessive inheritance patterns. See text. (From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's Genetics in Medicine, 6th ed. Philadelphia, WB Saunders, 2001.)

- The mutant gene is transmitted from an affected male to all his daughters.
- The trait is transmitted through a series of carrier females, and affected males in a kindred are related to one another through the females.
- For sporadic cases, there may be an increase in the age of the maternal grandfather at which he fathered the mother of an affected child—similar to the increase in paternal age for certain new dominant mutations.

In contrast to X-linked recessive inheritance, X-linked dominant disorders are nearly twice as common in females as in males (Fig. 1-29). For example, none of the sons of a male affected with vitamin D-resistant rickets is affected, but all his daughters receive the mutant gene from him, and because the mutant is dominant, they all have the disease. A female with one X-linked mutant dominant allele will have the disease, and the transmission to her progeny, assuming a hemizygous normal mate, will be indistinguishable from that seen in autosomal dominant inheritance. As a group, the X-linked dominant disorders are relatively uncommon. Vitamin D-resistant rickets (hypophosphatemia) is one, and the X-linked blood group X is another.

The distinguishing features of X-linked dominant inheritance are summarized as follows:

- All daughters of affected males have the disorder, but no sons are affected.
- Heterozygous affected females transmit the mutant allele at a rate of 50% to progeny of both sexes. If the affected female is homozygous, all her children will be affected.
- The incidence of X-linked dominant disease may be twice as common in females as in males.

Some rare disorders that are exclusively or nearly exclusively seen in females, such as Rett syndrome and incontinentia pigmenti type 2, appear to be X-linked dominant conditions in which affected males die before birth.

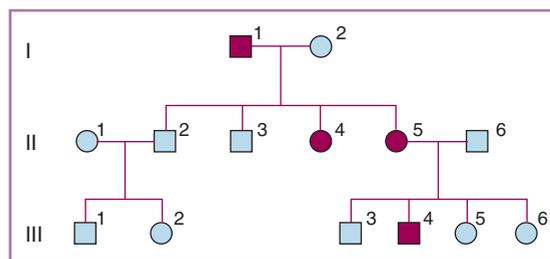

FIGURE 1-29 Stereotypical pedigree of X-linked dominant inheritance. Affected males have no affected sons and no normal daughters. (From Nussbaum RL, McInnes RR, Willard HF: Thompson and Thompson's Genetics in Medicine, 6th ed. Philadelphia, WB Saunders, 2001.)

Multifactorial Inheritance

In this age of genes and genomes, we should remember that not everything that runs in families is genetic and not everything that is genetic runs in families. Environmental and sociologic factors such as diet, age at first pregnancy, socioeconomic level, access to health care, and environmental conditions often segregate in families along with genes. An excellent example is the occurrence in families of cholera or tuberculosis. Although susceptibility to infectious diseases can be modulated by genetic inheritance, the susceptibility of a family to these diseases is most likely the result of unsanitary conditions (cholera) or chronic exposure (tuberculosis). On the other hand, some genetic disorders are sufficiently devastating that they are rarely if ever transmitted between generations, and most cases occur as de novo mutations. Examples of genetic disorders for which many patients have no family history include chromosomal abnormalities (e.g., Down syndrome), contiguous gene syndromes (e.g., Prader-Willi, Angelman, or Smith-Magenis syndrome), and single-gene disorders for which one copy of the gene is not enough (called *haploinsufficiency*) (e.g., neurofibromatosis type 1). Clinicians should be aware that common disorders often have both genetic and nongenetic components to their etiology. A clinician who might encounter either familial clusters or rare genetic disorders should be familiar with the concepts used to distinguish genetic from nongenetic transmission.

Heritability

A measure of the genetic contribution to disease is heritability, which is the amount of phenotypic variation explained by genes relative to the total amount of variation. A more detailed treatment of statistical estimates of heritability can be found in texts devoted to genetic analysis.^{19,20} High heritability does not imply the action of a single gene but rather a greater contribution of genes compared with environmental or stochastic factors for the characteristic being studied. Disorders (or susceptibility to them) may be inherited as monogenic, oligogenic, or polygenic in a given family. A disease with high heritability may also be inherited in different families through different genes. A disease caused by any of several mutations in the same gene is said to show *allelic heterogeneity*. A disease caused by changes in any of several different genes is said to show *locus heterogeneity*. A disease caused by environmental factors that mimics a genetic disorder is said to *phenocopy* that disorder.

Recurrence Risk

One common statistical measure used to estimate heritability is the recurrence risk to family members of an index case or proband. This is often expressed as the ratio of risk to a first-degree relative divided

by the risk in the general population. Recurrence risk to full siblings is a common measure, but depending on the structure of available patient populations, first cousin, grandparent/grandchild, and other comparisons have been used.

Twin Studies

Twin studies are often extremely valuable in distinguishing effects of shared genes from effects of shared environment, particularly for diseases with complex etiology. A genetic component to a trait or disease can be seen as a difference in recurrence risk or concordance rate between monozygotic twins (derived from a single fertilization event and therefore genetically identical) and dizygotic twins (derived by independent fertilization of two eggs released in the same cycle and therefore sharing half of their genes). All twins generally share both prenatal and postnatal environments. Monozygotic twins also share all their genetic complement, but dizygotic twins share only half of theirs. Any substantial difference in concordance rate (or recurrence risk) between monozygotic and dizygotic twins as a group is taken as evidence of a genetic component.

Complex Inheritance

Many common disorders show complex inheritance. Allergy, asthma, autism, cancer, cleft lip and palate, diabetes, dizygotic twinning, handedness, hypertension, multiple sclerosis, neural tube defects, obesity, and schizophrenia are all examples of such complex traits with population frequencies greater than 1%. Such disorders may have rare single-gene (monogenic) forms, but most cases have more complex etiologies. Complex disorders include examples of polygenic inheritance, in which several genes contribute to the disease in the absence of environmental effects, and multifactorial inheritance, in which genes and environment interact to produce disease. In practice, a complex trait may have monogenic, polygenic, and multifactorial forms—and possibly more than one of each. Although such etiologic heterogeneity makes identification of the underlying genes (and environmental risk factors) more difficult, several characteristic features help to identify disorders with complex inheritance.

Complex inheritance may involve either *quantitative traits* or *qualitative traits*. In a quantitative trait, each causal gene or nongenetic factor contributes incrementally to a measurable outcome, such as height, body mass index, or age at onset of disease. A qualitative trait has alternative outcomes that either are nonquantitative or are very imprecisely quantified in practice; each causal gene contributes to meeting a threshold for expression of the trait or contributes to the probability of expressing the trait, such as susceptibility to disease. Note that these modes are not completely distinct: Susceptibility genes may act quantitatively on the probability of disease for each individual, but clinical outcome may be qualitative (e.g., the presence or absence of disease). Disease genes may also act additively to reach a qualitative threshold for disease and beyond the threshold contribute to increased severity of disease. Stratifying patients by intermediate phenotypes, disease severity, or known risk factors may simplify the inheritance patterns of some complex traits.

Recent technical advances have greatly increased our ability to identify individual genes in complex disorders. The public availability of the consensus human genome sequence, along with deep databases of single nucleotide polymorphisms, copy number variations, and high-throughput genotyping platforms, allows investigators to interrogate the entire genomes of clinical subjects for genetic linkage or statistical associations to clinical phenotypes. Maps defining common human haplotypes (arrangements of alleles at successive loci along an individual chromosome) have added further power to study designs for

detecting disease genes in genome-wide association studies (GWAS—also called whole-genome association studies, or WGAS). Expanded repositories (and consortia of smaller repositories) for both clinical data and physical samples have begun to allow statistically highly significant genetic findings for disorders that previously had resisted less powerful analyses (e.g., see Wellcome Trust Case Control Consortium²¹). We should expect to see continued progress in identifying such genes over the next several years. This places additional importance on the ability of practicing doctors to identify clinical presentations and families that fit particular inheritance patterns. For the most up-to-date information on specific genes, loci, and disorders, the reader is encouraged to consult online sources, particularly the OMIM¹⁸ and PubMed databases maintained by the National Center for Biotechnology Information in the National Library of Medicine (www.ncbi.nlm.nih.gov).

CHARACTERISTIC FEATURES OF COMPLEX TRAITS

Regression to the Mean. Because complex traits involve the inheritance (or environmental presence) of many factors, offspring from extreme individuals tend to be less extreme than the parents; that is, they regress to the mean of the population. Independent assortment in meiosis results in different combinations of genes being passed to offspring, and change of environment results in different factors being experienced by the offspring. Using a familiar example of a nondisease trait, very tall parents will have taller than average children, but in general children of the tallest parents will not inherit all of the “tall factors” that the parents have.

Heritability. Complex traits have heritability estimates over a wide range. They are by definition less heritable than fully penetrant monogenic traits but more heritable than would be expected by chance alone. The range of heritability reflects the varying degree to which genes determine the outcome of each trait. The higher the ratio of recurrence risk to a family member to risk in the general population (or the higher the ratio of monozygotic twin concordance to dizygotic twin concordance), the more genetically tractable the disease is likely to be.

Threshold Traits. The rate of development can determine outcome in a threshold trait. The idea of a threshold trait is that if an event does not happen by a specified time in development (a developmental threshold), then a consequent phenotype, such as a physical malformation or cognitive deficit, will ensue. Developmental rates are generally determined by a combination of genetic and environmental factors.

Penetrance, Probability, and Severity. The likelihood of having the disorder or trait, given the right genotype, is called the *penetrance*. For simple mendelian disorders, penetrance may be at or near 100%. For traits with environmental cofactors or developmental threshold effects, the penetrance can be much lower. For some disorders, the penetrance (in terms of either likelihood or severity of the disorder) is part of the pattern of inheritance within a family. Affected relatives of a severely affected proband are likely to be more severely affected than the average case. This is the other side of regression to the mean: Returning to our nondisease example, the children of very tall parents may not be as tall as their parents but will probably be taller than average. Taking a disease example, if a liveborn infant has unilateral cleft lip, the recurrence risk to future siblings is 2.5%, but for a liveborn infant with bilateral cleft lip and palate, the recurrence risk is 6% (see below).

Increased Risk across Diagnostic Categories. Another frequent feature of complex inheritance is that relatives of the proband

may be at increased risk for related diagnostic categories. This has been suggested for categories of psychiatric illness, for some autoimmune disorders, and for some malformation syndromes. The implication of this is that overlapping sets of genes and environmental factors can lead to dysfunctions that present as related clinical entities.

Rarer Forms Show Increased Relative Risk. Forms of multifactorial disease that are less frequent in the general population tend to have higher recurrence risk ratios for families of an affected proband. For example, pyloric stenosis is five times more common in males than in females in the general population. As Table 1-8 shows, male relatives of any proband face a higher risk than their sisters, but relatives of female probands face much higher risk than relatives of male probands.

Common Disorders with Multifactorial Inheritance

CLEFT LIP AND CLEFT PALATE

The cleft lip malformation may occur with or without cleft palate (orofacial cleft) but is etiologically distinct from cleft palate alone.²²

TABLE 1-8 RECURRENT RISK OF PYLORIC STENOSIS FOR FIRST-DEGREE RELATIVES		
	Risk (%)	Relative to General Population Risk
Male relatives of male patients	4.6	×10
Female relatives of male patients	2.6	×25
Male relatives of female patients	18.2	×35
Female relatives of female patients	8.1	×80

From Kelly TE: *Clinical Genetics and Genetic Counseling*. Copyright © 1980 by Year Book Medical, Chicago. Reproduced with permission.

These common malformations occur in more than 200 described human syndromes, including several single-gene disorders, chromosomal abnormalities, and syndromes of teratogen exposure (including thalidomide). Developmentally, cleft lip with or without cleft palate results from a failure in the fusion of the frontal prominence with the maxillary process at about 7 weeks of fetal development. Incidence is two- to fourfold higher in males than in females and varies among ethnogeographic groups: 0.4 per 1000 births in African Americans, 1 per 1000 births in whites, and 1.7 per 1000 births in Japanese. However, the recurrence risk to first-degree relatives is lower in Japan than in Europe, suggesting a higher environmental influence in Japan.²³ Within a population, the recurrence risk varies with the severity of defect in the proband, as noted previously. Examples are shown in Table 1-9. Several loci for syndromic and nonsyndromic orofacial cleft (OFC) have been implicated by genetic linkage and association studies, although for several loci the specific genes involved are not yet resolved.

CLEFT PALATE

In cleft palate without cleft lip, the secondary palate fails to fuse. The general incidence is approximately 1 in 2500 and it is more common in females than males. Little ethnic variation is noted, and the recurrence risk is approximately 2%. Isolated cleft palate appears genetically distinct from cleft lip with or without cleft palate. At least one gene for isolated cleft palate, *SATB2*, has been identified.^{24,25}

NEURAL TUBE DEFECTS

This group of malformations is of special importance because they are prevalent, their risk can be significantly altered by diet, and there is a possibility of mid-trimester prenatal diagnosis and even perhaps prenatal screening of these disorders in all pregnancies. Expression of neural tube defects can be highly variable among individuals, ranging from anencephaly at one extreme to lumbar meningocele with little or no neurologic impairment at the other. The spectrum includes encephalocele, iniencephaly, meningomyelocele (usually involving the

TABLE 1-9 EXAMPLES OF RECURRENT RISKS FOR CLEFT LIP, WITH OR WITHOUT CLEFT PALATE, AND FOR NEURAL TUBE MALFORMATIONS		
Family History	Risk for Cleft Lip ± Cleft Palate (%)	Risk for Anencephaly and Spina Bifida (%)
No sibs affected		
Neither parent affected	0.1	0.3
One parent affected	3.0	4.5
Both parents affected	34.0	30.0
One sib affected

Adapted from Thompson MW: *Thompson and Thompson's Genetics in Medicine*, 4th ed. Philadelphia, WB Saunders, 1986; Based on data from Bonaiti-Pellié C: Risk tables for genetic counselling in some common congenital malformations. *J Med Genet* 11:374, 1974.

lower thoracic and lumbar spine and often called spina bifida cystica), and spina bifida. Defects arise through failure of the embryonic neural tube to close within 28 days from conception. The incidence in European-derived populations can vary substantially, from less than 1 per 1000 to nearly 1 per 100 births. One recent study of medical records showed an approximately 10-fold decrease in neural tube defects in England and Wales between 1964 and 2004, attributable both to a reduction in the occurrence of neural tube defects and to termination after early diagnosis.²⁶ The overall U.S. incidence is approximately 1 per 1000, but it is lower for individuals of African or Asian ancestry. Recurrence risks for anencephaly and spina bifida probands are shown in Table 1-9.

Epidemiologic and experimental animal studies have suggested that neural tube defects have characteristics of threshold traits as well as substantial environmental factors. For example, recent attention has been paid to the importance of dietary folate in preventing neural tube defects. Incidence of this defect in Canada decreased by 50% after folate supplementation of cereals in the United States and Canada in 1998.²⁷ Known genetic risk factors include genes for folate and homocysteine metabolism as well as loci thought to present folate-independent risk. Work in animal models has suggested inositol as another potential metabolic factor.²⁸⁻³⁰

PYLORIC STENOSIS

Pyloric stenosis is the most common disorder requiring corrective surgery in infants, with an incidence of 1 to 5 per 1000 live births. Heritability is inferred from the high recurrence risk to relatives. Carter and Evans first proposed sex-modified multifactorial inheritance in 1969.³¹ Males are at higher risk than females, irrespective of family history, but the ratio of recurrence risk to general risk is higher in females (see Table 1-8). Mitchell and Risch³² concluded that family studies were inconsistent with a single major locus causing pyloric stenosis and set model-based limits for the effect of any single locus at no more than a fivefold increase in recurrence risk across the general population. However, single-gene effects can be seen in some extended families. Evidence from patient material³³ and targeted mutations in mice^{34,35} indicate that neuronal nitric oxide synthase gene, *NOS1*, is one locus for pyloric stenosis. An additional locus and further evidence for genetic heterogeneity have been identified by linkage analysis in a multigenerational family with 10 affected members.³⁶

CELIAC DISEASE

Autoimmune reaction in celiac disease causes inflammatory injury to the mucosa of the small intestine, resulting in malabsorption. Once thought uncommon, celiac disease (or gluten-sensitive enteropathy) is now thought to affect as many as 1 in 120 to 1 in 300 people in Europe and North America. Several factors point to multifactorial inheritance. Recurrence risk to siblings is 10% or higher. Concordance rates for monozygotic twins is more than fourfold higher than for dizygotic twins.³⁷ Exposure to wheat gluten (or other grains, such as rye and barley) are environmental factors for genetically susceptible individuals. Genetic linkage to human leukocyte antigen has been reported, as well as linkage to several additional genetic loci.³⁸⁻⁴⁰ Among regions showing significant linkage, variations in the *CTLA4* and *MYO9B* genes show strong association with disease.

INFLAMMATORY BOWEL DISEASE (CROHN DISEASE)

Genetic components of autoimmune disease directed against the gastrointestinal tract have also been mapped for findings of Crohn disease and ulcerative colitis. Together these somewhat overlapping

diagnoses occur in 2 to 3 people per 1000 in the United States. Genetic effects of at least 11 distinct loci for inflammatory bowel disease have been identified in this complex trait, including linkage to the human leukocyte antigen region of chromosome 6p. As an interesting example of molecular analysis in a complex trait, Rioux and coworkers⁴¹ mapped one locus on chromosome 5q, *IBD5*, to a cluster of inflammatory cytokine genes; several of the genes in this interval were polymorphic between patients and population control subjects, but causality for any one gene could not be determined because of strong linkage disequilibrium across the implicated region. An uncommon allele of IL-23R cytokine receptor was identified as a protective effect in a genome-wide association study.⁴²

HIRSCHSPRUNG DISEASE

Congenital megacolon caused by lack of enteric ganglia along the intestine is a relatively well-studied complex genetic trait. Incidence is about 1 in 5000 births, including both short-segment and long-segment forms. Both dominant inheritance and recessive inheritance have been observed, and penetrance is variable. Single-gene mutations associated with varying penetrance for Hirschsprung disease have been identified that illuminate biochemical pathways with unique importance for the establishment of enteric ganglia. Aganglionic megacolon also occurs in more complicated disorders, including cartilage-hair hypoplasia, Smith-Lemli-Opitz syndrome type II, and primary central hypoventilation syndrome. Variations in the *RET* oncogene appear to be the major risk factor in Hirschsprung patients. Mutations in endothelin 3, endothelin receptor B, and endothelin converting enzyme, as well as neurturin, glial-derived neurotrophic factor, and the transcriptional regulator *SOX10* have been identified as risk conferring in both human and animal studies. An exhaustive search for genetic linkage implicated two additional loci that act as oligogenic determinants of the expression of mild *RET* alleles.⁴³ Interestingly, mutation of a transcriptional enhancer of the autosomal *RET* gene confers sex-dependent risk for Hirschsprung disease.⁴⁴

CONGENITAL HEART DEFECTS

The overall incidence of congenital heart disease is 5 to 7 live births per 1000 and is the leading cause of death from birth defects.⁴⁵ This heterogeneous group of defects can be caused by single-gene mutations, chromosomal abnormalities (trisomy 21), and teratogens such as rubella and maternal diabetes. Table 1-10, abstracted from the classic

TABLE 1-10 FREQUENCY OF SIX COMMON CONGENITAL HEART DEFECTS IN SIBS OF PROBANDS

Anomaly	Frequency in Sibs* (%)	Expected Frequency† (%)

study of Nora,⁴⁶ summarizes the empiric recurrence risk for six common congenital heart defects. More recent familial recurrence data support heritability of additional congenital heart defects, including transposition of the great arteries and congenitally corrected transposition of the great arteries (reviewed by Calcagni and coworkers⁴⁷). Patients with heart malformations associated with chromosomal abnormalities often present differently despite having the same cytologic findings. Allelic heterogeneity at some single-gene loci or modifying effects of either environmental factors or other genes may account for some diversity in clinical findings. For example, rare alleles of *NK2*, which encodes the transcription factor *NKX2.5*, have been separately implicated in atrial septal defects, hypoplastic left heart syndrome, and tetralogy of Fallot. Similarly, mutations in the *GATA4* transcription factor are reported for both atrioventricular canal defects and atrial septal defects. Mutations in the *Notch* signaling pathway are also seen in different forms of congenital heart defects.

Mitochondrial Inheritance

Mutations in mitochondria produce unique patterns of inheritance. All mitochondria inherited at conception come from the mother—termed *matrilineal* inheritance. Mitochondria are the only organelles in animal cells that carry their own DNA (mitochondrial DNA [mtDNA]). Human mitochondria contain a circular genome of 16,571 base pairs that encodes just 37 genes (GenBank reference sequence NC_001807). In contrast to nuclear genes, which are present in two copies per diploid cell, the mitochondrial genome is present once per mitochondrion and therefore in a variable number of copies per cell. Perhaps because of the generation of free radicals during energy production, mtDNA is subject to a relatively high rate of mutation. Mutations in mtDNA create a mixture of normal and mutant mitochondria, called *heteroplasmy*. At cell division, mitochondria segregate randomly to the two daughter cells. This *replicative segregation* can ultimately result in a cell lineage inheriting only mutant mtDNA (*homoplasmy*). Segregation of either inherited or de novo mtDNA mutations among cell lineages can also result in a mosaic pattern across tissues of a single individual.

Phenotypic expression of mitochondrial mutations depends on the extent of heteroplasmy, the cell type involved, and the fraction of the cell type affected. Organ systems most frequently affected by mitochondrial mutations are those with high energy requirements, particularly muscle and brain. Mutations that reduce energy production by mitochondria may produce disease whenever energy production capacity falls below a threshold level. This may be episodic if the energy threshold is crossed only during exertion or other stressors. Leber optic atrophy is perhaps the best-known example of inherited disease caused by mutations in mtDNA. Mitochondrial myopathy (a complex including neurodegeneration, pigmentary retinopathy, and Leigh syndrome), MERRF disease (myoclonic epilepsy with ragged red fibers), MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes), and hypertrophic cardiomyopathy are also attributable to mutations in mtDNA. Most of these are not identifiable at birth but become evident with age as later-onset, maternally inherited disorders.

Dynamic Mutations and Trinucleotide Repeats

Repetitive DNA sequences can give rise to mutations through a variety of mechanisms. Repeats of two, three, or four nucleotides are especially

prone to changes in repeat length. The mutation rate depends on repeat length of the starting allele, the genomic context, and other factors. Small changes in allele repeat length have been attributed to “slippage” of the DNA polymerase (or more probably, the newly synthesized DNA fragment) during replication. Much larger changes in repeat length are more likely to be caused by unequal crossing over during meiosis.⁴⁸ Alleles that change within a pedigree are said to be *dynamic*. Dynamic mutations can show other unusual features of inheritance. *Pre-mutation alleles* are those that are expanded sufficiently to be highly dynamic but are not yet disease causing. Further expansion of the repeat results in transmission of disease alleles to offspring at a high frequency. Disease alleles are themselves dynamic and if transmitted may give rise to alleles with more severe phenotypes and earlier onset. This is called *anticipation*. Most dynamic mutations seen in humans thus far are caused by instability of *trinucleotide repeats*—specifically, CAG repeats encoding polyglutamine in the protein and other trinucleotides in noncoding sequences that alter expression of the encoded products.

Expanded polyglutamine repeats cause neurodegenerative disorders that have several features in common. These disorders show dominant inheritance, mature onset, and neurologic symptoms that include motor signs. Examples include Huntington disease, several forms of spinocerebellar ataxia, dentatorubropallidolusian atrophy, and spinobulbar muscular atrophy. Although these disorders typically have mature onset, age at onset varies inversely with the length of repeat, and extremely rare childhood Huntington disease patients have been reported as young as 2 years of age. Expanded polyglutamine-containing proteins have been shown to be cytotoxic in several experimental contexts. The interpretation of these disorders is that expanded polyglutamine destabilizes protein structure, and that the misfolded protein, often found in insoluble aggregates, impairs cell function and ultimately leads to cell death. For a given repeat length, toxicity increases with solubility,⁴⁹ which favors a surface area model for toxicity.⁵⁰

Amplification of polyaniline homopolymers can also be associated with disease, including some evident at birth. An amplified GCG repeat encoding polyaniline in the poly(A)-binding protein gene (*PABPN1*) is associated with autosomal dominant oculopharyngeal muscular dystrophy, apparently through a toxic gain-of-function mechanism.⁵¹ Nondynamic amplification of polyaniline (including each of the alanine codons) in the homeobox gene *HOXD13* causes synpolydactyly, and the severity of phenotypes correlates with the extent of amplification.^{52,53} Expanded polyaniline in another homeobox gene, *ARX*, results in an X-linked infantile spasm syndrome equivalent to that seen by inactivating mutations of the same gene and recessive in female carriers, suggesting that, in at least one example, polyaniline expansions may act by inactivating the protein rather than through gain of toxicity. All 10 polyaniline expansions associated with human disease to date have been nucleic acid-binding proteins. In-frame loss of polyaniline repeats in at least some of these sites is also mutagenic, including premature ovarian failure for *FOXL2* polyaniline reductions and congenital central hypoventilation syndrome for *PHOX2B* and *ASCL1*.

Trinucleotide repeat expansions in noncoding sequences can also cause disease by altering gene expression. One example is Friedreich ataxia, an autosomal recessive neurologic disorder with juvenile onset. The most common form is caused by loss-of-function alleles of the *FRDA* (*frataxin*) gene. The most frequent class of *FRDA* allele in patients is expansion of a GAA repeat in an intron of the gene, accounting for 98% of mutant alleles.⁵⁴ Extremely long repeats induce an epigenetic loss of expression of that copy of the gene. GAA expansion

alleles and rare protein-inactivating alleles have roughly the same effect on gene function. Another example of a mutation caused by a non-coding repeat expansion is fragile X syndrome (which includes mental retardation, macro-orchidism, and facial dysmorphism). The most frequent cause of fragile X syndrome is expansion of a CGG repeat in the 5' untranslated region of the *FMR1* gene. CpG dinucleotides are targets for methylation,⁵⁵ and DNA of the expanded allele is hypermethylated compared with both normal and premutation (stable intermediate-length repeat) alleles. Hypermethylation in or near transcriptional control elements results in loss of *FMR1* expression of the expanded allele in affected males. Expanded CGG alleles are equivalent to isolated cases hemizygous for missense and splice-site mutations, confirming that this repeat expansion acts as a loss-of-function allele. Autosomal dominant myotonic dystrophy (MD1) is a third example. Expansion of a CTG trinucleotide repeat in the 3' untranslated region of the *DMPK* protein kinase gene is strongly correlated with the disease and shows anticipation in families; however, the pathogenic mechanism remains unclear.

Imprinting

Besides the modes of inheritance already discussed, several atypical patterns of inheritance have been described. We discuss one of these patterns, called *imprinting*. Although most genes seem to have equivalent expression from alleles inherited from the father and the mother, it is now known that the expression of several genes differs between the parental alleles. This phenomenon has been termed genomic imprinting, because it appears that the two parental alleles are distinguished by some sort of mark. It appears that this mark is a reversible form of chromatin modification, perhaps methylation of one of the parental alleles, that occurs during gametogenesis and before fertilization. The mark then suppresses expression of this allele after conception. This mark is reversible in the germline, so that the parent-of-origin mark can be placed anew during gametogenesis.⁵⁶

Prader-Willi and Angelman syndromes are good examples of the phenotypic effects of imprinting. Prader-Willi syndrome is characterized by neonatal hypotonia, childhood obesity with excessive eating, small hands and feet, hypogonadism, and mild mental retardation. Angelman syndrome is characterized by severe mental retardation, seizures, a characteristic spastic movement disorder, and an abnormal facial appearance. Although it is now known that these syndromes are caused by different genes, both syndromes can result from deletions of the same region of chromosome 15q11-q13. In about 70% of cases, Prader-Willi syndrome results from the deletion of this region inherited from the father, so they have only the maternal copy of this region. Strikingly, in about 70% of cases of Angelman syndrome, the same region is deleted and inherited from the mother, so they have only the paternal copy of this region.

Several rare disorders have now been attributed to imprinting effects. At this point, it is unclear if imprinting is an important factor in more common disorders, but it is likely that it is involved in several human genetic disorders.

Genetic Testing and DNA Diagnostics

The realization in the 1980s that DNA variations, or polymorphisms, between individuals occur fairly frequently led to the development of

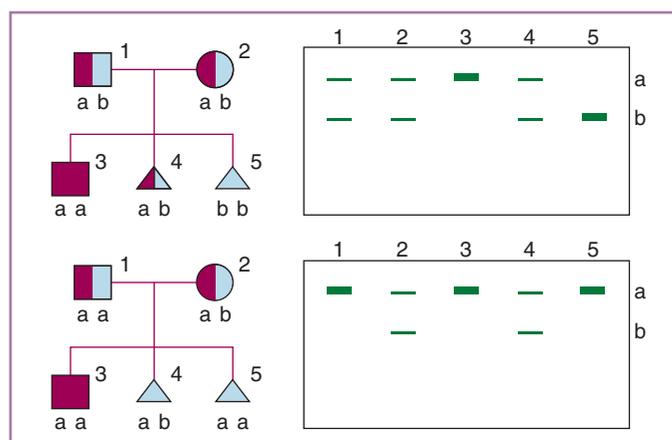

FIGURE 1-30 Schematic illustration of linkage by DNA probe analysis of restriction fragment length polymorphisms (RFLPs). **Left**, Pedigrees for two families. The darker symbols represent heterozygosity or homozygosity for the disease gene. Members tested are listed numerically. Lighter triangles represent fetuses in putative pregnancies. Letters *a* and *b* represent DNA restriction fragment lengths. **Right**, Gel electrophoresis patterns for the RFLPs. (Modified from Emery AEH: An Introduction to Recombinant DNA. New York, John Wiley & Sons, 1980.)

both DNA forensics and molecular diagnostics for genetic disorders and risk factors.⁵⁷ DNA diagnostics in medicine can use either direct assays for a specific mutation or linkage analysis with polymorphisms linked to a disease locus. Direct assays for specific mutations are most useful when relatively few distinct mutations account for most patients with a particular form of disease. As analysis methods become faster, cheaper, and more highly automated, performing direct tests on each nucleotide of a disease gene without knowing the precise mutation will become increasingly practical, particularly for genes in which a high proportion of patients have de novo mutations. Indirect assays using linkage analysis (Fig. 1-30) have traditionally been most useful for risk assessment when a disease gene has been mapped in pedigrees but not yet identified at the molecular level. Linkage analysis requires cooperation of other family members, including usually at least one affected member, to identify marker alleles on the disease-associated chromosome in that particular pedigree. Recombination between the marker and the disease gene is a potential caveat if a single marker is used; use of markers on each side of the disease gene at least makes this evident, and the likelihood of recombination can be built into the risk assessment. In practice, linkage assays for identified diseases become less necessary as a higher proportion of significant disease genes can be assayed directly. However, linkage analysis and family studies remain crucial to the successful identification of disease and disease susceptibility genes.

The initial molecular diagnostics to come out of the recombinant DNA revolution were based on restriction fragment length polymorphisms (RFLPs) (see Fig. 1-30). RFLPs are typically assayed by Southern blotting,⁵⁸ which requires substantial amounts of DNA and is relatively labor intensive and difficult to automate, making it relatively expensive. This approach is still used to identify large repeat expansions for genes known to be subject to dynamic mutations. The development of PCR by Mullis and coworkers in the mid-1980s allowed selective amplification of any desired sequence of DNA and radically changed the power of DNA diagnostics in terms of sample require-

ments and the types of assays one could perform.^{59,60} Linkage markers in current use include simple sequence repeat length polymorphisms (SSLPs, or microsatellites) and, increasingly, biallelic SNPs. SNPs in particular have the advantage of being assayable in multiplex formats, such that many distinct polymorphic sites may be interrogated in a single biochemical reaction. Several different technologies for SNP detection have been and continue to be developed to allow simultaneous detection of larger numbers of loci at smaller marginal cost. Finally, as more is known about normal copy number variation and those associated with specific diseases, the detection of CNVs will become increasingly used in diagnostics.

Methods Used in Genetic Testing

Hybridization-Based Methods

Nucleic acid hybridization is a simple physical chemical process with well-described parameters,^{61,62} and it forms the basis for a wide variety of molecular genetic tests. The rate and stability of nucleic acid duplexes depend on the concentration of each strand, temperature, ionic strength of the solution, and the presence of hydrogen bond competitors such as urea and formamide. Tests based on whole-genome Southern blots were among the first available for mutations with no cytologic correlate. As discussed earlier, hybridization of fluorescently labeled probes to fixed chromosomal spreads (FISH, spectral karyotyping) allows the identification of microdeletions, microduplications, translocations, and other cytologic abnormalities that would be difficult to detect without molecular probes. Other methods include hybridization of patient DNA to allele-specific oligonucleotides to discriminate

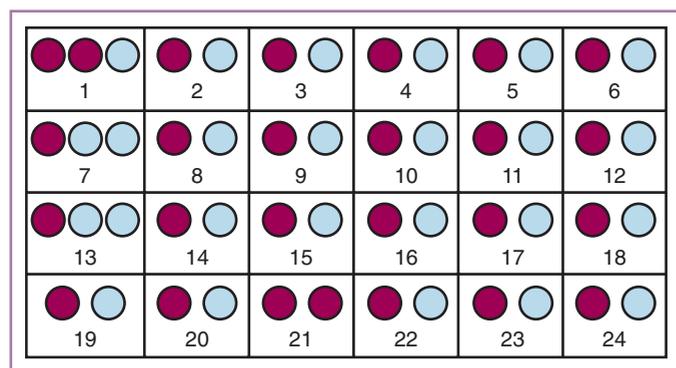

FIGURE 1-31 Reverse dot-blot analysis for cystic fibrosis (CF) mutations. Twenty-seven CF mutations were analyzed in this study. The complete panel in this figure represents a single filter, subdivided into 24 sections. Each section is numbered for specific mutation analysis. Sections 1, 7, and 13 analyze two separate mutations. Circles on the left in each numbered section contain normal oligonucleotide sequences from the CF gene region on chromosome 7. The sequences in each section represent different regions on the gene where a mutation has been identified. Thus, complementary normal sequences, amplified by polymerase chain reaction (PCR), hybridize as indicated by the red circles. The blue circles represent effort at hybridization between mutant sequences fixed to the filter and DNA sequences obtained from the patient and amplified by PCR. If the patient does not have a CF mutation among the group of 27 in this analysis, there is no hybridization and the circle remains open. In this analysis, sections 1 and 21 demonstrate that this patient has two CF mutations and would be designated a compound heterozygote. This individual would most likely have clinical manifestations of CF.

single base changes. An example of detection by allele-specific oligonucleotides is given in the reverse dot-blot analysis shown in Figure 1-31. In a reverse dot-blot analysis, the probe sequence is bound to the support matrix while the amplified patient sample is labeled and hybridized to the oligonucleotides; using this approach, a patient sample can be tested for several mutations in a single assay.

Southern blotting is used to detect variations in size or amount of a defined DNA fragment (Fig. 1-32). To produce the defined fragments from whole genomic DNA, restriction endonuclease enzymes are used to cut intact DNA at specific sites. Restriction enzymes occur in bacteria, where they form part of the host defense against bacterial viruses. Different bacterial species produce enzymes that recognize and cleave

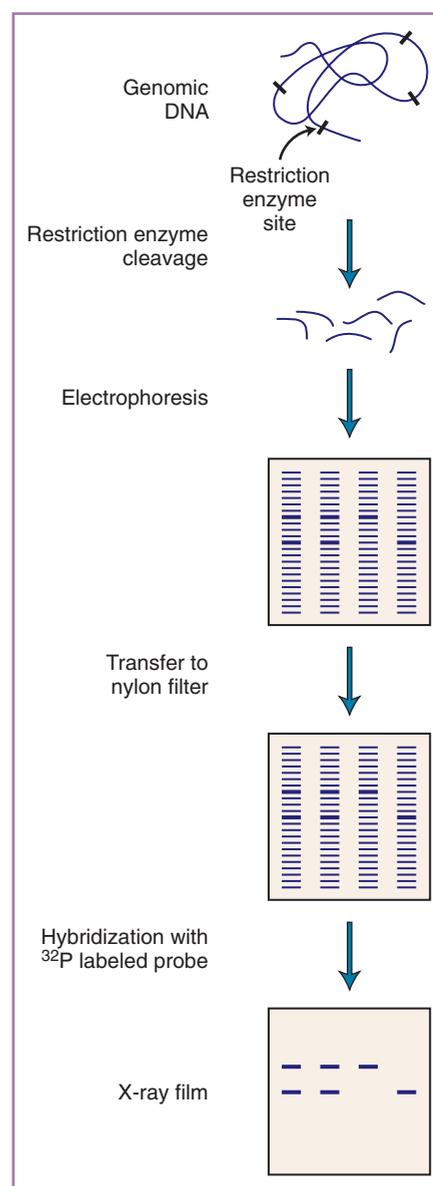

FIGURE 1-32 Southern blotting. DNA is cleaved by a restriction enzyme, separated according to size by agarose gel electrophoresis, and transferred to a filter. After hybridization of the DNA to a labeled probe and exposure of the filter to x-ray film, complementary sequences can be identified.

DNA at different sites. Each restriction enzyme cuts DNA at a defined sequence, usually a palindrome four to eight base pairs in length. For example, EcoRI cuts the palindromic site 5'-GAATTC-3' between the G and the A:

After digestion with restriction enzymes, DNA is size-fractionated by gel electrophoresis (moving through a gel matrix that retards larger fragments more than smaller fragments as they move in response to an electric field). DNA is then denatured into single strands by hydroxide and then transferred (blotted) from the gel to a membrane capable of binding the DNA, usually nitrocellulose or derivatized nylon. Single-stranded DNA on the membrane is then available for hybridization by base pairing with a “probe” sequence. The probe is labeled with either a radionuclide (usually phosphorus 32 [^{32}P]) or a chemical (biotin, digoxigenin, or fluorescein) tag for detection. After hybridization and removal of excess probe, the hybrid fragments are detected by film autoradiography for ^{32}P probes or antibody conjugate-based methods (chemiluminescence or chromogenic reactions). By quantifying the radiologic signal from a Southern blot, it is also possible to assess the copy number of the DNA fragment in the genome relative to known standards. Southern blots have been used to detect insertions and deletions that change the length of the restriction fragment, sequence changes that affect a specific restriction site, and duplications and deficiencies that change the copy number of the fragment.

Polymerase Chain Reaction

Amplification of DNA segments through PCR revolutionized DNA diagnostics for both medicine and forensics beginning in the mid-1980s.^{59,63-65} Synthetic oligonucleotides are used to prime DNA synthesis so that synthesis directed from each primer includes the sequence complementary to the other primer (Fig. 1-33). Multiple cycles of DNA denaturation, primer annealing, and elongation of DNA synthesis create an exponential amplification of the DNA sequence between the two primers. The phases of this cycle are controlled by temperature. Using PCR to amplify specific DNA fragments, multiple diagnostic tests can be performed on minimal amounts of starting material.

Variations in length, such as in dynamic mutations, can be assayed directly by PCR amplification followed by gel electrophoresis to determine the size of the PCR product. For example, diagnostic tests for expanded alleles are available for dentatorubropallidolusian atrophy, Huntington disease, and fragile X syndrome that are based on determining the size of the allele by amplification of patient DNA using oligonucleotide primers that flank the site of expansion.

Anonymous marker loci, such as SNPs and SSLPs, can be assayed in the same way for gene mapping and forensic studies. SNPs are amplified singly or in a multiplex combination of loci and detected by electrophoretic, hybridization, or spectroscopic methods. SNP-based assays are expected to have increasing clinical impact in coming years because they allow highly parallel analysis. Multiplex PCR amplifications can allow parallel analysis of many genetic loci simultaneously. Software modification can allow SNP-based assays to detect CNVs. As noted earlier, as more is known about normal CNVs and those associated with specific diseases, the detection of CNVs will become increasingly used in diagnostics.

Common mutations can also be assayed by PCR using primers specific for each allele or by allele-specific oligonucleotide hybridiza-

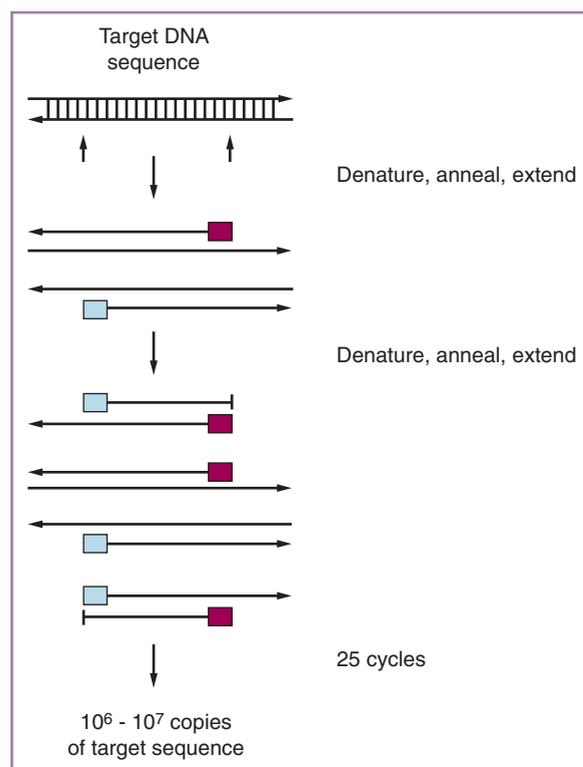

FIGURE 1-33 Polymerase chain reaction (PCR). Repeated synthesis of a specific target DNA sequence (upward arrows) results in exponential amplification. The reaction proceeds from the primers (blue squares, red squares) in the 3' direction on each strand. The first two cycles of the PCR are shown.

tion. For genes in which no single mutation is common among patients, such as the hereditary hearing loss gene *JGB2*, novel sequence variations can be identified by direct DNA sequencing of PCR products from that gene.

DNA Sequencing

Modern genetics, and clinical diagnostics in particular, relies heavily on knowing the exact sequence of nucleotides in genes. Methods to identify sequences of small RNA molecules first began to appear in the late 1960s. However, the appearance of two methods for DNA sequencing of longer fragments in 1977 was a major breakthrough. The *chemical cleavage method*⁶⁶ uses base-specific chemistries to cleave a specified base from its sugar, followed by a second reaction to cleave the phosphodiester bond adjacent to the resulting abasic site. The *chain termination method*⁶⁷ uses enzymatic synthesis of DNA in the presence of dideoxynucleotides; dideoxynucleotides prevent further synthesis beyond their site of incorporation because they lack the 3' hydroxyl group (see Fig. 1-1). The chain termination method is by far the most widely used today. It has been further developed to include fluorescent labels for automated detection and thermostable polymerase enzymes to allow multiple cycles of DNA synthesis for each template molecule. An important extension of this approach for diagnostics is the use of single nucleotide extension products (termed mini-sequencing) to determine alleles based on a single nucleotide change without the added labor and expense of gel or capillary electrophoresis. For example, tests for hereditary hemochromatosis use a version of mini-sequencing called Pyrosequencing to detect the *C282Y* mutation and the *H63D* and *S65C* alleles of the *HFE* gene.

Other Considerations

Current technology is quite powerful and still developing. Vanishingly small specimens can now be used to query ever-expanding numbers of known genes and anonymous DNA markers. Future developments seem likely to continue this trend toward making molecular genetic tests faster, less expensive, and more reliable. This technologic facility and the link between diagnostics and forensics raises numerous ethical, legal, and social issues (often referred to as ELSI). In current practice, one needs to pay particular attention to informed consent, restrictions on use of clinical material in research, and what has been termed genetic privacy. These issues are beyond the scope of this chapter but are as vital to the practitioner who requests genetic testing as they are to the practitioner in the diagnostic laboratory.

Linkage Analysis

Linkage analysis uses DNA polymorphisms as markers to follow the inheritance of a gene within a family. This approach is used to identify unknown genes that contribute to disease, and to follow disease-associated chromosomal segments in affected families before the causal mutation is pinpointed. Linkage analysis takes advantage of meiotic recombination by counting how frequently two loci are inherited together. By comparing the inheritance of a disease with inheritance of alleles at several known DNA polymorphisms (marker loci), it is possible to map the positions of disease genes. Theoretically, any single-gene disorder should be amenable to carrier identification and prenatal diagnosis by linkage analysis once the gene is mapped.

DNA polymorphisms are codominantly inherited, meaning each allele carried by an individual should be detected in a well-designed assay. Several kinds of DNA polymorphisms are frequent in the human genome and have been used in linkage studies.

RFLPs arise through insertions (often of mobile repetitive elements, such as Alu), deletions, and base changes at restriction sites (particularly through deamination of C residues in CG dinucleotides). Assays for RFLP markers by Southern blotting were described previously. RFLPs that have diagnostic importance are usually either converted to a PCR-based assay for the underlying sequence change or replaced for diagnostic use by a linked polymorphism that is more easily assayed.

Insertions and deletions occur frequently in the human genome. These range in size from a single base pair to multigene segments and arise by multiple mechanisms. Small insertion-deletion polymorphisms (also called indels) most likely occur through errors in DNA replication and repair. Larger insertions and deletions arise through several mechanisms, including retrotransposition (such as for Alu repeat sequences) and illegitimate recombination at sites of sequence homology (a frequent finding in microdeletion syndromes). Insertions and deletions were initially detected as RFLPs by Southern blotting. Now indel polymorphisms are usually detected using PCR-based methods designed to be compatible with detecting SNPs, CNVs, or both.

Variable number tandem repeats are more polymorphic than RFLPs and can occur in several alleles, varying by the number of repeat copies present at the locus. Variable number tandem repeats can be detected by Southern blot more sensitively than RFLPs because multiple copies are present. Some variable number tandem repeats are small enough to be assayed by PCR and can be used along with other PCR-based markers.

SSLPs (also called short tandem repeats, simple sequence repeats, or microsatellites) are simple repeats of two, three, or four nucleotides

(such as CACACACACACA). Like variable number tandem repeats, SSLPs can have several possible alleles. The spontaneous mutation rate to a new allele size ranges from 10^{-3} to 10^{-6} . This high mutation rate makes microsatellites useful as markers for genetic mapping: They mutate frequently enough to be highly polymorphic in a population but are stable enough to be transmitted reliably in a pedigree. Simple sequence repeats (microsatellites) occur approximately every 30 kilobases in the human genome (depending on the repeat-length threshold one sets), and a high proportion are polymorphic to some extent across human populations. These markers are easily assayed on a moderate scale but still must be resolved by electrophoresis. Although this is practicable on a modest scale, such as diagnostics for linkage to a mapped but still unknown disease mutation segregating within a family, and has been used for genome-wide scans for genetic linkage, identifying the correct size of each allele is the most significant bottleneck for applications requiring very high throughput with many markers.

SNPs are by far the most frequent class of polymorphism in the human genome. On average, any two copies of the human genome have a polymorphism approximately every 1000 base pairs. Millions of SNPs have been cataloged across the human genome.⁶⁸ On a small scale, these polymorphisms can be detected using the direct analysis methods described for detecting specific mutations. However, for large linkage studies, the number of single genotypes that must be generated is quite large, and higher throughput methods have been and continue to be developed. Competing methods for large-scale genotyping include variations on allele-specific PCR that allow detection by hybridization, highly parallel allele-specific oligonucleotide hybridization on high-density oligonucleotide arrays produced by photolithography,⁶⁹ and mini-sequencing detected by fluorescence or mass spectroscopy.⁷⁰ These recently developed methods will impact DNA diagnostics in both the discovery of new genes involved in disease and in parallel testing for multiple disorders.

Identifying New Disease Genes

Linkage data to identify new disease genes are analyzed by computer algorithms that assess their statistical significance. Although many linkage analysis packages are available, a recurrent question arises with respect to the statistical threshold for declaring linkage. As pointed out by Lander and Kruglyak,⁷¹ each genome scan is really a series of discrete hypotheses. Statistical thresholds must be set to account for the number of hypotheses tested. Lander and Kruglyak argue that in the current era, the number of hypotheses that must be accounted for in linkage studies is a function of genome size, as one could (and does) continue testing markers until the genome is covered. They suggested using statistical thresholds based on the likelihood of false-positive findings in a complete genome linkage scan (genome-wide significance) rather than in a discrete test of any one specific locus (pointwise significance). Computer simulations in the absence of linkage and permutation testing of real linkage data support the idea that genome-wide significance levels are needed to minimize reporting of false-positive findings.

Association and Linkage Disequilibrium

A concept related to linkage analysis is genetic association. Rather than explicitly following coinheritance of traits and markers through a family pedigree, association studies follow covariation of traits and markers in a population. Case and control samples are compared for alleles at each locus to ask whether one or more alleles are significantly overrepresented (disease-associated alleles) or underrepresented (protective alleles) in disease cases. One of the best-studied examples of

genetic association is the increased risk of late-onset Alzheimer's disease for individuals with certain alleles of the apolipoprotein E gene (*APOE*).^{72,73} The amino acid variants encoded by the E4 allele of *APOE* are thought to be directly responsible for the increased risk. However, a strong association of a polymorphism with disease does not necessarily mean that the polymorphism causes the disease, although it does provide immediate diagnostic value. Associations that are not causal occur by *linkage disequilibrium*. Linkage disequilibrium essentially means that specific alleles at two loci are inherited together throughout a population. This occurs when the genetic distance between the loci is small compared with the number of generations in which the two alleles could have separated by recombination in that population. Association studies that take best advantage of population-based linkage disequilibrium may provide the next opportunity to discover genes that act in multifactorial and genetically heterogeneous diseases. Current efforts in this area include both maps of human DNA polymorphisms⁶⁸ and maps of regions coinherited by linkage disequilibrium in the general population.⁷⁴

The technical feasibility of simultaneously following very large numbers of DNA variations in large numbers of clinical subjects has allowed the development of very powerful genome-wide association studies, also called whole-genome association studies (as mentioned earlier). A substantial number of these studies first appeared in 2007, including a large study that combined analysis of several unrelated diseases and traits simultaneously.²¹ By examining variations chosen to represent most if not all common variations (either directly or through linkage disequilibrium with the tested variations) and combining subjects ascertained by collaborating clinical groups, such studies have enormous statistical power for detecting previously unsuspected genetic susceptibilities for disease and will play a large role in the development of personalized medicine.

Impact of the Human Genome Project and Genomics

In 2001, a draft of the human genome was published simultaneously by the publicly funded Human Genome Project² and a private company, Celera.³ Both groups had covered approximately 90% of the genome, and, as discussed previously, estimates of the number of genes had ranged from 30,000 to 40,000 human genes in these first published studies^{2,3} to substantially higher estimates.^{75,76} Then, in 2004 the complete human sequence became available from the Human Genome Project.⁷⁷ The International HapMap Consortium⁴ determined a large fraction of the variations in DNA sequences over populations by cataloging SNPs, and more recently, efforts to catalog CNVs have begun.⁵ As discussed in the introduction to this chapter, these tremendous advances have already had a profound impact on biomedical research. It is the consensus that this research will revolutionize our approach to diagnosis and treatment of human disease over the next decade and beyond, especially with respect to the identification of genetic risk factors for some of the most common disorders today, including cancer, hypertension, coronary artery disease, diabetes, susceptibility to infectious diseases, and obesity. Certainly, diagnostic testing by methods outlined in this chapter will be improved with this information. It is difficult to estimate when these advances will make their way into clinical practice, although some have ventured to gaze into the future.¹

Conclusion

As noted in the beginning of this chapter, genetics plays an important role in the day-to-day practice of obstetrics. We have summarized the basic concepts of genetics as they apply to the understanding and treatment of human diseases and have emphasized those areas most pertinent to the practice of obstetrics. Clinical genetics will increasingly become a discipline that physicians will be expected to use for the care of their patients. Research in molecular biology and molecular genetics, along with the genetic information provided by the Human Genome Project and genomics, will provide the information necessary for physicians to formulate new clinical approaches to medical diagnostics and therapeutics.

Acknowledgments

We acknowledge the contributions of the authors of earlier editions of this book, O. W. Jones and T. C. Cahill, for the organization and many of the figures and tables used in the present chapter. We also thank Dr. Karen Arden for providing the spectral karyotyping image (see Fig. 1-14).

Chapter 2

Normal Early Development

Kurt Benirschke, MD

The developing fertilized ovum enters the uterine cavity on about the 4th day after fertilization. During its journey through the fallopian tube, its cells proliferate within the zona pellucida (Fig. 2-1), and shortly before entering the uterus, a blastocyst cavity is formed. Differentiation of a human ovum into embryonic and future placental cells first occurs in a 58-cell morula, as described by Hertig.¹ His specimen was 6 days old and had five embryonic cells (the “inner cell mass,” or “stem cells”), and 53 trophoblastic cells constituted the wall of this uterine blastocyst. The polar bodies and an apparently degenerating zona pellucida were still present in the specimen, features destined to be lost shortly before implantation. These landmarks are of importance now when embryonic stem cells are being harvested and when prenatal diagnosis, intracytoplasmic sperm injection (ICSI), and other aspects of assisted reproductive technology (ART) are actively being pursued.

Proliferation of the trophoblastic shell after this stage of development is rapid, and a segmentation cavity develops, with the more slowly reproducing embryonic cells assuming a marginal “polar” position. The adjacent trophoblastic cells enlarge and secure implantation, which is assumed to take place on about the 6th or 7th day after fertilization (Fig. 2-2). Attraction to certain regions of the endometrium is presumed to take place because of molecular signals expressed on the respective surfaces^{2,3} and occurs only during the “window of receptivity” that is regulated by hormonal action on the endometrium.⁴ With the very rapid enlargement occurring in the anchoring trophoblastic cells, the endometrial cells are dissociated by mechanisms to be discussed later (see Microscopic Development). The entire blastocyst thus comes to assume an “interstitial” position (i.e., it sinks entirely into the endometrium at the site of attachment). The process may well be aided by the collapse of the blastocyst cavity that occurs at this time (see Fig. 2-2). A deposition of fibrin or occasionally a coagulum at the site of penetration are common events thereafter, and then the implanted trophoblastic shell comes to be surrounded by endometrium (decidua) on all sides (Fig. 2-3). Perhaps some endometrial proliferation at the edges seals the defect.

The portion of decidua lying between blastocyst and myometrium is the decidua basalis; the portion covering the defect is the decidua capsularis. Eventually, the latter comes to lie on the outside of the placental membranes. The decidua of the opposite side of the uterus is the decidua vera. At the time of implantation, the 0.1-mm blastocyst can be detected only by a dissecting microscope. Within a few days, however, it will constitute a polypoid protrusion that can readily be seen by careful inspection of the endometrium. Thus, the approximately 14-day-old ovum (Fig. 2-4) looks like a polyp and already

has a differentiated, elongated embryo with amnion and yolk sac cavities.

Occasionally, a small blood clot is attached to the implantation site, the *Schlusskoagulum*, whose presence may be detected clinically by spotting (Hartman sign) and may lead to misinterpretation of the length of gestation. Decidual hemorrhages and small areas of necrosis at the site of trophoblastic penetration are common at this time and later.

Macroscopic Development

In most recorded sites of early implantation, the ovum was found in the upper portion of the fundus and the development of the placenta has been followed by ultrasonography. Thus, Rizos and colleagues⁵ found the 16-week placenta to be attached anteriorly in 37% of patients, posteriorly in 24%, in a fundal position in 34%, and both anteriorly and posteriorly in 4%. Others have used sonography to measure placental size and volume prenatally and have correlated their findings with fetal outcome.⁶ Of interest in this context is the finding from sonographic study that low implantation of the placenta in the uterus occurs frequently, with the formation of an apparent placenta previa. Moreover, a low implantation may change through differential growth of the placenta and uterus and apparent marginal placental atrophy. Thus, even though low implantation is observed in early gestation, at term the situation often does not clinically resemble placenta previa.⁷ In the report of Rizos and colleagues, only 5 of 47 patients in whom placenta previa was diagnosed with ultrasound between 16 and 18 weeks actually had this condition when delivery occurred at term. These findings are important in the interpretation of the shape of the placenta at term and necessitate revision of former impressions.

Most commonly, the placenta develops at the uterine fundus. Through rapid expansion of the extraembryonic cavity (the exocoelom) and proliferation of the trophoblastic shell, the ovum bulges into the endometrial cavity at the time of the first missed menstrual period. The surface is flecked by tiny hemorrhages and necrotic decidua. With continued expansion of the embryonic cavity, the surface becomes attenuated, the peripheral villi atrophy, and the future placental “membranes” form. They consist of decidua capsularis on the outside, hyalinized villi and trophoblast in the middle, and the membranous chorion laeve (and amnion) on the inside.

The relationship of these membranes to the remainder of the uterus was sequentially traced in numerous pregnant uteri in a series collected

FIGURE 2-1 Two-cell stage (30 hours) and eight-cell morula.

by Boyd and Hamilton.⁸ Their observations suggested that the membranes truly fuse with the decidua vera of the side opposite to implantation in the 4th month of pregnancy, thereby obliterating the endometrial cavity. The decidua capsularis appeared to degenerate in their specimens before this time, and what is present on the outside of the term-delivered placenta was construed to be decidua vera attached to chorion. With the atrophy of peripheral villi and attachment of the membranes to the opposite side of the uterus, the macroscopic delineation of the placenta is essentially completed. Next, the formation of amnion, yolk sac, and body stalk is described.

Figures 2-3 through 2-7 demonstrate the developing placenta and finally an embryo at 7 weeks with an embryonic crown-rump length of 15 mm; the width of the entire specimen is approximately 25 mm. With the “herniation” of the chorion laeve into the endometrial cavity, its surface has been smoothed and stretched. At the edge, the decidua is thrown into a fold and minute coagula are present. When a tangential section is removed, the extension of the villous tissue for some distance onto the abembryonic pole of the cavity can be seen. The villi have already completely atrophied at the apex. The embryo is contained within the amniotic sac, which does not completely fill the chorionic cavity (see Fig. 2-8). It is suspended within the cavity by a gel (the magma reticulare) that liquefies on touching. When the sac is opened, the embryo and umbilical cord emerge (see Fig. 2-7).

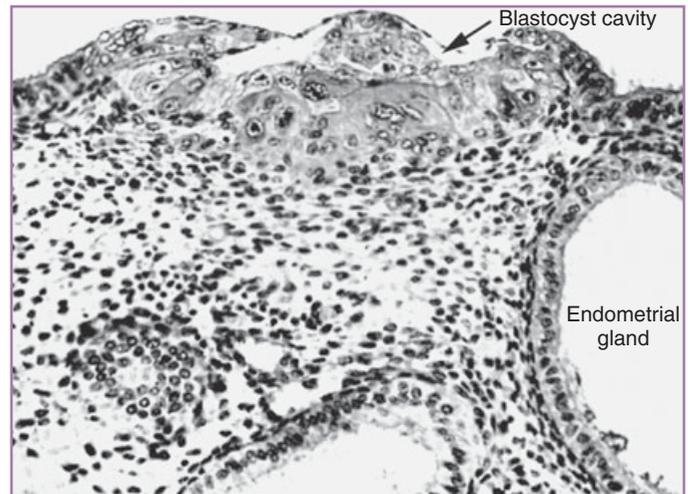

FIGURE 2-2 Implanted human embryo at a gestational age of approximately 7½ days. The blastocyst cavity has collapsed, and early invasion into the endometrial cavity has occurred with giant cells. The embryo is a small ball in the blastocyst cavity. (Courtesy of A. T. Hertig.)

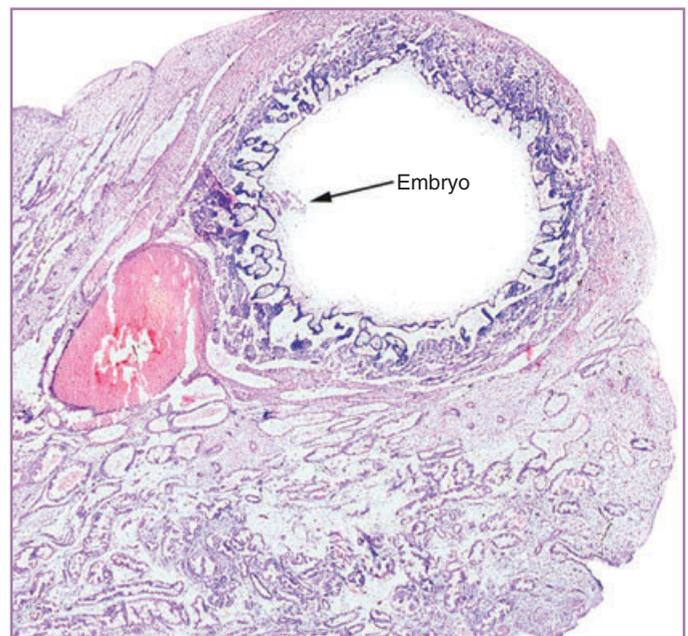

FIGURE 2-3 An embryo sectioned longitudinally at approximately 14½ days of gestation.

An understanding of the morphogenesis of these structures is essential and can be gained from a study of Figure 2-4. In this histologic section, the embryo is sectioned longitudinally. The ectoderm appears as a dark streak and is contiguous with the amniotic sac epithelium that lies below. On the other side of the embryo lie the endoderm and yolk sac. The mesoderm is seen to “flow” from the left caudal pole of the embryo onto the inner surface of the trophoblastic shell. This streak of mesoderm ultimately becomes the substance of the umbilical cord. As the embryo grows and folds in such a manner as to enclose the endoderm, the amnion enlarges and the embryo may be thought of as herniating into this amniotic sac. A portion of the

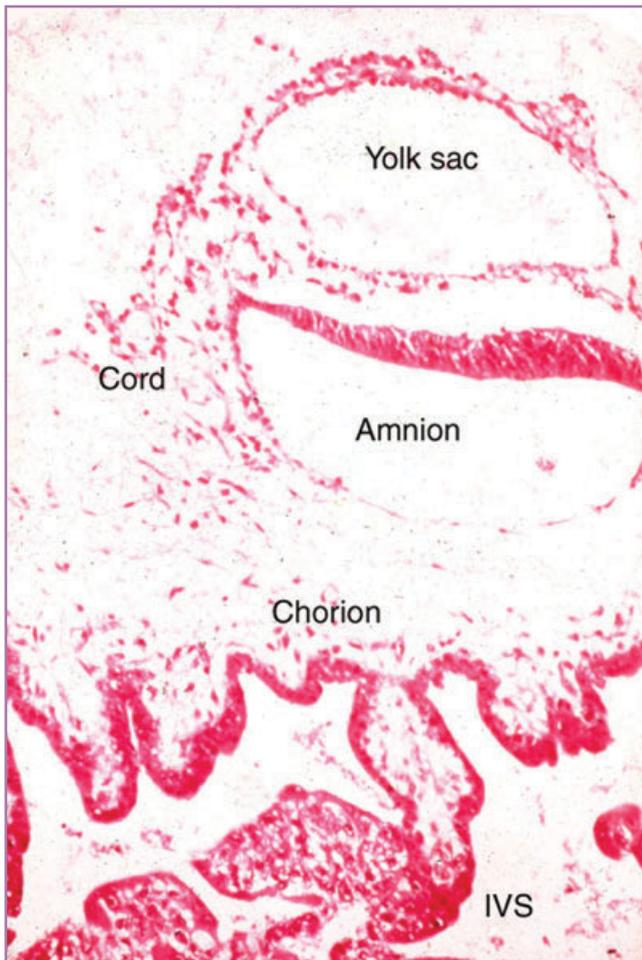

FIGURE 2-4 Human embryo at approximately 14 days' development. The chorion extends its connective tissue into the developing villi. The umbilical cord develops from the embryonic mesoderm. The amnion is contiguous with the embryonic ectoderm and will fill with fluid, and then the embryo will "herniate" into this amniotic cavity. IVS, intervillous space.

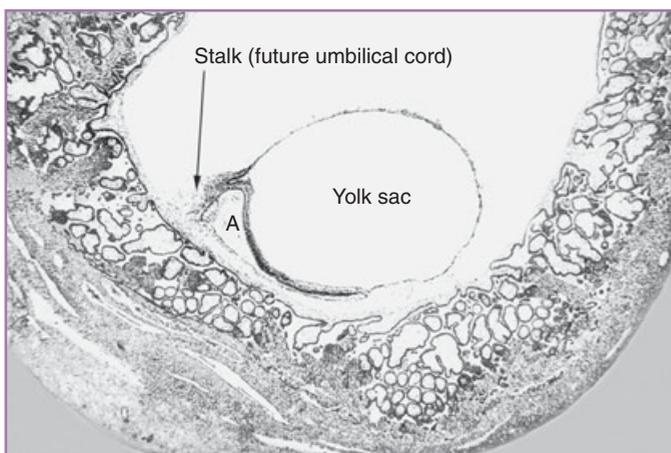

FIGURE 2-5 Implanted human embryo at 19 days' development, with villous development circumferentially. (Courtesy of A. T. Hertig.)

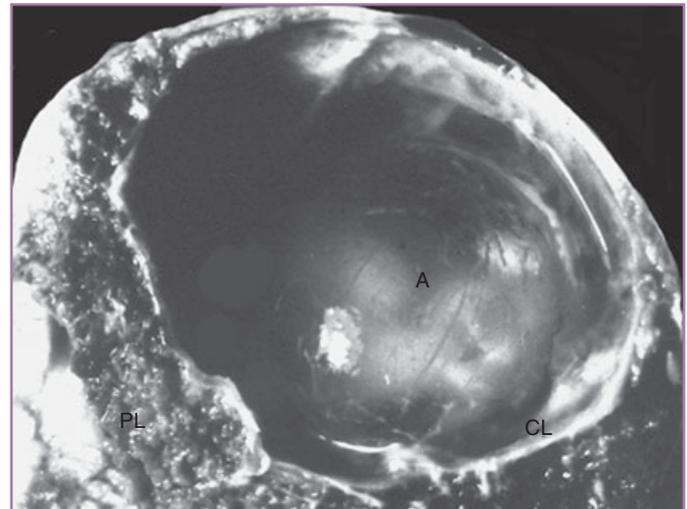

FIGURE 2-6 Seven-week gestation. A portion of the chorion laeve (CL) is removed to show partial atrophy of membranous villi, formation of definitive placenta (PL), and amniotic sac (A), which only partially fills the chorionic cavity at this age. (Courtesy of Dr. Jan E. Jirasek, Prague.)

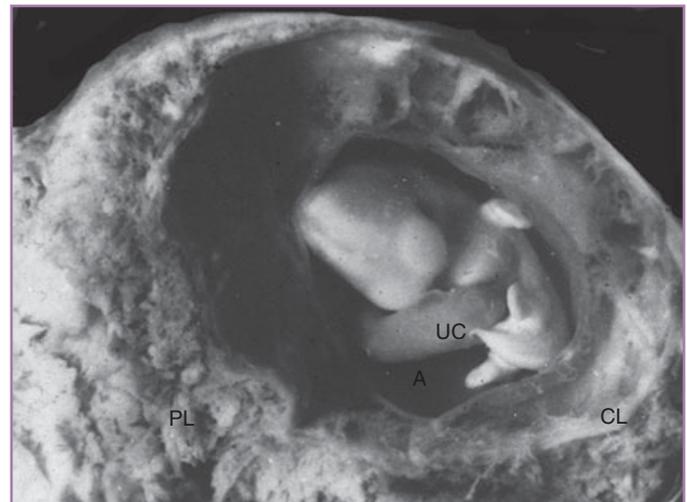

FIGURE 2-7 Seven-week gestation. Same specimen as in Figure 2-6, with the amnion (A) opened to disclose the 15-mm embryo and its umbilical cord (UC). CL, chorion laeve; PL, placenta. (Courtesy of Dr. Jan E. Jirasek, Prague.)

primitive yolk sac will be enclosed by the embryo to become its gut; another portion will be exteriorized (i.e., will lie outside the amniotic sac) and will be connected by the omphalomesenteric (vitelline) vessels and duct. Most often, these yolk structures disappear completely in later development; only in occasional term placentas can the calcified atrophic remnant of yolk sac be found at the periphery as a tiny (3-mm), yellow, extra-amniotic disk.

Once the amniotic sac has enclosed the entire embryo, it reflects on the umbilical cord, whose entire length it will eventually cover and to which it will be strongly adherent. At 8 weeks, the amnion is a thin translucent membrane (Fig. 2-8). It does not fully expand to cover the inside of the entire chorionic sac until about 12 weeks. It never completely grows together with the chorion, however, so that in most term

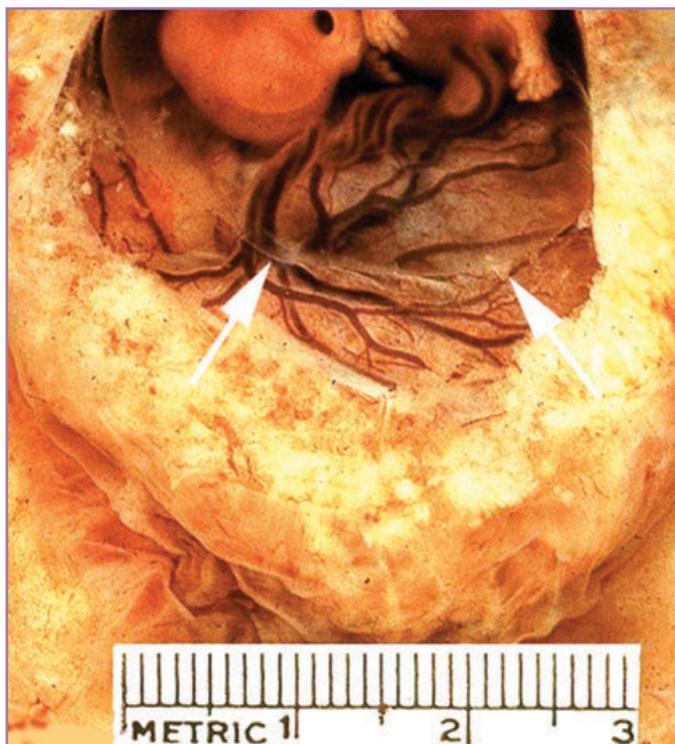

FIGURE 2-8 Pregnancy at 8 weeks with 20-mm embryo. The top portion of chorion laeve has been removed, thus disclosing amnion at arrows.

placentas the amnion may be dislodged from the chorion and the placental surface. This becomes particularly obvious in meconium discharge. The amnion does not have any blood vessels but is composed of a single layer of ectodermal epithelium, peripheral to which is a layer of delicate connective tissue with some macrophages.⁹ Sophisticated studies have now shown that amnion and chorion also possess sheets of delicate elastic membranes.¹⁰ It is presumed that these aid in the elasticity of the membranes and help prevent premature rupture. Betraying the ectodermal origin of the amnion are small plaques of squamous metaplasia near the insertion of the term placenta's umbilical cord that must not be mistaken for amnion nodosum.

When the embryonic cells differentiate into mesoderm, endoderm, and ectoderm, the mesoderm is first clearly seen at the caudal pole of the embryonic disk (see Fig. 2-4). The mesodermal cells rapidly proliferate and send a column of cells streaming toward the inner surface of the trophoblastic cavity, which they then come to line. This column is ultimately destined to become the umbilical cord, and blood vessels and a rudimentary allantoic sac grow into this body stalk from the primitive yolk sac—hence the term *chorioallantoic vessels*. It is commonly thought that the inner cell mass, the future embryo, lies centrally in the early stages of implantation and that for this reason the umbilical cord comes to be attached to the center of the placenta.

Aberrant attachment, such as at the margin or to the membranes (velamentous insertion), may be explained by one of two contradictory hypotheses. According to one hypothesis, the embryo had a less than perfect central position at the time of implantation and was perhaps even on the opposite side; thus, when the mesoderm proliferated, the location of the cord was established on the surface of the endometrium, the area destined to become membranes. The second hypothesis suggests that normal central implantation occurred but the area of implantation was less than optimal for placental development. Subse-

quently, the expansion of the placenta occurred to one side rather than in a uniform centrifugal manner. The already established location of the cord therefore changed from a central to a lateral position, a process called trophotropism that is also witnessed in the “migration” of a placenta that was earlier thought to be previa.

This second hypothesis is supported by the much more common marginal or velamentous position of cords in multiple pregnancy, in which one can imagine there is competition for space by and collision of expanding placentas. In term placentas, moreover, marginal placental atrophy is often found, and the finding of succenturiate (accessory) lobes can best be explained by this mechanism. Also, the ultrasonographic finding of a “wandering” placenta favors this assumption, as does the fact that most of the few early embryos studied had a relatively central implantation. The first hypothesis is supported by the finding of a much higher frequency of velamentous insertion of the cord in aborted specimens than in term placentas.¹¹

The umbilical cord measures approximately 55 cm in length at term, but extreme variations occur for largely unknown reasons. Because a normal cord weighs as much as 100 g and the segments of cord supplied with the placenta vary so much, the cord and membranes should be removed before the placental weight is ascertained. More often than not, the cord is spiraled, most commonly in a sinistral manner. Numerous theories have been presented to explain this helical arrangement, but the cause remains largely unknown. Because such twists do not exist in species with longitudinal orientation in bicornuate uteri and because of the observed mobility of the primate fetus in its uterus simplex, it is most likely that fetal movements are the cause of the cord twisting.^{12,13} Further support for this explanation comes from the entwinement of cords in monoamniotic twins.

The cord contains two umbilical arteries and one vein. A second rudimentary vein, the omphalomesenteric (vitelline) vessels, and the allantoic duct of early embryonic stages atrophy, and only on rare occasions are often discontinuous remnants of these structures found in the term cord. The two umbilical arteries anastomose through a variably constructed vessel within 2 cm of the insertion of the cord in almost all normal placentas; this is the so-called Hyrtl anastomosis. There are no nerves in the cord. True knots occur in a few umbilical cords, particularly in very long ones, but much more common are so-called false knots. They represent redundancies (varicosities) of umbilical vessels that may protrude on the cord surface and have no clinical significance.

The surface vessels of the placenta represent ramifications of the umbilical vessels and pursue a predictable course on the chorionic surface. In general, one arterial branch is accompanied by one branch of the vein, and each terminal pair of vessels supplies one fetal cotyledon. The arteries may be recognized by their superficial location (i.e., they cross over the veins). Anastomoses between superficial vessels do not occur; for that matter, no such connections ever develop between villous vessels. Each district is isolated and distinct from the others.

Two types of surface vascular arrangements have been observed, a very coarse and sparse vasculature and finely dispersed vessels. No significantly different fetal outcomes correlate with these features, however, and mixtures of the two types exist in single placentas. The number of terminal perforating vessels determines the number of fetal-placental cotyledons or districts. In most placentas, this number is about 20, somewhat more than the number of lobules that can be seen from the maternal side of mature placentas. In general, there is correspondence of fetal lobules with maternal septal subdivisions when injection studies are performed of both circulations.¹⁴

Authors who have performed such dual injections envisage that the intervillous circulation is achieved by the injection of blood from a

decidual artery into the center of a fetal cotyledon, which there disperses from a central cavity in the villous tissue to the periphery of the cotyledon and to the undersurface of the chorion, from where it is drained by veins in the septa and decidual base.¹⁵ The loose central structure of cotyledons can easily be demonstrated when a placenta is horizontally sectioned. This more conventional model of cotyledonary arrangement of villous structure and intervillous circulation has been challenged by Gruenwald,¹⁶ who envisaged a different lobular architecture, with arterial openings occurring at the periphery of cotyledons, a concept that has not yet been unequivocally refuted. The former notion that all intervillous blood flows laterally to the marginal sinus, however, is no longer acceptable.

The normal term placenta from which membranes and cord have been trimmed weighs between 400 and 500 g. There is enormous variability in placental size and shape, as there is in fetal weight. Some variations can be explained by racial differences, altitude, pathologic circumstances of implantation, diseases, or maternal habits such as smoking. In many cases, however, the deviations from “normal” are as difficult to explain as the factors that ultimately determine fetal and placental growth in general. Systematic studies of placental structure have given some insight into the complexities; they have been summarized in the careful analysis by Teasdale.¹⁷ Absolute growth, as determined by DNA, RNA, and protein content, occurs in the placenta to the 36th week of gestation. Thereafter, proliferation of cells does not normally occur, and the placenta undergoes only further maturational changes. Previous studies have suggested an expansion of villous surface to between 11 and 13 m² at term, whereas Teasdale’s careful measurements suggest that the maximum is reached with 10.6 m² at 36 weeks, decreasing to 9.4 m² at term. The fetal-to-placental ratio is estimated to change from 5:1 in the third trimester to 7:1 at term, most rapidly increasing during the last month of gestation. Reasons for discrepancies of these measurements reported in the literature are partly explained by inconsistent handling of the organ at delivery. Thus, a variable amount of blood may be trapped, depending on the time of cord clamping. It is widely accepted now that the delivered placenta has a smaller volume, in particular is less thick, than before delivery, as ascertained by sonography.¹⁸ Therefore, for quantitative assessment, a histometric analysis must accompany such correlative study. Apparently, the slight increase in placental volume occurring in the last month of pregnancy results from an expansion of the “non-parenchymal” space (i.e., villous capillary size, decidua, septa, and fibrin). Thus, during the last month of gestation, fetal growth occurs without a commensurate increase in placental volume, indicating that changes must occur in perfusion or transport function of the placenta to ensure enhanced delivery of metabolic substrates to the fetus. Significant advances in technology are likely to discover new factors that regulate fetal and placental growth. Thus, the evolution of microarrays for the ascertainment of gene activity promises to become of major importance.¹⁹

Macroscopically, a delivered normal term placenta can be described as a disk-shaped, round, or ovoid structure measuring 18 × 20 cm in diameter and approximately 2 cm thick. The cord is normally inserted near the center of the disk (marginal in 7% and on the membranes in 1%); it measures 40 to 60 cm in length and 1.5 cm in thickness. It has two arteries, one vein, and a number of helical spirals. The membranes are attached at the periphery of the placental disk and have some degenerated yellow decidua on their outer surface and a smooth glistening inner amniotic surface. The amnion is only slightly adherent to the chorionic face of the placenta, from which it can be stripped by forceps, but it is firmly attached to the cord, upon which it reflects.

The fetal surface of the placenta is blue because of the fetal villous blood content seen through the membranes; most maternal blood has been expelled by the uterine contractions that expelled the placenta. Irregular whitish plaques of subchorionic fibrin project slightly between fetal vessels and produce what has been referred to as a bosselated surface; the plaques are indicative of a mature organ and result from eddying of the maternal blood in the intervillous space as it turns direction.

The maternal surface usually has a film of loosely attached blood clot, which when removed discloses the thin, grayish layer of decidua basalis and fibrin that comes away with delivery. In the fibrin, yellow granules and streaks of calcification characterize maturity. They are extremely variable in amount and have no clinical significance. The maternal surface is usually broken up into irregular lobules (cotyledons) by crevices that continue into partial or complete septa between fetal cotyledons. These septa are constructed of decidual cells and cellular trophoblast. On sectioning, the dark red villous tissue reflects the content of fetal blood. Loosely structured areas represent intervillous lakes, the presumed sites of first blood injections (“spurts”) from decidual arteries.

Microscopic Development

It is likely that some adhesion molecules are essential for blastocyst attachment to the endometrium.^{2,20} Once the trophoblastic shell has attached, marked changes occur on its surface and invasion is accomplished by dissociation and ingestion of endometrial cells. A completely interstitial implantation of the blastocyst is accomplished on the 9th day of gestation. The trophoblastic shell has proliferated appreciably, particularly at its basal portions, and most trophoblastic cells possess disproportionately large nuclei and form a syncytium. Within this mass of trophoblastic cells develop clefts (lacunae) that coalesce to form the most primitive type of the future intervillous space.

At about this time or on the next day, the somewhat congested decidual vessels are tapped into by the trophoblast. The first maternal leukocytes have been observed on day 11 in this primitive intervillous space, later to be followed by blood, thus establishing the primitive intervillous circulation.¹ At the same time, the trophoblastic cells can be seen to differentiate into a central cellular type (cytotrophoblast and extravillous trophoblast, and into the future Langhans layer) and peripheral syncytiotrophoblast (Fig. 2-9). The syncytial nuclei never undergo mitosis and grow only by the incorporation of cytotrophoblastic nuclei and cytoplasm; only the latter cells are capable of mitosis.^{21,22} Recent studies indicate that the formation of the syncytium from cytotrophoblast is very complex. Thus, Debieve and Thomas²³ provided evidence that inhibin is involved; others have identified that it requires a protein (“syncytin”) derived from a genetic contribution of a retroviral envelope gene.²⁴⁻²⁶

On day 13, the first connective tissue may be observed in the central portion of the future villi. It will rapidly expand peripherally into the cell columns of trophoblast. Evidence suggests that this connective tissue core derives from the mesoderm of the extraembryonic space and perhaps the body stalk (see Fig. 2-4) and not by central “delamination” from trophoblast. By the 30th day, a truly villous ovum is formed, and the basic future development of the villous structure is delineated. Villi are found around the entire circumference at first, only to atrophy over the pole later. Commencing almost simultaneously, on the 14th day and subsequently, is the development of villous capillaries. Moreover, fetal macrophages (the Hofbauer cells) infiltrate the villi. Although in 1968 Hertig¹ discussed in great detail how villous capillaries also

derive from delaminated trophoblastic cells by the internal detachment of angioblastic cells, more likely their origin is from fetal mesoderm or endoderm. These are not idle problems of the embryologist but pertain directly to an understanding of the genesis of hydatidiform moles. If villous connective tissue and vessels are definitely derived from the embryo (rather than the trophoblast), hydatidiform moles must at one time have had an embryo. Occasionally, complete hydatidiform moles

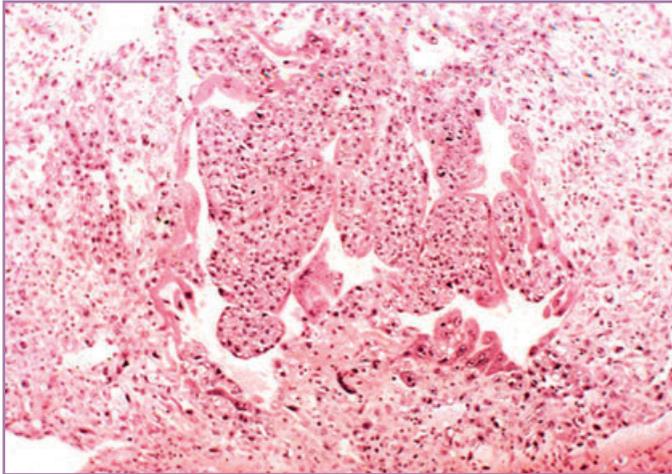

FIGURE 2-9 Trophoblastic shell of a 13-day-old ovum. Cell columns composed of solid cytotrophoblast are covered by syncytiotrophoblast lining the entire intervillous space, which is still devoid of maternal blood. H&E, $\times 300$.

have been shown to contain degenerated embryos, but in most cases the embryo and its vessels have disappeared.^{27,28} Villous vessels coalesce and connect to the omphalomesenteric and later allantoic vessels of the embryonic body stalk, and a true fetal circulation is active by 21 days.²⁹ The initial fetal blood cells come from yolk sac, and only after the 2nd month do they issue from fetal hematopoietic islands. With an established circulation, the villi are now called tertiary villi.²⁰

The villous structure changes appreciably during further development, and the gestational age can be crudely estimated from the histologic appearance of the villi. In young placentas, the mesenchymal core of villi is extremely loosely structured, appearing almost edematous (Fig. 2-10). Capillaries are filled with nucleated cells and lie very close to the villous surface. This surface is uniformly covered by an inner layer of cellular cytotrophoblast, which contains numerous mitoses and in turn is covered by a thick layer of syncytium that contains abundant organelles in its metabolically active cytoplasm. The syncytium is functionally the most important part of the placenta. With advancing age the villi elongate, lose their central edema, branch successively, and decrease in diameter. At term they contain little mesenchyma and are filled with distended capillaries. Cytotrophoblastic mitoses are rare after 36 weeks in normal placentas. The syncytium tends to form buds and “knots,” many of which break loose and are swept into the intervillous circulation, by which they reach the maternal lung. They are destroyed in the lung as they have no mitotic capability, and they are presumably the source of the large quantities of “free DNA” in the maternal circulation that is now used for genotyping.³⁰ Fibrin and fibrinoid, also eosinophilic but composed of a variety of novel protein compounds, are normally accumulated in ever-increasing quantities on the surface of villi, in the subchorionic area,

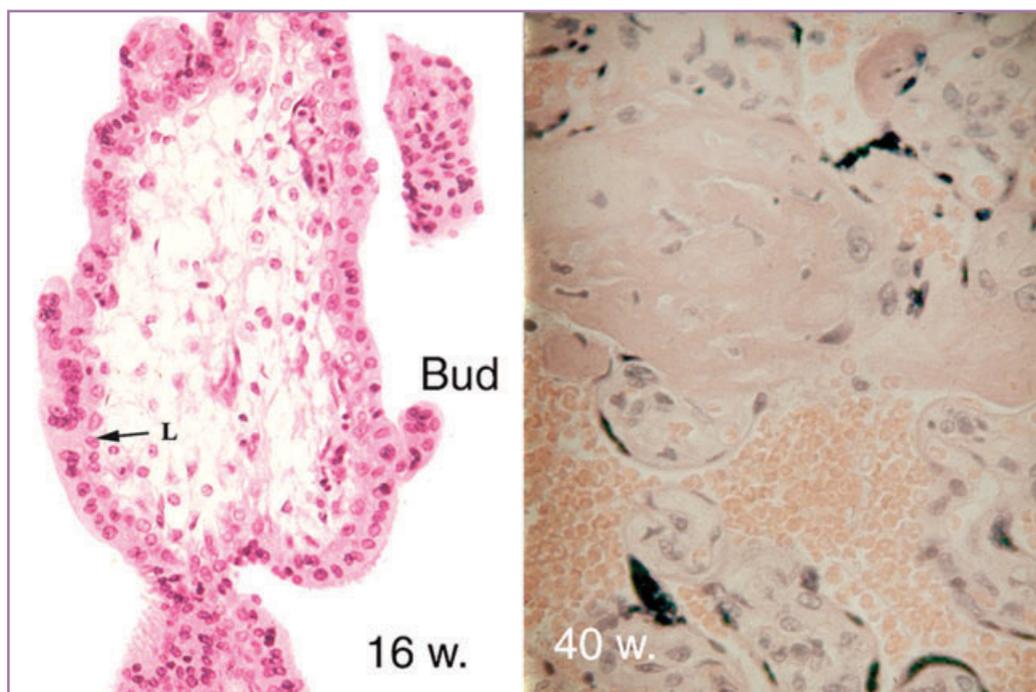

FIGURE 2-10 Placental villi. **Left:** Villi of 16-week-old placenta. Note the very loosely structured mesenchymal core containing isolated macrophages, the thin-walled fetal capillaries filled with nucleated red blood cells, and the double-layered trophoblastic surface. and along the floor of the placenta, where the Rohr and Nitabuch fibrin layers mingle with the decidua basalis. Fibrinoid of the placenta is a complex admixture of true fibrin and a variety of proteins such as laminins and collagens.³¹ Near term, some of these fibrin deposits become calcified in a normal process that may become excessive in the postmature placenta. The amount of calcium varies greatly but has no deleterious influence on placental function. The placental septa, composed of cellular extravillous trophoblast ("X cells" or intermediate trophoblast) and decidua, often undergo cystic change as a sign of maturity.

The X cell, now more commonly called the extravillous trophoblast, has recently been the focus of attention. It is a separate lineage of trophoblast that is intimately related to fibrinoid deposition, the production of the major basic protein and placental lactogen. Most so-called placental site giant cells are X cells and are often confused with decidual stromal elements.^{27,32} From these basal trophoblastic elements come a variety of enzymes, especially stromelysin-3, to prepare for the invasion of the decidual floor and blood vessels.³³ These cells also infiltrate into the orifices of basal decidual spiral arterioles (Fig. 2-11). Hustin and colleagues^{34,35} offered evidence that these extravillous trophoblastic cells completely occlude these vessels in early pregnancy, thus allowing only a filtrate of maternal blood to enter the intervillous space. This hypothesis was challenged with studies using Doppler flow in rhesus monkeys.³⁶ These investigations showed an early vascular connection of the maternal arterial circulation with the intervillous space, although flow was of low resistance and pulsatility from day 20 on. The population of Hofbauer cells derives from circulating fetal blood, increases in the first 36 weeks, and falls thereafter.¹⁷ Although their precise function

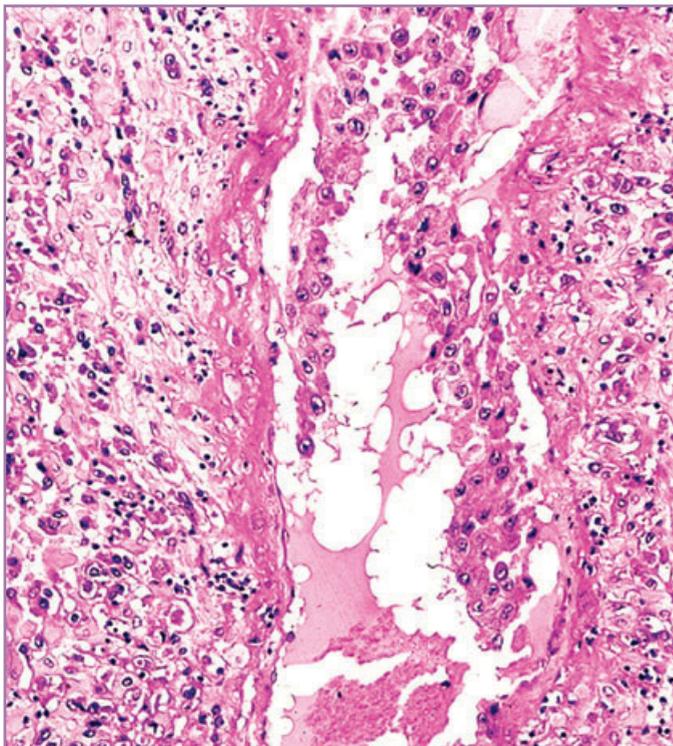

FIGURE 2-11 Term placental floor with infiltration of extravillous cytotrophoblast into a spiral arteriole. The walls of the arteriole have been transformed with fibrin deposits. The dark cells in the endometrial stroma are also extravillous trophoblast. H&E, $\times 128$.

is not well understood, immunohistochemical studies show that this large population of cells represents fully differentiated phagocytes.³⁷ After hemolysis, they are seen to produce hemosiderin; in the chorionic surface, they actively transport meconium after its discharge, and it is speculated that they remove antifetal antibodies.

At the site of implantation, trophoblastic cells intermingle extensively with decidua basalis; indeed, they penetrate into the superficial portions of myometrium. These areas are often characterized by scattered lymphocyte infiltration and decidual necrosis.³⁸ Cytotrophoblastic cells enter the opened mouths of maternal arterioles and penetrate deeply along their endothelial linings; indeed, packets of villi "herniate" into open maternal vessels.³⁹ Some trophoblastic cells infiltrate the decidua and myometrium, often fusing to form placental giant cells (Fig. 2-12); others invade the spiral arterioles from the outside. They cause considerable local change, including fibrin deposition, and alter the normally contractile vessels to presumably rigid uteroplacental arteries. Thrombosis is not found normally but is a common finding when hypertensive changes are superimposed.

Electron microscopic study of placental villi in general supports the findings made by light microscopy, but it adds significant new details.

FIGURE 2-13 Scanning electron micrograph of mature villi at the periphery of the cotyledon. Note the fine uniform structure, rare adherence, and microvillous velvety surface of the terminal villi ($\times 100$). (From Sandstedt B: The placenta and low birth weight. *Curr Top Pathol* 66:1, 1979.)

The arborization of villi and their complexity are best appreciated in scanning electron micrographs (Fig. 2-13). In the more peripheral areas of cotyledons, the villi appear histologically more mature (i.e., they are smaller and have more branches and less stroma). The syncytial surface is covered by numerous minute microvilli, and syncytial bridges are occasionally seen. In the central portion of the cotyledon, the villi are plump and less branched. Freeze-fracture scanning electron microscopy discloses the proximity of fetal vessels to the basement membrane and the profusely microvillous surface of the syncytium (Fig. 2-14). With advancing maturity, the Langhans cytotrophoblastic layer not only becomes less prominent but also is interrupted in many more places. Here, then, the fetal capillaries abut a thin layer of syncytium, presumably the most efficient site of transfer.

These electron micrographic features of maturity are also found more frequently in the periphery of cotyledons than in their more immature-appearing centers, but qualitative differences do not exist.⁴⁰ The slightly different electron micrographic features of villi in part relate to the state of contraction of fetal capillaries (Fig. 2-15), and they may in part be the result of oxygen supply. Desmosomes have been identified by scanning and transmission electron microscopy in trophoblast.⁴¹ They interlock syncytium with cytotrophoblast, and when found with free membranes in the cytoplasm of the syncytium, they presumably represent the remnants of the fusion-incorporation process of cytotrophoblast into syncytium. The structure of the syncytiotrophoblastic cytoplasm is extremely complex. It is filled with minute vacuoles, ribosomes, mitochondria, and the other usual cytoplasmic components. On the other hand, the cytotrophoblastic cytoplasm is relatively simple, reflecting its presumed primary function as precursor cells for syncytium.

Chapter 3

Amniotic Fluid Dynamics

Marie H. Beall, MD, and Michael G. Ross, MD, MPH

Amniotic fluid (AF) is necessary for normal human fetal growth and development. It protects the fetus from mechanical trauma, and its bacteriostatic properties may help to maintain a sterile intrauterine environment. The space created by the AF allows fetal movement and aids in the normal development of both lungs and limbs. Finally, AF offers convenient access to fetal cells and metabolic byproducts and therefore has been used for fetal diagnoses more often than any other gestational tissue.

The existence of AF has been appreciated since ancient times. Leonardo drew the fetus floating in the fluid, and William Harvey hypothesized that the fetus was nourished by it. Only in the late 19th century, however, did AF become available for study other than at delivery, and fluid sampling by amniocentesis was rarely performed until the second half of the 20th century. Genetic amniocentesis for fetal sex determination was first performed in 1956.¹ Research on the characteristics of AF is therefore a relatively recent development. This chapter reviews the current state of knowledge regarding the volume, composition, production, resorption, and volume regulation of AF.

Volume of Amniotic Fluid

In the first trimester of pregnancy, the amnion does not contact the placenta, and the amniotic cavity is surrounded by the fluid-filled exocoelomic cavity.² The exocoelomic fluid participates in the exchange of molecules between mother and fetus; at this stage, the function of the AF is uncertain.

By the end of the first trimester of human gestation, the exocoelomic cavity has been progressively obliterated, and the amniotic cavity becomes the only significant deposit of extrafetal fluid. AF volumes in the first half of pregnancy have been directly measured and are found to increase logarithmically.³ AF volumes were first estimated in the latter two thirds of pregnancy using dilution techniques, and these original quantitative findings were supported by semiquantitative measurements performed with ultrasound (Fig. 3-1).⁴ All methods demonstrate that AF volume increases progressively between 10 and 30 weeks of gestation. Typical volumes increase from less than 10 mL at 8 weeks³ to 630 mL at 22 weeks, and to 770 mL at 28 weeks of gestation.⁵ After 30 weeks, the increase slows, and AF volume may remain unchanged until 36 to 38 weeks, after which the volume tends to decrease. If the pregnancy proceeds after the term date, AF volume decreases sharply, averaging 515 mL at 41 weeks. Subsequently, there is a 33% decline in AF volume per week,⁶⁻⁸ consistent with the increased incidence of oligohydramnios in post-term gestations.

The rate of change of AF volume depends on the gestational age. The rate of AF volume increase is 10 mL/wk at the beginning of the fetal period, and it increases to 50 to 60 mL/wk at 19 to 25 weeks' gestation before undergoing a gradual decrease until the rate of change equals zero (i.e., volume is at maximum) at 34 weeks. Thereafter, AF volume falls, with the decrease averaging 60 to 70 mL/wk at 40 weeks. Although the basic mechanisms that produce these alterations in AF volume throughout gestation are unclear, it is important to note that, when expressed as a percentage of total AF volume, the rate of change decreases consistently throughout the fetal period. Thus, the decrease in AF volume near term represents a natural progression rather than an aberration.

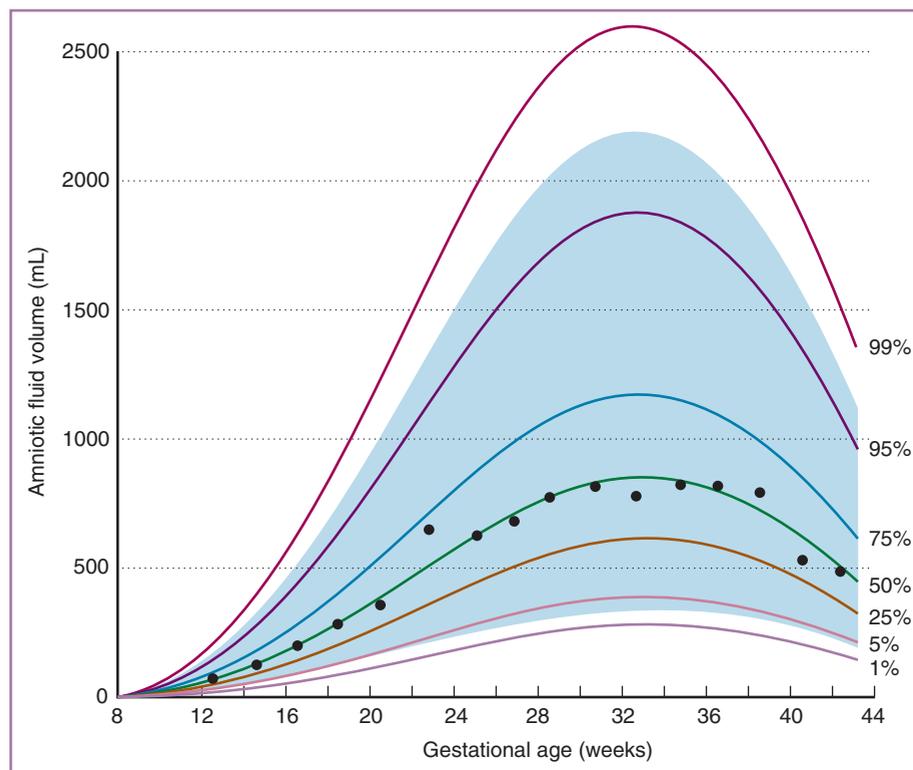

The volume of AF may be dramatically altered in pathologic states. Excessive AF (polyhydramnios) may total many liters, and the volume of AF in conditions of reduced fluid (oligohydramnios) may be near zero. Fetal anatomic abnormalities such as renal agenesis or esophageal atresia may impact on the normal processes for production and resorption of AF, leading to abnormal fluid volumes. In addition, transient changes, such as maternal dehydration or fetal anemia, may alter AF production or resorption and therefore AF volume. Abnormalities of AF volume may also occur without apparent cause and have been associated with poorer perinatal outcomes⁹⁻¹²; specifics are discussed elsewhere in the text.

Production of Amniotic Fluid

The AF in the first trimester of pregnancy has rarely been the subject of study. It appears that in the first trimester, human AF is isotonic with maternal or fetal plasma¹³ but contains a minimal amount of protein. First-trimester AF also demonstrates an extremely low oxygen tension and exhibits an increased concentration of sugar alcohols, the product of anaerobic metabolism.¹⁴ It is thought that early AF arises as a transudate of plasma, either from the fetus through non-keratinized fetal skin, or from the mother across the uterine decidua or placenta surface, or both, although the actual mechanism is unknown.¹⁵

In the second half of pregnancy, the human fetus produces dilute urine, which is a major component of AF and causes its composition to be different from that of serum. In particular, human AF osmolality decreases by 20 to 30 mOsm/kg with advancing gestation, to levels that are approximately 85% to 90% of maternal serum osmolality.¹⁶ In the same period, amounts of AF urea, creatinine, and uric acid increase, resulting in AF concentrations of urinary byproducts two to three times higher than in fetal plasma.¹⁶

FIGURE 3-1 Amniotic fluid volumes from 8 to 44 weeks of human gestation. Dots represent mean measurement for each 2-week interval. Shaded area covers the 95% confidence interval (2.5 to 97.5 percentiles). (From Brace RA, Wolf EJ: Normal amniotic fluid volume changes throughout pregnancy. *Am J Obstet Gynecol* 161:382-388, 1989.)

AF production and resorption have been extensively studied in the latter half of pregnancy, most commonly in the sheep model. Evidence suggests that the entire volume of AF turns over on a daily basis,¹⁷ making this a highly dynamic system. The volume of AF is influenced by a complex interplay of productive and absorptive mechanisms (Fig. 3-2).¹⁸ These mechanisms act to maintain the AF volume, and there is some evidence that they may be regulated to normalize AF volume in pathologic conditions.

The major contributors to AF volume in the latter portion of pregnancy are fetal urine and fetal lung fluid. In addition, minor contributions occur from transudation across the umbilical cord and skin, and from water produced as a result of fetal metabolism. Although some data on these processes in the human fetus are available, the bulk of our information about fetal AF circulation is derived from animal models, primarily the sheep.

The largest contributor to late-gestation AF volume is the fetal urine. Although the mesonephros can produce urine by 5 weeks of gestation, the metanephros (the adult kidney) develops later, with nephrons formed at 9 to 11 weeks,¹⁹ and at this point urine is excreted into the AF. The amount of urine produced increases progressively with advancing gestation, and it constitutes a significant proportion of the AF in the second half of pregnancy.²⁰ Human fetal urine production has been estimated by the use of ultrasound assessment of fetal bladder volume.²¹ Although there continues to be uncertainty about the accuracy of noninvasive measurements, human fetal urine output appears to increase from 110 mL/kg/24 hr at 25 weeks to almost 200 mL/kg/24 hr at term,^{21,22} in the range of 25% of bodyweight per day or nearly 1000 mL/day near term.^{21,23} In near-term fetal sheep, with direct methods used for measuring urine production rates, similar high values have been found.²⁴⁻²⁶ There may be a tendency for the urine flow rate to decrease after 40 weeks' gestation, particularly if oligohydramnios is present.²⁷

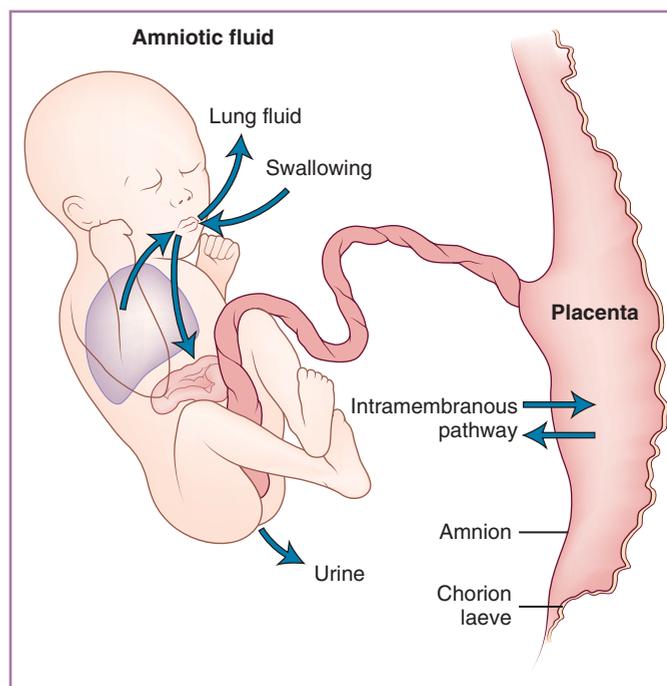

FIGURE 3-2 Circulation of amniotic fluid water to and from the fetus. (Modified from Seeds AE: Current concepts of amniotic fluid dynamics. *Am J Obstet Gynecol* 138:575, 1980.)

Reduction or absence of fetal urine flow is commonly associated with oligohydramnios, indicating that urine flow is very likely necessary to maintain normal AF volume. The mature fetus can also respond to changes in internal fluid status by modulating urine flow. In sheep, increased fetal blood pressure stimulates fetal secretion of atrial natriuretic factor²⁸ and an accompanying diuresis,²⁹ whereas increased plasma osmolality stimulates fetal arginine vasopressin (AVP) secretion and an antidiuretic response.^{30,31} These findings indicate that AF volume could be regulated through the mechanism of altered fetal urine flow. Whereas human fetal hypoxia has been associated with oligohydramnios,^{32,33} ovine fetal hypoxia is associated with increased urine flow,³⁴ during which AF volume is maintained. These data suggest that regulation of AF volume is mediated by other mechanisms in addition to changes in urine production.

The major secondary source of AF volume is fluid derived from the fetal lung. It appears that all mammalian fetuses secrete fluid from their lungs into the AF. The secretion of fetal alveolar phospholipids (lecithin, sphingomyelin, and phosphatidylglycerol) into the AF, used to predict human fetal lung maturity, is evidence that human fetuses are not exceptions to this statement. As the rate of fluid production by the human fetal lungs has not been directly measured, available data are derived from the ovine fetus. During the last third of gestation, the fetal lamb secretes an average of 100 mL/day/kg fetal weight from the lungs. Under physiologic conditions, half of the fluid exiting the lungs enters the AF and half is swallowed³⁵; therefore, total lung fluid production approximates one-third that of urine production, whereas the net AF fluid contribution is only one-sixth that of urine. Fetal lung fluid flow is mediated by active transport of chloride ions across the lung epithelium,³⁶ and the lung fluid is isotonic to plasma, unlike the hypotonic urine. Lung fluid production is affected by a diversity of fetal physiologic and endocrine factors. Increased AVP,³⁷ catecholamines,³⁸ and cortisol³⁹ decrease lung fluid production, effects that may help explain enhanced clearance of lung fluid in fetuses delivered after labor, as compared with those delivered by elective cesarean section.^{40,41} Nearly all active stimuli, including arginine vasopressin,³⁷ catecholamines,³⁸ and cortisol,³⁹ have been demonstrated to reduce fetal lung liquid secretion. Modulation of lung fluid production is therefore unlikely to be a significant regulator of AF volume. Current opinion is that fetal lung fluid secretion is probably most important in providing for pulmonary expansion, which promotes airway and alveolar development.

Other proposed sources for AF water include transudation across fetal skin before keratinization, transudation across the umbilical cord, saliva, and water produced as a byproduct of fetal metabolism. Fetal skin keratinizes at the beginning of the third trimester, making it an unlikely source for AF in the latter part of pregnancy.^{42,43} Fetal oral and nasal secretions do not appear to be a significant source of AF water.⁴⁴ Little is known about the value of other sources of AF water, but they are not thought to be important contributors to AF volume.

Resorption of Amniotic Fluid

One major route of resorption of AF is fetal swallowing. Studies of near-term pregnancies suggest that the human fetus swallows 190 to 760 mL/day.^{45,46} This is considerably less than the volume of urine produced each day, although these estimates may be unreliable, as fetal swallowing may be reduced beginning a few days before delivery.⁴⁷ In fetal sheep, the daily volume swallowed increases from approximately 130 mL/kg/day three-quarters of the way through gestation to over 400 mL/kg/day near term,⁴⁸ in contrast to a relatively constant urine

production of 300 to 600 mL/kg/day,⁴⁹ again suggesting that the fluid produced exceeds the swallowed volume.

A series of studies have measured ovine fetal swallowing activity with esophageal electromyograms, and have measured swallowed volume using a flow probe placed around the fetal esophagus.⁵⁰ These studies demonstrate that near-term fetal swallowing increases in response to dipsogenic (e.g., central or systemic hypertonicity⁵¹ or central angiotensin II⁵²) or orexigenic (central neuropeptide Y⁵³) stimulation, and decreases with acute arterial hypotension⁵⁴ or hypoxia.^{35,55} Thus, near term, fetal swallowed volume is subject to periodic increases as mechanisms for “thirst” and “appetite” develop functionality. However, despite the fetal ability to modulate swallowing, this modulation is unlikely to be responsible for AF volume regulation. Fetal sheep subject to hypoxia maintain normal AF volume,⁵⁶ despite decreased swallowing and increased urine flow, suggesting that another mechanism is responsible for AF volume regulation.

The amount of fluid swallowed by the fetus does not equal the amount of fluid produced by the kidneys and lungs in either human or ovine gestation. As the volume of AF does not greatly increase during the last half of pregnancy, another route of fluid absorption is implied. The most likely route is the intramembranous (IM) pathway.

The IM pathway refers to the route of absorption from the amniotic cavity across the amnion into the fetal vessels. Injection of distilled water into the AF is followed by a lowering of fetal serum osmolality,⁵⁷ indicating absorption of free water. This occurs before any change in maternal osmolality, suggesting absorption directly to the fetus. In sheep, the permeability of the amnion to inert solutes such as technetium and inulin is greater from the AF to the fetal circulation than in the other direction. This asymmetry of membrane permeability is not seen in vitro. These findings suggest that a continuous flow of water and solutes from AF to the fetal circulation (IM flow) occurs in vivo,⁵⁸ and bidirectional (diffusional) flow is seen both in vivo and in vitro. Other experiments support the thesis that solutes can cross directly from the AF to the fetal circulation, as both vasopressin⁵⁹ and furosemide⁶⁰ are taken up into the fetal circulation and are biologically active when injected into the AF after fetal esophageal ligation. Experimental estimates of the net IM flow range from 200 to 400 mL/day in fetal sheep.^{57,61,62} This, combined with fetal swallowing, approximately equals the flow of urine and lung liquid under homeostatic conditions. Although it has never been directly detected in humans, indirect evidence supports the presence of IM flow. For example, studies of intra-amniotic chromium-51 injection demonstrated appearance of the tracer in the circulation of fetuses with impaired swallowing.⁶³ In nonhuman primates, IM flow would explain the absorption of AF technetium⁵⁷ and vasopressin⁵⁹ in fetuses after esophageal ligation. Mathematical models of human AF dynamics also suggest significant IM water and electrolyte flows.^{64,65} Other routes of absorption of AF have been investigated but were not found to be important in the movement of water out of the AF. In particular, transmembranous water flow (AF to maternal blood) is extremely small in comparison with IM flow.^{66,67} In the following discussion, IM flow will be assumed to be the mechanism for fluid resorption from the AF by nonswallowing mechanisms, understanding that there is the potential for other pathways as yet undiscovered.

As just described, fetal urine and lung output and fetal swallowing can all be modulated, but there is little evidence that this modulation serves as a mechanism for the maintenance of normal AF volume. By contrast, some experimental observations suggest that IM flow rates may be regulated to normalize AF volume. In the following description of membrane water flow and fetal membrane anatomy, some proposals for the mechanism and regulation of IM flow are offered.

Membrane Water Flow

The AF serves as a fetal water compartment. Water ultimately derives from the mother via the placenta, making cell membrane water permeability of interest in the accumulation and in the circulation of AF. The water permeability of biologic membranes can be described mathematically, and values of membrane permeability thus defined can be used to compare one membrane with another. To discuss the possible mechanisms of water flux in pregnancy, a review of the basics of membrane water permeability is provided.

Five major routes of membrane transfer (of any moiety) can be distinguished as follows: (1) simple diffusion of lipophilic substances (e.g., oxygen), (2) diffusion of hydrophilic substances through transmembrane channels (the common mechanism for membrane water flow), (3) facilitated diffusion (as occurs with D-glucose), (4) active transport (as for certain electrolytes), and (5) receptor-mediated endocytosis (a mechanism of transfer of large molecules, such as IgG).⁶⁸ In addition to transcellular flow across the cell membrane, water and solutes may cross biologic membranes between cells (paracellular flow).

Except for the specific active transport systems, simple diffusion of any compound (moles per second) across the membrane along physical gradients can be described as follows:

$$J_s = PS(c_1 - c_2) + \frac{(c_1 - c_2) \cdot (1 - \sigma)}{\ln(c_1/c_2)} \cdot J_v + \frac{t^+ \cdot I}{F},$$

where it is assumed that c_1 and c_2 in mol/m³ represent the unbound solute concentrations on opposite sides of the membrane, with c_1 greater than c_2 . P represents the solute permeability of the membrane in m/sec, S stands for the surface area for diffusion in m², σ is the reflection coefficient (dimensionless, a measure of the exclusion of the solute by the membrane), J_v is the volume (water) flux in m³/sec, t^+ is defined as the cationic transfer number, without dimension, with I as the electrical current in coulomb/sec and F as the Faraday constant in coulomb/equivalent.⁶⁹ J_s is influenced by the solubility of the compound under investigation, so lipid-insoluble compounds have low flow and, in turn, low permeability in the absence of membrane channels. Importantly, however, the mathematical description presented here makes no assumption about the route of passive membrane flow. The volume (water) flow can be simplified to become the well-known Starling equation, with R being the gas constant in Nm/kmol and T being the temperature in degrees Kelvin:

$$J_v = LpS[\Delta P - \sigma RT(c_1 - c_2)],$$

where the flow depends on the magnitude of the hydrostatic and osmotic pressure difference.⁶⁹⁻⁷¹

Experimental studies on biologic membranes often report the membrane permeability (P) (usually in cm/sec) or the flux (J) (mL/sec/cm²). At times, the filtration coefficient (LpS) (mL/min per unit of force [mm Hg or mOsm/L] per specimen [kilogram or organ]) is also reported. Flux is used when the reflection coefficient of the solute responsible for the osmotic force is unknown. The filtration coefficient is used when the surface area of the membrane being tested is unknown; this is often the case, for example, in whole-placenta preparations.⁷² Membrane water permeabilities are reported as the permeability associated with flow of water in a given direction, and under a given type of force, or as the (bidirectional) diffusional permeability. As one membrane

may have different osmotic, hydrostatic, and diffusional permeabilities,⁷³ an understanding of the forces driving membrane water flow is critical in understanding flow regulatory mechanisms (see later).

Understanding the forces driving membrane water flow may have real clinical relevance. There is evidence that maternal dehydration is associated with oligohydramnios, presumably on an osmotic basis,^{74,75} and that rehydration can increase fetal urine flow and AF volume.^{76,77} Hypoproteinemia, with decreased maternal plasma oncotic pressure, may be associated with an increase in AF.⁷⁸ In addition, water flow considerations have been used to describe the physiology of twin-twin transfusion syndrome, with an accurate prediction of the success of various treatment modalities.^{79,80} Finally, knowledge of the natural mechanisms regulating AF volume may yield insights into possible therapies for abnormalities of AF volume.

The anatomy of the fetal membranes suggests mechanisms for IM flow. In sheep, an extensive network of microscopic blood vessels is located between the outer surface of the amnion and the chorion,⁸¹ presumably providing the surface area for IM flow. In primates, including humans, IM flow most likely occurs across the fetal surface of the placenta, where fetal vessels course under the amnion. In vivo studies of ovine IM flow suggest that membrane water flow is proportionate to the AF volume, and that water flow can be independent of the clearance of other molecules.⁸²⁻⁸⁴ In sheep, the filtration coefficient of the amnion has been estimated to be 0.00137 mL/min/mm Hg per kilogram fetal weight,⁷² although IM flow rates under control conditions in vivo have not been directly measured. In the human, fetal membrane ultrastructural changes are noted with polyhydramnios or oligohydramnios,⁸⁵ suggesting that alterations in IM flow may contribute to idiopathic AF clinical abnormalities, or that marked changes in AF volume or pressure may have an impact on fetal membrane structure.

IM flow is presumably dependent on the water permeability of the fetal membranes and blood vessels. Despite the relative ease of measurement, chorioamnion permeability to water in vitro has rarely been assessed. In one experiment, human amnion overlying the chorionic plate was studied in a Ussing chamber at 38° C. The membrane diffusional permeability (P) to water was measured at 2.2×10^{-4} cm/sec.⁸⁶ Another experiment found an osmotic permeability of 1.5×10^{-2} cm/sec in human amnion.⁷³ These values are similar to values obtained in renal tubular epithelium⁸⁷⁻⁸⁹ and would indicate that the amnion is a "leaky" epithelium with the potential for significant water flux, which would then be subject to modulation. When human amnion and chorion were both tested, the amnion appeared to be a more effective barrier to the diffusion of water.⁹⁰ Similarly, in the sheep, the permeability of amniochorion was $2.0 \pm 0.3 \times 10^{-4}$ cm/sec, not different from the permeability of amnion alone, which was $2.5 \pm 0.7 \times 10^{-4}$ cm/sec.⁸² This, coupled with the fact that the fetal vessels occur between the amnion and chorion, would suggest that the amnion is the more likely to be involved in regulating IM water flow.

Studies in the ovine model suggest that flow through the IM pathway can be modulated to achieve AF volume homeostasis, specifically under conditions potentiating excess AF volume. Because fetal swallowing is a major route of AF fluid resorption, esophageal ligation would be expected to increase AF volume significantly. Although AF volume did increase significantly 3 days after ovine fetal esophageal occlusion,⁹¹ longer periods (i.e., 9 days) of esophageal ligation reduced AF volume in preterm sheep despite continued production of urine.⁵⁶ Similarly, esophageal ligation of fetal sheep over a period of 1 month did not increase AF volume.⁹² In the absence of swallowing, with continued fetal urine production, normalized AF volume suggests an increase in IM flow. In addition, AF resorption increased markedly

after infusion of exogenous fluid to the AF cavity⁹³ or after increased fetal urine output stimulated by a fetal intravenous volume infusion.⁸⁴ Collectively, these studies suggest that IM flow may be under feedback regulation. That is, AF volume expansion increases IM resorption, ultimately resulting in a normalization of AF volume. Importantly, however, factors downregulating IM flow are less well characterized; there is no evidence of reduced IM resorption as an adaptive response to oligohydramnios. Downregulation of IM flow is possible, as prolactin reduces the upregulation of IM flow caused by osmotic challenge in the sheep model,⁹⁴ and it may reduce diffusional permeability to water in human⁹⁵ and guinea pig⁹⁶ amnion.

The specific mechanism and regulation of IM flow are probably the key to AF homeostasis. Bulk water flow across an epithelial membrane requires a motive force. IM flow may be driven by the significant osmotic gradient between the hypotonic AF and isotonic fetal plasma⁵⁷ in the human and sheep, although in rats and mice the osmotic gradient does not favor AF-to-plasma flow.⁹⁷⁻⁹⁹ One explanation may be that solute concentration at the membrane surface may differ significantly from that in the plasma or AF as a whole, a phenomenon known as the “unstirred layer” effect.¹⁰⁰ Gross hydrostatic forces are unlikely to drive AF-to-fetal flow, as the pressure in the fetal vessels exceeds that in the amniotic cavity. Hydrostatic forces could be developed between the AF and the interstitial space, with another force promoting water flow into the bloodstream. Local changes in hydrostatic or osmotic pressure have been proposed to drive IM flow, but none of these has been demonstrated *in vivo*.

A variety of mechanisms have been proposed for the regulation of IM flow. As esophageal ligation of fetal sheep resulted in upregulation of fetal chorioamnion vascular endothelial growth factor (VEGF) gene expression,¹⁰¹ it was proposed that VEGF-induced neovascularization could potentiate AF water resorption. Those authors further speculated that fetal urine or lung fluid, or both, may contain factors that upregulate VEGF, although their recent work demonstrates no effect of lung liquid on the rate of IM flow (J. Jellyman, personal communication). The association of increased VEGF, and presumably vessel growth and permeability,¹⁰² with increased IM flow, coupled with the difference noted between the asymmetrical flow *in vivo* and the symmetrical permeability of amnion *in vitro*, have also led to the suggestion that the rate of IM flow is regulated by the fetal vessel endothelium, rather than by the amnion.⁵⁸

In animals in which the fetal urine output had been increased by an intravenous volume load, an increase in AF resorption occurred, despite a constant membrane diffusional permeability to technetium.⁸⁴ In addition, artificial alteration of the osmolality and oncotic pressure of the AF revealed that IM flow was highly correlated with osmotic differences; however, there was a component of IM flow that was not osmotic dependent. As this flow pathway was also permeable to protein, with a reflection coefficient of near zero, this residual flow was felt to be similar to fluid flow in the lymph system.¹⁰³ These findings, in aggregate, have been interpreted to indicate active transport of bulk fluid (i.e., water and solutes) from the AF to the fetal circulation, either in the amnion or in the fetal vessel wall. Daneshmand and colleagues⁸⁴ have proposed that this fluid transport occurs via membrane vesicles, and they point out the high prevalence of intracellular vesicles seen on electron microscopy of the amnion.¹⁰⁴ This theory has not been widely accepted, as vesicle water flow has not been demonstrated in any other tissue and would be highly energy dependent. Rather, most authors believe that IM flow occurs through conventional *para*- and *trans*-cellular channels, driven by osmotic and hydrostatic forces, perhaps modulated through an unstirred layer effect. Mathematical modeling indicates that relatively small IM sodium fluxes could be associated

with significant changes in AF volume, suggesting that active transport of sodium may be a regulator of IM flow.⁶⁵ The observation that a portion of IM flow was independent of osmotic differences, however, suggests that other forces may also be significant.¹⁰³

Importantly, upregulation of VEGF or sodium transfer alone cannot explain AF composition changes after fetal esophageal ligation, because AF electrolyte composition indicates that water flow increases disproportionately to solute (i.e., electrolyte) flow.⁶¹ The passage of free water across a biologic membrane is a characteristic of transcellular flow, a process mediated by cell membrane water channels (aquaporins [AQPs]). AQPs are hydrophobic intramembranous proteins.^{105,106} They organize in the cell membrane as tetramers, but each monomer forms a hydrophilic pore in its center and functions independently as a water channel.¹⁰⁶ Although the majority of AQP structural studies have been performed on AQP1, similarities in sequence suggest that the three-dimensional structure of all AQPs is similar, although in addition to water, some AQPs also allow passage of glycerol, urea, and larger molecules. Multiple AQPs have been identified (up to 13, depending on the species). Some are widely expressed throughout the body; others appear to be more tissue specific.

Regulation of water flux depends on the location and concentration of AQPs in the cell membrane. In the kidney, AQP3 and AQP4 are both present in the basolateral membrane of the collecting-duct principal cells, whereas AQP2 is present in the apical portion of the membrane of these cells.¹⁰⁷ The presence of different AQPs on different portions of the same cell is thought to regulate water transfer across the cell by differentially promoting water entry from the collecting duct lumen and from the interstitial fluid. AQP concentration in the membrane may be influenced by the insertion or removal of AQP into the membrane from the intracellular compartment, or by the promotion of AQP production. Both of these events may be the result of cellular stimulation by hormones or by the external environment. In the renal tubule, AQP2 is transferred from cytoplasm vesicles to the apical cell membrane in response to AVP¹⁰⁸ or forskolin (a stimulator of cAMP production).¹⁰⁹ AQP8 is similarly transferred from hepatocyte vesicles to the cell membrane in response to dibutyryl cAMP and glucagon.¹¹⁰ In longer time frames, expression of various AQPs may be induced by external conditions. For example, AQP3 expression in cultured keratinocytes is increased in hypertonic medium.¹¹¹ In the intact organism, AQP3 expression in the kidney is upregulated by dehydration,¹⁰⁷ an effect mediated by AVP. Together with permeability data, these findings indicate that AQPs are important in the regulation of water flow across biologic membranes, and that their expression and activity are regulated according to the needs of the organism.

Studies have demonstrated AQP1, -3, -8, and -9 mRNA (gene) expression in fetal membrane and placenta in a variety of species. In addition, recent data suggest that membrane AQP1 may specifically regulate AF volume. Mice lacking the AQP1 gene have been reported to have significantly increased AF volume.¹¹² Furthermore, AQP1 expression was increased in human amnion derived from patients with increased AF volumes¹¹³; this upregulation was postulated to be a compensatory response to polyhydramnios. AQP1 protein increased in ovine chorioallantoic membranes when the fetus was made hypoxic, suggesting a mechanism for the increased IM flow associated with ovine fetal hypoxia.¹¹⁴ AVP levels may be higher in the AF of fetuses with oligohydramnios,¹¹⁵ and some work suggests that AVP and cAMP may upregulate AQP expression in cultured human amnion.¹¹⁶⁻¹¹⁹ Upregulation of amnion AQP1 by AVP is a possible explanation for oligohydramnios resulting from increased IM flow. These results suggest that AQP1, and possibly -3, -8, and -9, could participate in the regulation of gestational water flow.

Summary

AF is an important component of successful gestation. When present in normal amounts, it provides an environment for normal development and an extrafetal water store. It also serves as a convenient source of diagnostic material. Normal AF volumes can vary widely between individuals, and a variety of pathologic conditions may be associated with frankly abnormal AF volume. Early in gestation, AF appears to be a transudate of fetal serum, although the specifics of AF production and resorption are little studied. In the second half of pregnancy, human AF is hypo-osmolar to serum and contains increased concentrations of urea and creatinine. Although the formation of AF is reasonably well described, the mechanisms for establishing and maintaining AF volume are poorly understood. Similarly, the cause of abnormal AF volumes in certain pathologic conditions is unknown. Although all of the major mechanisms for production and resorption of AF can be modulated by the near-term fetus, modulation of IM flow appears today to be the most likely to serve as a mechanism for normalizing AF volume. Regulation of AF volume remains an active area of investigation, as the ability to therapeutically alter the production or resorption of AF would represent an important advance in the management of pregnancy.

Chapter 4

Multiple Gestation The Biology of Twinning

Kurt Benirschke, MD

Incidence of Twinning

The incidence of twinning is increasing as our population ages and a new technology—assisted reproductive technology (ART)—is becoming widely used. Not only have artificial reproductive techniques led to a marked increase in higher-order multiple births (triplets, quadruplets) but also they are followed by an increase in prematurity rates and congenital anomalies.¹⁻³ The statistics, which are usually derived from national or regional birth records and rely on reporting by physicians or other personnel attending births, do not accurately reflect the occurrence of twins at conception because the much higher prenatal mortality of twins (as abortion or fetus papyraceus) is not taken into account. Thoughtful reviews of the multiple gestation “epidemic” are available.⁴⁻⁶ Some countries have chosen to deny transfer of more than one blastocyst.⁷ An additional finding of interest is that there appears to be an increase in monozygotic twinning (identified as being mono-chorionic) when various ART procedures are used; also, placental abnormalities are more frequent.⁸

Guttmacher⁹ suggested that 1.05% to 1.35% of pregnancies were twins, the reason for this wide variation being that the frequency of the twinning process varies widely among different populations. Data collated from various countries reveal that the variability relates largely to the ethnic stock of the population under consideration. Moreover, although the dizygotic (DZ) twinning rate varies widely under different circumstances, the monozygotic (MZ) twinning rate is considered to be “remarkably constant,” usually between 3.5 and 4 per 1000,¹⁰ although Murphy and Hey¹¹ found the rate to have slightly increased in recent years. In recent national statistics, of 4 million births in the United States, 3.3% were multiple, or 1 in 30 gestations.

When the twinning rate of a population is known, the frequencies of triplets, quadruplets, and so on can be roughly calculated by Hellin’s hypothesis, which states that when the frequency of twinning is n , that of triplets is n^2 , of quadruplets n^3 , and so on. The highest number recorded so far is nine offspring.¹² Since 1973, there has been a steady rise in the incidence of twins and triplets, so that currently at least 1 in 43 births is a twin and 1 in 1341 pregnancies results in triplets.^{2,13} In part, this increase was attributed to delayed childbearing, but the use of ovulation-enhancing drugs has also been implicated. Although

acknowledging the increased DZ twinning frequency attributed to clomiphene, Tong and coworkers¹⁴ found that the DZ-to-MZ ratio has significantly declined from 1.12 (1960) to 0.05 (1978) and suggested adverse environmental factors as a possible cause.

Types of Twins

Twins who possess characteristics that make them virtually indistinguishable are referred to as identical, whereas twins who are unlike are considered fraternal. Identical twins always have the same sex, but fraternal twins may be of different sexes. The terms *identical* and *fraternal*, although popular, are scientifically less useful and are best replaced by the terms *monozygotic* and *dizygotic*, respectively, to indicate the mechanism of origin of the two types of twins. An important reason for this preference is that MZ twins with discordant phenotypes (e.g., cleft lip) would be misclassified as fraternal.

To assess the frequency of MZ and DZ twins, investigators have commonly used the Weinberg differential method. This method suggests that the frequency of MZ twins can be deduced from a twin sample when the sex of the twin pairs is known. Thus, if the numbers of male and female conceptuses were approximately equal and all twins were fraternal (DZ), there would be 50 male-female pairs, 25 male-male pairs, and 25 female-female pairs in every 100 pairs of twins. Any excess of like-sex twins is therefore assumed to be the population of MZ twins. This number then can be calculated by using the following formula:

$$\text{MZ twins} = \frac{\text{like-sex pairs} - \text{unlike-sex pairs}}{\text{number of pregnancies}}$$

When this formula is applied to national birth statistics, approximately one third of twins in the United States are MZ, although it must be said that the tautology of Weinberg, as Boklage¹⁵ calls it, has often been criticized. Moreover, the very high twinning rate of the Yoruba tribe in Nigeria results from a higher frequency of double ovulation, whereas the low twinning rate in Japan is the result of a lower frequency of double ovulation. This formula also supports the notion that MZ twinning occurs with a relatively uniform incidence

in different populations and rises only slightly with advancing maternal age.¹⁰ In contrast, the rate of DZ twinning increases with maternal age to about 35 years and then falls abruptly. The rate also increases with parity, is higher in conceptions that occur in the first 3 months of marriage, and decreases in periods of malnutrition, such as during World War II. James¹⁶ deduced that DZ twinning also increases with coital frequency, and numerous studies indicate that DZ twins occur in certain families, presumably because of the presence of genetic factors leading to double ovulation. These factors are expressed in the mother but may be transmitted through males. Only a few pedigrees suggest that MZ twinning is inherited, and most authorities have concluded that it is a random event. There is also some, occasionally disputed, evidence that assisted reproductive technology has increased the frequency of MZ twin births as well, perhaps because of damage to the blastocyst.¹⁷⁻²¹

Much has been written about the possible occurrence of “third twins,” or the uncommon twins that may arise from possibly irregular ovulation events, such as polar body fertilization. Bulmer¹⁰ concluded that such an event is unlikely to have been described. Bieber and colleagues,²² however, suggested that the development of an acardiac triploid twin (a malformed MZ twin without a heart) represents such an example. As explained later, the topic is important only because the evidence that DZ twins come from two ovulations does not rest on very firm knowledge. Goldgar and Kimberling²³ developed a genetic model to discriminate between DZ and polar body twins. They found that only near-centromeric genetic loci can be confidently used to make such a crucial distinction.

Twins may also originate from fertilization by sperm of two fathers, and the suggestion by James¹⁶ that DZ twinning is influenced by coital rates relates to this phenomenon of superfecundation. Few cases have been verified. In the ninth reported case, one white male twin and one African-American male twin were presumably conceived by two documented events 1 week apart.²⁴

Causes of Twinning

The causes of both MZ and DZ twinning are incompletely understood. It is commonly assumed that DZ twinning occurs because of double ovulation, and occasional case descriptions support this assumption. Meyer and Meyer²⁵ described two 14-day implantation sites with two corpora lutea of similar age in contralateral ovaries. Moreover, multiple pregnancy can be induced by hormonal induction of ovulation, and the polyovulation can be followed via ultrasonography.^{26,27} Serum gonadotropin levels in twin-prone Nigerian women are higher than in control subjects,²⁸ and lower levels are found in Japanese women, who are less likely to produce fraternal twins.²⁹ For these and other reasons, it is reasonable to assume that DZ twinning is the result of somewhat elevated serum gonadotropin levels, leading to double ovulation. Moreover, it is assumed that gonadotropin levels are influenced by maternal age, nutrition, parity, and, among other factors, maternal genotype. It has now also been found that DZ twinning correlates with a mutation on chromosome 3 that codes for a receptor gene,³⁰ whereas Healey and colleagues³¹ questioned a relationship to the fragile X syndrome. More recently, a number of additional factors have been found to affect the ovulation rate. Thus, in sheep and cattle, specific mutations have been correlated with multiple ovulation,³² and insulin-like growth factor-1 has been found to interact with ovulation and folliculogenesis.³³

Although these assumptions may be correct, they are not proven, and the existence of two corpora lutea is rarely ascertained when

twins are born. It is of interest to learn that the use of ovulation-enhancing agents has also led to an increase in MZ twins, but this is most easily identified in triplets.³⁴ We observed the same phenomenon in placental examination of triplets and quadruplets. This finding seems at first contradictory, but accidents in preservation of the zona pellucida have been witnessed in assisted reproduction of domestic animals, and these accidents are presumably also the basis for these unexpected events. In addition, the occurrence of two ova in one follicle is well documented, as are many abnormal fertilization events.

More important questions about the validity of this concept of DZ twinning are statistical, however, and they are as yet unanswered. Non-right handedness is found not only in MZ and DZ twins but also in their close relatives at a higher rate than would be expected in the general population.³⁵ The same observations have been made with respect to certain forms of schizophrenia, suggesting that the traditional MZ and DZ divisions may be incorrect, a full spectrum may exist between the two classes, and the MZ twinning process relates to a factor interfering with the brain symmetry development of the embryo. It has indeed been suggested that there is a continuum between the MZ and DZ twinning propensity.

The mechanism leading to MZ twinning is even more obscure. That such twins exist can be verified not only by their physical similarity but also by their identity in genetic characters. Exhaustive blood group analysis, finding no differences in the face of different parental markers, was formerly used to verify identity. Chromosomal markers had been used for the diagnosis of MZ twins with apparently greater assurance,^{36,37} but most recently the direct comparison of DNA variations is being used for zygosity diagnosis. The determination of restriction fragment length polymorphism compares fragments of DNA and is decisive. Moreover, this technique can use a variety of tissues, including blood and placenta.^{38,39} This methodology has now been greatly simplified and automated so that zygosity diagnosis can be achieved quickly, reliably, and inexpensively.⁴⁰ The facts that MZ twins occur slightly more frequently with advancing maternal age,¹⁰ that discordant malformations often occur, that conjoined twins develop, and that MZ twinning can be induced by teratogens⁴¹ have led to the hypothesis that MZ twins result from a teratologic event. Boklage³⁵ suggested a disturbance in the process of symmetry development in the embryo. It has been possible to produce MZ twins by the separation of early blastomeres in a few animal genera (e.g., *Triturus*, *Ovis*, *Bos*, *Mus*), but such physical events do not occur in early human embryonic stages. On the other hand, there is some evidence that MZ twinning may be more frequent after ART procedures although some have disputed this. Nevertheless, Steinman and Valderrama,^{42,43} who have had an interest in the mechanism, have suggested that the possible reduction of calcium ions (needed for cell adhesion) may be causative because of the composition of the culture fluids and length of exposure in *in vitro* fertilization.

Because of these uncertainties, it has been convenient to speak of the “twinning impetus,” an external and perhaps teratogenic agency, that is randomly distributed and that may lead to twins only up to a certain stage before the embryonic axis is established. Experiments in mice with vincristine support this hypothesis.⁴¹ If teratogens had their effect later, twins would not be resulting; rather, anomalies in the singleton might develop. It is further assumed that this twinning impetus may lead to separation of only the embryonic cells but that it will not lead to the splitting of already formed cavities. Therefore, when the embryonic events are plotted against embryonic age, one may deduce from the placental configuration the approximate timing of the twinning process (Fig. 4-1).

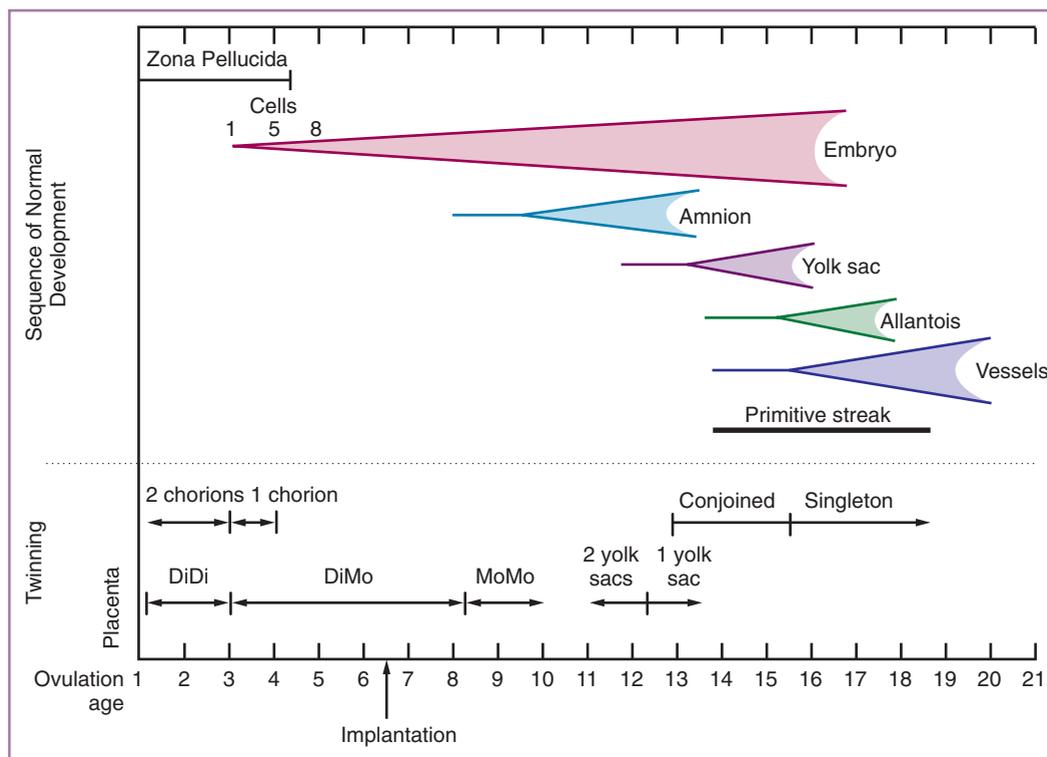

FIGURE 4-1 Schematic representation of monozygotic twinning event superimposed on temporal events of embryogenesis. The embryonic events in the upper portion are sketched according to the publications of early human embryos by Hertig (1968). The twinning event is depicted in the lower portion, with resulting placental types indicated. DiDi, diamniotic dichorionic; DiMo, diamniotic monochorionic; MoMo, monoamniotic monochorionic. (From Benirschke K, Kim CK: Multiple pregnancy. *N Engl J Med* 288:1276, 1973. Reprinted by permission from The New England Journal of Medicine.)

Placentation in Twinning

There are two principally different placental types, monochorionic and dichorionic placentas (Fig. 4-2), and it is essential that they be so identified at birth. Indeed, it is also desirable to differentiate these placentas prenatally by ascertaining the thickness of the “dividing membranes” sonographically. Winn and associates⁴⁴ established criteria for this measurement and suggested that, with an 82% accuracy, a maximal thickness of 2 mm is diagnostic of monochorionicity. More recent studies have shown the reliability of this methodology, especially in the mid-trimester. Oligohydramnios is its most serious limitation.^{45,46} Numerous surveys of placental types of twins have shown that heterosexual (assuredly DZ) twins virtually always have a dichorionic placenta, and that monochorionic twins have always been of the same sex. These basic facts led us to assume that all monochorionic twins are MZ; however, exceptions have also been reported on very rare occasions.^{47,48}

Some MZ twins may be endowed with dichorionic placentas (i.e., twins that separated in the first 2 days after fertilization) (see Fig. 4-1). Most MZ twins, however, have a placenta with diamniotic and monochorionic membranes (Fig. 4-3). Monoamniotic twins, which are by necessity also monochorionic, occur least commonly (approximate incidence, 1%). Conjoined twins are monoamniotic and are less common still, because it probably becomes increasingly difficult for a rapidly growing embryo to submit to the twinning impetus.

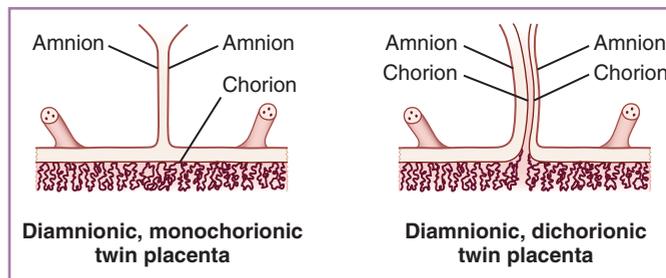

FIGURE 4-2 The two principal types of twin placentation. **Left,** Diamniotic monochorionic placenta, always monozygotic. **Right,** Diamniotic dichorionic placenta, which may or may not be fused.

DZ twins always have dichorionic placentation. Their placentas may be separated or intimately fused (Figs. 4-4 and 4-5). If the placentas are fused, a ridge develops in the central fusion plane that allows easy distinction from the monochorionic placenta. With rare exceptions,^{49,50} blood vessels never cross from one side to the other in dichorionic twin placentas, and when the dividing membranes (that portion separating the two sacs) are carefully dissected, four separate layers can be identified: one amnion on either side and two chorions in the middle. Between the two chorions, one finds degenerated trophoblast and atrophied villi, features that render the dividing membranes of a diamniotic dichorionic twin pair opaque. Differential expansion of the

fetal sacs often causes the membranes of one placenta to push away those of the other (Fig. 4-6), a feature that must not be confused with monochorionic placentation. It is referred to as *irregular chorionic fusion*. Very few verified DZ twins with monochorionic placenta have occurred, even with occasional anastomoses and with consequent blood chimerism. They are so rare that perhaps most have not been reported because they are not ascertained.

Although 20% to 30% of MZ twins have a dichorionic placentation, most often the placentas of monozygotic twins are monochorionic.

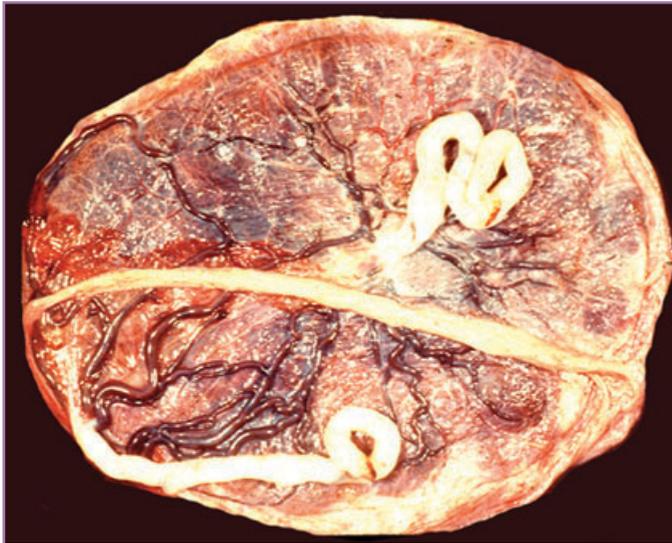

FIGURE 4-3 Diamniotic monochorionic twin placenta with numerous vascular anastomoses.

The latter type is invariably fused, and the dividing membranes consist of two translucent amnions only. When these amnions are separated from each other, the single chorion on the placental surface is evident. The chorion carries the fetal blood vessels and various types of inter-fetal vascular communications that occur regularly in monochorionic twins.

The two principal types of membrane relationships are shown in Figure 4-2. Monoamniotic twins are least common and carry a mortality rate of approximately 50% to 60% because of the frequent encircling of the cords, and knotting may lead to cessation of umbilical blood flow. Fetal demise usually occurs in the first part of pregnancy; after 32 weeks' gestation, no further mortality can be expected from entangling,^{51,52} which can then be identified sonographically.⁵³ The chronic stasis induced by cord entanglement can lead to stillbirth and also to thrombosis with calcification of fetal vessels (Fig. 4-7). The possibility also exists that formerly diamniotic membranes become disrupted during gestation, with increased fetal mortality ensuing.⁵⁴ The perinatal mortality rate of diamniotic monochorionic twins is next highest (approximately 25%), because of the high frequency of the inter-fetal twin-to-twin-transfusion syndrome. The mortality rate is lowest for dichorionic twins (approximately 8.9%). This has been verified by a large study of twins in Belgium.⁵⁵

The relationship of placentas among triplets, quadruplets, and higher-orders multiple births generally follows the same principles, except that monochorionic and dichorionic placentations may coexist (Fig. 4-8). With these higher numbers, there is more frequent association of placental anomalies, particularly marginal and velamentous insertions of the umbilical cord (see Figs. 4-8 and 4-9) and single umbilical artery (Fig. 4-9). The etiology of these anomalies may be related to the crowding of placentas and competition for space, or to primary disturbances of blastocyst nidation.

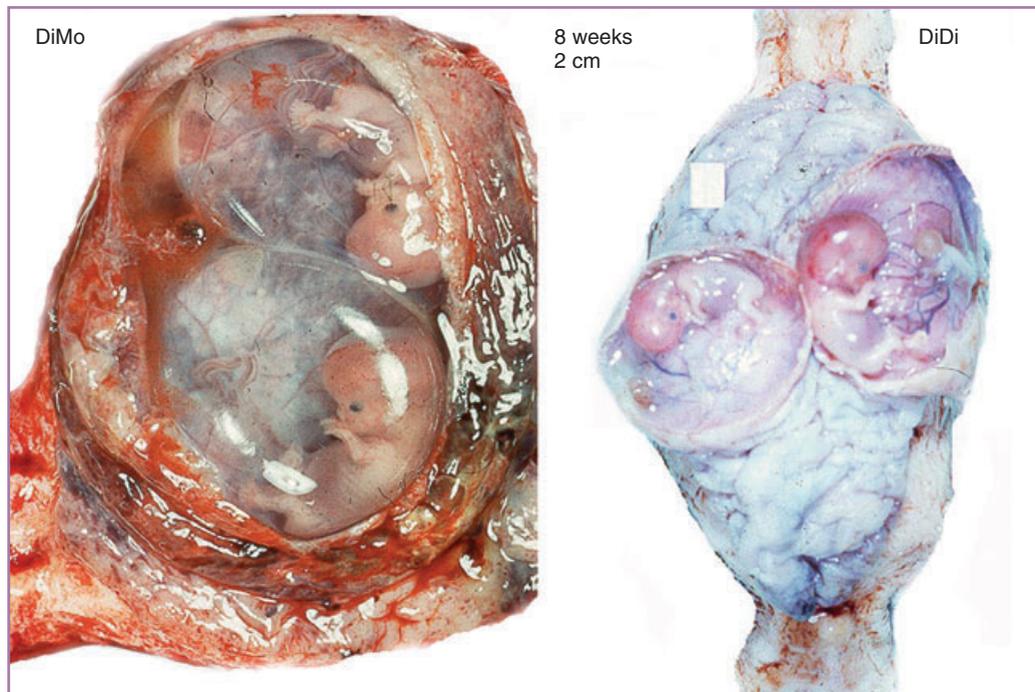

FIGURE 4-4 Twin gestations in utero, both at 8 weeks. **Left**, Monochorionic diamniotic twins. **Right**, Dichorionic diamniotic twins.

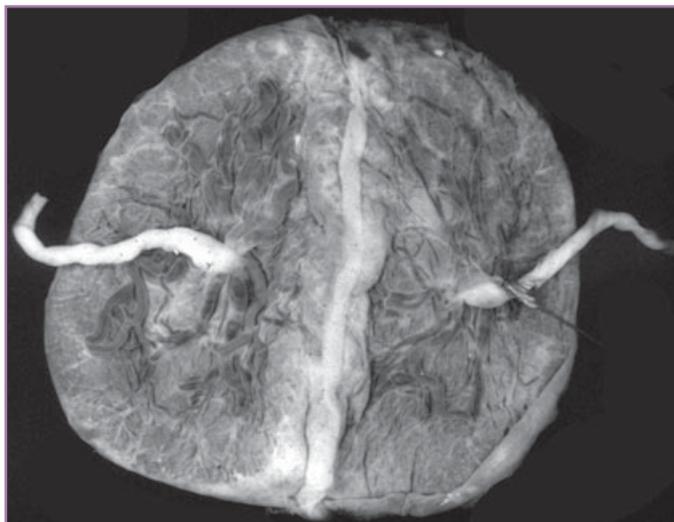

FIGURE 4-5 Diamniotic dichorionic twin placenta, fused. The umbilical cord on the left had a single umbilical artery. Note the close approximation of two placental disks with ridge formed by membranes in center.

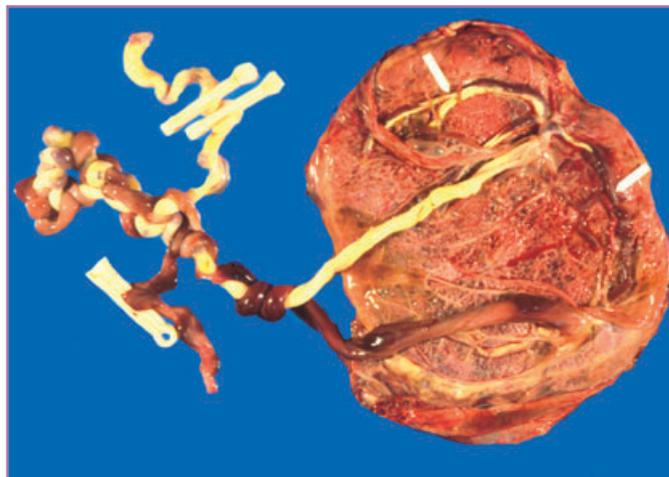

FIGURE 4-7 Monoamniotic twin placenta. There is marked encircling of the umbilical cords and fetal demise of dark cord's twin. The other twin died also and had massive CNS damage. Note the thrombosis of surface vessels and calcifications (yellow) of organized thrombi (white arrows).

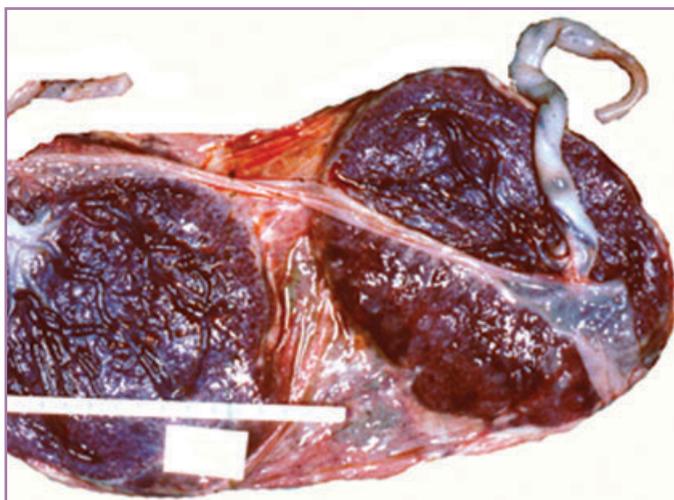

FIGURE 4-6 Diamniotic dichorionic (separate) twin placenta. The membranous sac of the left twin has pushed away the right membranes so that fusion of dividing membranes occurs over the right placenta ("irregular chorionic fusion").

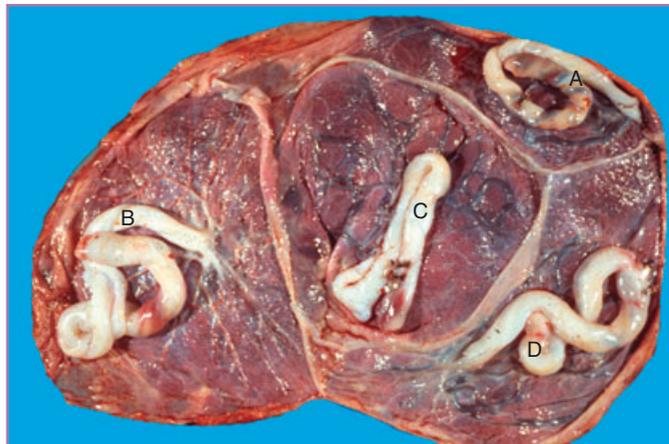

FIGURE 4-8 Placenta of quadruplets at 28.5 weeks. A, C, and D are female; B is male. Placenta is tetrachorionic and intimately fused. Birth order is indicated by letters. Cord A is marginally inserted. Despite intimate fusion, there are no anastomoses.

Velamentous Insertion of Umbilical Cord and Vasa Praevia

With the six- to nine-times-higher incidence of velamentous umbilical cord insertion in twin placentas and an even higher incidence in higher-order multiple births, the presence of vasa praevia in multiple pregnancy must be anticipated. It is a serious complication and often lethal because of exsanguination during delivery (see Fig. 4-10). Membranous vessels originating from a cord with velamentous insertion radiate toward the placental surface and are not protected by Wharton's jelly. Therefore, they may thrombose or may be compressed during labor. When the membranes are ruptured during delivery and

these vessels accidentally have a transcervical position (vasa praevia), the rupture may lead to exsanguinating hemorrhage. Not only may the first twin exsanguinate but, as has been described, the second twin may exsanguinate through interfetal placental anastomoses if the placentation is monochorionic. Vasa praevia may exist not only over the cervical os but also over the dividing membrane when the second twin's cord has a velamentous insertion on the dividing membranes. Fetal hemorrhage leading to death within 3 minutes has been observed when the diamniotic dichorionic membranes of the second twin were ruptured.⁵⁶ In nine cases collected by Antoine and colleagues,⁵⁷ no first twin survived and 62.5% of the second twins eventually succumbed as the result of this hemorrhage. The clinical management of vasa praevia is discussed in detail in Chapter 37.

Please refer to the printed publication.

FIGURE 4-9 Immature monochorionic quintuplet placenta. All infants died from hyaline membrane disease and one had a single umbilical artery. There are numerous anastomoses. (From Benirschke K, Kaufmann P, Baergen RN: *The Pathology of the Human Placenta*. New York, Springer-Verlag, 2006.)

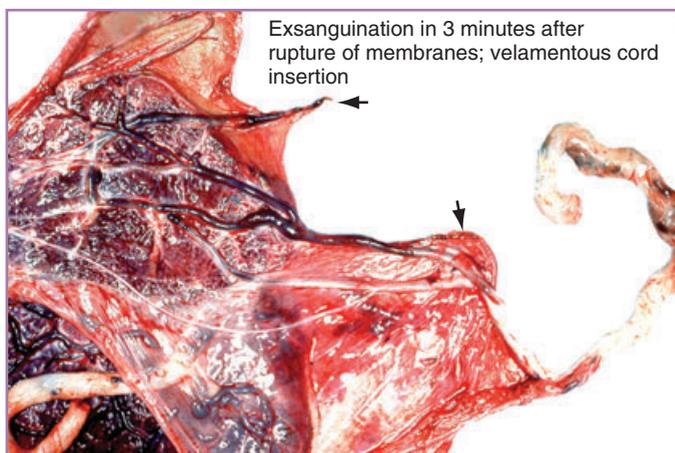

FIGURE 4-10 Fatal vasa praevia in twin A of an intimately fused diamniotic dichorionic twin placenta. The disrupted vessel is indicated by arrows. The mother was admitted 4 hours after rupture of membranes with no history of significant bleeding. Twin A had an Apgar score of 1 and could not be resuscitated. Twin B lived. The left half of the placenta had marked pallor (on maternal surface) because of fetal hemorrhage.

Monoamniotic Twins

Monoamniotic twins are all MZ, and all must also have a single chorion. Monoamniotic twins are the least common. Their occurrence is variably recorded as from 1 in 33 to 1 in 661 twin births. In the series reported by Benirschke and coworkers,⁵⁶ 3 of 250 pairs had this type of placenta, and three of the six fetuses died from various complications.

The most common complication is encircling and knotting of cords with cessation of umbilical blood flow (see Fig. 4-7). The extent of the knotting of cords is at times astonishing and testimony to the degree

of fetal movements. In the past, double survival of monoamniotic twins was so uncommon that such cases were deemed worthy of report.⁵⁸ Preterm delivery, at 32 to 34 weeks' gestation, has led to increased survival of monoamniotic twins. Locking of the twins during delivery is rarely observed with monoamniotic twins, because almost all are delivered by cesarean section.

Most monochorionic twins have interfetal placental anastomoses, but such vessel communications are not invariably found. It was formerly believed that blood was exchanged between the twins through these anastomoses, and that if one twin succumbed before birth, thromboplastin, possibly originating in the macerating fetus, might lead to disseminated intravascular coagulation in the surviving twin. This phenomenon would be restricted to monochorionic placentation and was thought to occur in triplets as well. An alternative view for the demise of the second twin, and one that now has assumed greater likelihood, is that severe and acute hypotension develops through exsanguination into an already dead twin via large anastomoses,⁵⁸⁻⁶⁰ very much like that which led to the demise of Eng when Chang of the notorious Siamese twins died.

Because of the high mortality rate, it is imperative to make an antepartum diagnosis. With such a diagnosis, a clear course of action awaited accumulation of adequate statistics that would delineate exactly when in the course of pregnancy one or both twins are likely to succumb from cord encircling. Rodis and colleagues⁶¹ provided some of these data; they showed a 90% survival when adequate antenatal care was provided.

The umbilical cords of monoamniotic twins usually arise near each other on the placenta, and in rare circumstances they are partially fused. Less often, they are velamentous. The fusion of cords represents a gradual transition to the invariably monoamniotic conjoined twins that are thought to form only slightly later, at the end of the twinning spectrum shown in Figure 4-1. Conjoined twins may have two cords with three vessels each, forked cords, anomalous vessels, or, at the other end of the spectrum, one cord with only one artery and one vein. Congenital anomalies, although more common among twins in general, are particularly common in monoamniotic and conjoined twins. The more frequent occurrence of sirenomelia—100 to 150 times more common in twins than in singletons—has led to insights into the relationship of this anomaly with pulmonary hypoplasia, a regular finding in sirens because of a deficient urinary tract. When one monoamniotic twin is a siren and the other is normal, the amniotic fluid produced by the second twin apparently protects the siren from experiencing pulmonary hypoplasia. When the placenta is diamniotic, this protection does not occur.⁶²

Diamniotic Monochorionic Twins

Diamniotic monochorionic twins are MZ, the placenta is fused, and the umbilical cords often have a marginal or velamentous insertion. The diagnosis is readily apparent from the absence of a ridge at the base of the dividing membranes (see Figs. 4-3 and 4-4) and the translucency of the dividing membranes. When the membranes are dissected, one amnion can be readily stripped from the other, leaving a single (placental) chorionic plate that carries the fetal blood vessels. The amnions do not necessarily meet at the vascular equator of the two placental beds but may shift irregularly from one side to the other, presumably because of fetal movements and the relative fluid contents of the two sacs. The diamniotic monochorionic placenta is the most common type seen in MZ twins; approximately 70% have this conformation (see Fig. 4-1), and a recent review details all its major complications.⁶³

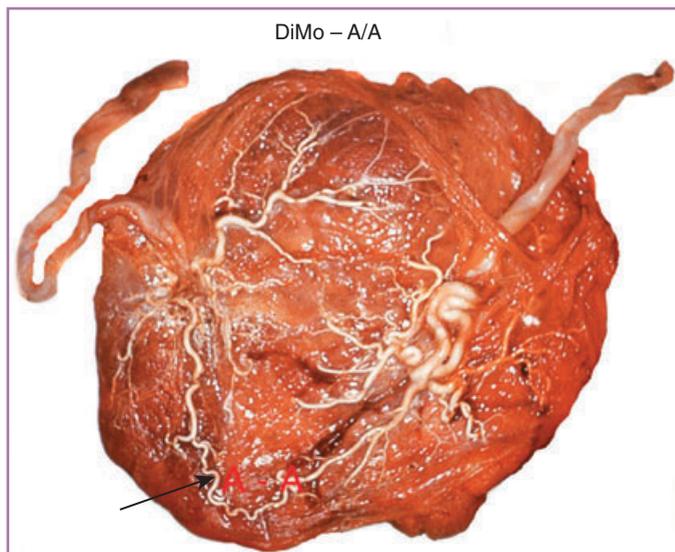

FIGURE 4-11 Diamniotic monochorionic (DiMo) twin placenta. One large direct A/A (artery-to-artery anastomosis) after injection with milk is shown.

The diamniotic monochorionic placenta and, less commonly, the monoamniotic twin placenta nearly always possess interfetal blood vessel communications (Fig. 4-11, and see Fig. 4-12). The anastomosis is more often an artery-to-artery (arterioarterial) (see Fig. 4-11) than a vein-to-vein communication, and sometimes both types are present and multiple. These vessels allow blood to shift readily from one side to the other, equalizing volumes and pressures. They are most readily demonstrated, after the amnion has been removed, by careful inspection, by stroking blood from one side to the other, or by injection. It is generally impractical to inject the entire placenta from the cord vessels, because rather large volumes are needed and the placental blood must not have been clotted. One can verify the existence of anastomoses more readily by first cutting off the cords and then injecting water or milk into those vessels that are thought to be anastomotic (see Fig. 4-12).

The large anastomoses have important practical clinical implications. Through these communications, the second twin may exsanguinate if vasa praevia of the first twin are ruptured or, of course, if the cord of the first twin is not clamped. In the rare event that the diagnosis of a twin gestation is not made until the time of delivery, the practice of permitting placental transfusion to occur, or removing umbilical cord blood, should be done only when it is confirmed that twins do not exist. Otherwise, the second twin may rapidly exsanguinate through these commonly large-caliber vessels (Fig. 4-13).

It must also be realized that the interfetal anastomoses of larger caliber may lead to significant shifts of blood between fetuses. This is particularly important when one fetus dies. The vascular bed of the dead twin relaxes, and a substantial amount of blood from the survivor may enter the dead twin, causing anemia in the survivor, possibly with destructive consequences. It now appears likely that the appreciable frequency of cerebral palsy of a surviving monochorionic twin results from acute hypotension after one twin dies, because of major blood shifts between the twins through placental anastomoses.^{58,64} This feature is then grossly similar to the appearance of the twins shown in Figure 4-14, who died from the transfusion syndrome due to an arteriovenous anastomosis. One twin has much more blood than the other, and when this is the result of large blood vessel anastomoses rather

FIGURE 4-12 Placenta of twin-to-twin transfusion syndrome. Milk is being injected into the arteries of the donor twin. Several arteriovenous shared cotyledons can be seen. A, artery; V, vein; Y, remains of yolk sac.

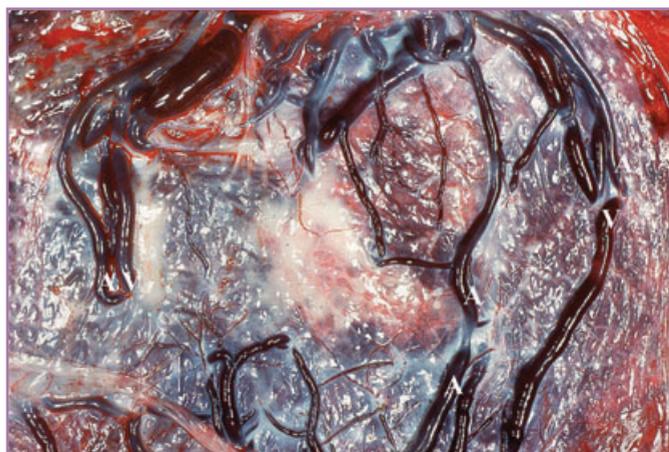

FIGURE 4-13 Diamniotic monochorionic twin placenta showing a portion of the vascular equator. The amnions have been stripped off; only the chorionic surface is seen. Arteries lie on top of veins. Twin A (*top*) displays a normal cotyledonary supply at left, with an artery feeding the cotyledon and a vein returning it to the same fetus. Toward the right (*right* to the yellow patch of subchorionic fibrin) is an artery-to-artery (A/A) anastomosis. An arteriovenous shunt (A-V) is demonstrated at the right. These twins came to term because the A/A anastomosis immediately compensated for any irregularity of blood volume arising from the A-V shunt shown at the right.

than the arteriovenous shunt to be described next, such twins have been erroneously said to have the classic transfusion syndrome. Twins with such marked differences in blood content near term are never the result of the twin-to-twin transfusion syndrome (TTTS).

The Twin-to-Twin Transfusion Syndrome

The most important anastomosis, the arteriovenous shunt, is also the most difficult to diagnose at inspection of the placenta after delivery. It is not a direct communication; instead, it occurs when one cotyledon

FIGURE 4-14 Diamniotic monozygotic twins. The plethoric twin (*right*) had died earlier and as a consequence, the larger fetus (*left*) bled back, through the shared vessels, into the now plethoric fetus. The smaller fetus had a velamentous cord insertion.

is fed by an artery from one twin and the blood is then drained by a vein into the other twin. The arteriovenous shunt is diagrammatically shown in Figure 4-15, and the common vascular relationships at a twin vascular equator are seen in Figure 4-13. To recognize such a shared cotyledon, one must follow all terminal arterial branches (arteries cross over veins) and ascertain whether a vein is returning to the same twin, as is normally the case (see Fig. 4-13, *left*) or whether the cotyledon is drained to the other twin (see Fig. 4-13, *right*). To verify the existence of a common or shared cotyledon, one may inject the artery with water; the shared cotyledon rises and blanches, and the water then drains from the vein of the other twin, thus blanching the common or shared cotyledon (Fig. 4-16). This arrangement has been referred to as the third circulation. It is incorrect, however, to assume that there are other “deep” anastomoses, as are often discussed. Villi are never connected only deep in the placenta, and they can exchange blood only through common shared cotyledons. The situation is different after laser surgery, as has recently been demonstrated (Fig. 4-17).⁶⁵

Arteriovenous shunts may exist singly or may be multiple, and they may be in opposing directions. When they are not accompanied by artery-to-artery or vein-to-vein anastomoses, then one fetus continuously donates blood into the recipient (Figs. 4-18 through 4-20). This is the basis of the twin-to-twin transfusion syndrome, which leads to plethora and hypervolemia (hypertension) of the recipient and anemia (hypotension) of the donor. Cardiac compensation (hypertrophy in

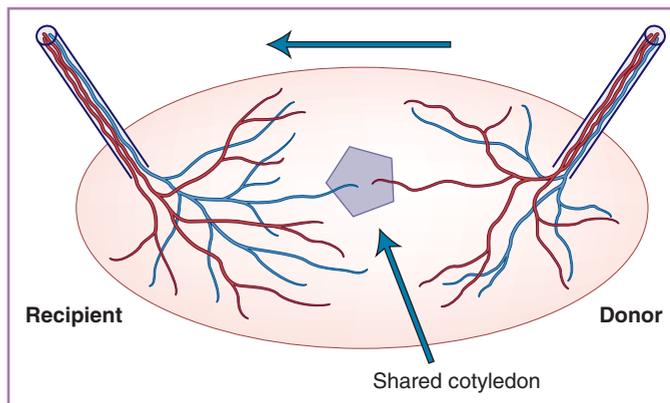

FIGURE 4-15 Diagram of the basis for the twin-to-twin transfusion syndrome.

FIGURE 4-16 Immature placenta. In this cross section of an immature placenta, one cotyledon had been injected with water and, consequently, the villous tissue blanched. This “shared cotyledon” is the basis for the twin-to-twin transfusion syndrome.

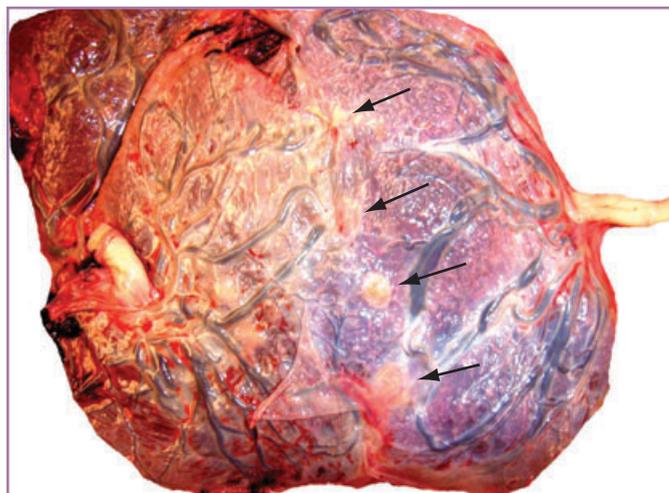

FIGURE 4-17 Monozygotic twin placenta of a laser-treated, twin-to-twin transfusion syndrome pregnancy. The laser-occluded districts are indicated by *arrows*. After laser therapy the pregnancy lasted another 2 months and the twins did well.

the recipient) ensues first and can be seen in abortuses afflicted by the TTTS; this is followed by a wide spectrum of bodily growth differences (Fig. 4-21, and see Fig. 4-18). A common symptom is rapid uterine expansion resulting from hydramnios of the recipient, presumed to be secondary to excessive fetal urination. The hydramnios usually manifests between 20 and 30 weeks of pregnancy, may reach enormous quantities, and is frequently the cause of preterm labor. The amniotic sac of the donor may be dry, and amnion nodosum may develop. The donor fetus is referred to as being “stuck.” The severity and time of

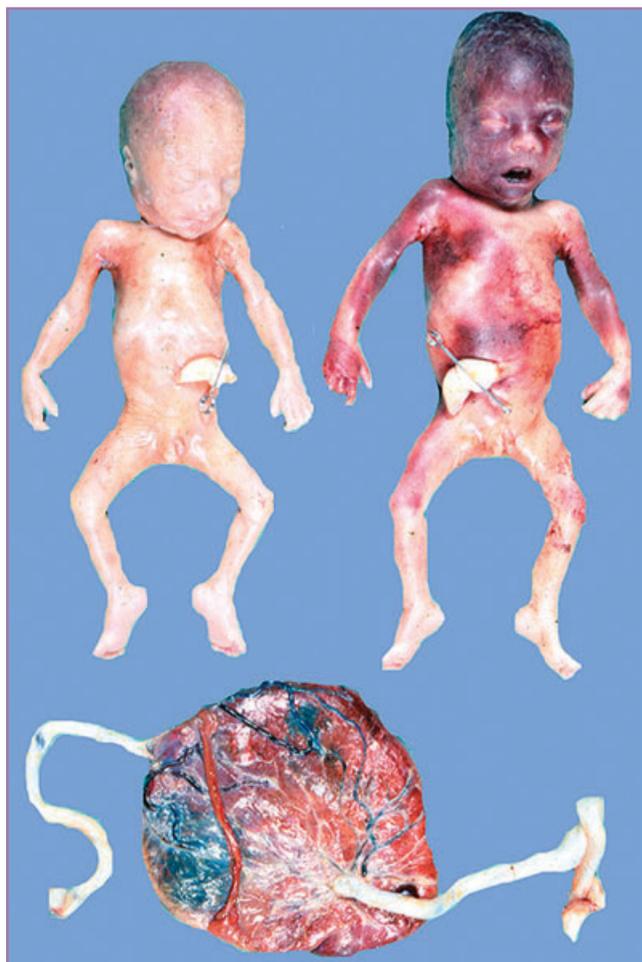

FIGURE 4-18 Diamniotic monochorionic twin abortus resulting from twin-to-twin transfusion syndrome. The recipient (*right*) is plethoric and larger, and the donor (*left*) is anemic and smaller. The monochorionic twin placenta is shown below, and its maternal side is seen in Figure 4-13.

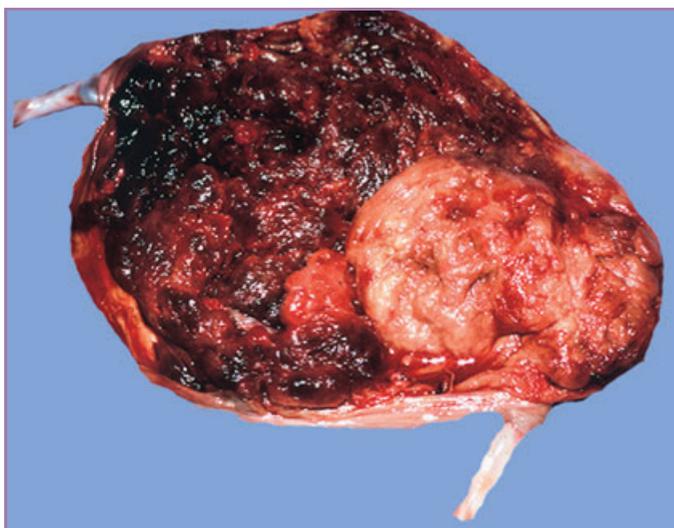

FIGURE 4-19 Twin placenta of twins with twin-to-twin transfusion syndrome, maternal side. This is the set of twins seen in Figure 4-18. Note the smaller quantity and anemia of the donor villous tissue.

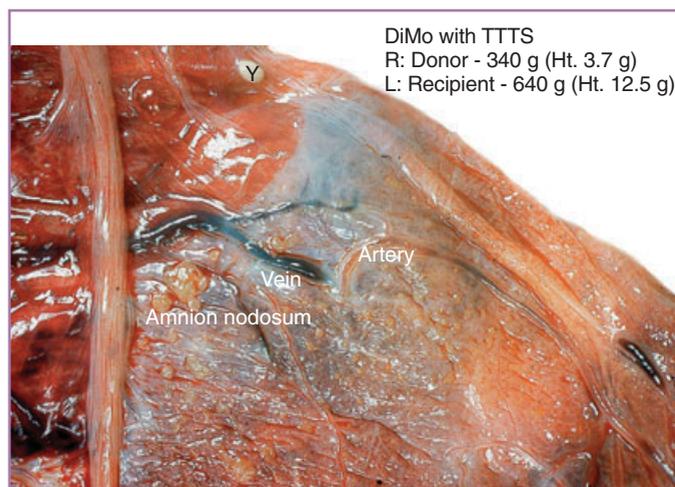

FIGURE 4-20 Placenta of diamniotic monochorionic twins with twin-to-twin transfusion syndrome (TTTS). A single arteriovenous anastomosis (A-V) with common duct is present. The donor side had amnion nodosum; the diamniotic dividing membranes are seen at *left*. Y, remains of yolk sac.

FIGURE 4-21 Aborted monochorionic twins with twin-to-twin transfusion syndrome at 11 weeks' gestation. The recipient (*left*) has a heart size of 440 mg; the donor's heart was 193 mg. Otherwise, the growth differential at this young gestational age is less significant (31 versus 20 g).

noted growth discrepancy probably depends on the size and the number as well as the direction of arteriovenous shunts. On occasion, the syndrome first becomes symptomatic when a formerly balanced blood exchange becomes unstable because of spontaneous thrombosis of a placental vein.⁶⁶

At times, one twin dies in utero, the hydramnios disappears, and the pregnancy goes to term with one twin normal and the other a fetus papyraceus.⁵⁶ When the twins are born, usually prematurely, they may differ remarkably in size; indeed, they may be so discordant that they seem to be DZ twins. Catch-up growth occurs postnatally but often is incomplete, and the twins remain discordant even though they are MZ.

Clinical management of the various complications of twin gestation described here are outlined in detail in Chapter 25.

Abnormalities of Twin Gestation

Fetus Papyraceus

When one or more of the fetuses in a multiple gestation dies before birth and the pregnancy continues, the fluid of the dead twin's tissues is gradually absorbed, the amniotic fluid disappears, and the fetus is compressed and becomes incorporated into the membranes (Fig. 4-22). Hence, it is called a fetus compressus, fetus papyraceus, or membranous twin. The condition occurs in both DZ and MZ twins and is a regular finding when multiple gestations are surgically reduced. This has become much more common in recent years as many fetuses are conceived with ART.^{67,68}

The existence of the fetus papyraceus has important practical and theoretical implications. First, a birth with such an association is not usually entered into statistics as a twin gestation; hence, the frequency of twinning is underestimated. Furthermore, the presence of a fetus papyraceus is often not recognized at birth. Figure 4-23 shows a twin

FIGURE 4-22 Diamniotic dichorionic twin pregnancy with one fetus papyraceus. This fetus had died because of cord entanglement around the leg.

placenta from what was thought to be an abruptio placentae of a singleton birth. One placenta was normal and the other was a shriveled, diminutive, and separate organ of a DZ fetus papyraceus. The small embryo presumably died early, but the preservation of the cord is remarkable. It is possible that this fetus papyraceus was a chromosomally abnormal conceptus that would ordinarily have been aborted had it not been for the normal twin. This would support one hypothesis for the rapid fall in the rate of twin gestations in women over age 35 years. Another less well understood hypothesis purports ovarian failure in older women to be the cause of the decline.¹⁰ Such a fetus papyraceus in diamniotic monochorionic twins is also often overlooked. The example illustrated in Figure 4-23 was small and compressed. This fetus papyraceus is particularly interesting because it was associated with aplasia cutis of the surviving twin. The diffuse form of this unusual skin condition has always been associated with MZ twins, one a fetus papyraceus, in cases in which the placenta has been examined.⁶⁹ The inference is that diffuse patchy aplasia cutis (in contrast to that in the scalp midline) is the result of a prenatal insult associated with the death of one MZ twin.

Another insight into prenatal life afforded by the fetus papyraceus relates to the mechanism that leads to amnion nodosum. When one twin dies, so does the amnion of its sac. This occurs earliest on the diamniotic dividing membranes (Fig. 4-24). Because the amnion does not possess blood vessels, its growth and maintenance must be supported by nutrients and oxygen from adjacent tissues. The large area of dividing membranes, which are in contact only with amniotic fluid, must be maintained by this fluid. The amnion dies because of the disappearance of fluid or deficiency of its oxygen content. Amnion nodosum, or impaction of vernix, occurs secondarily after epithelial death.

Acardiac Twin

The most bizarre malformation recorded, acardiac twin, occurs only in one twin of a pair of MZ twins. The normal twin maintains the acardiac twin by perfusion through two anastomoses, one artery to artery and one vein to vein. The circulation of the acardiac twin is

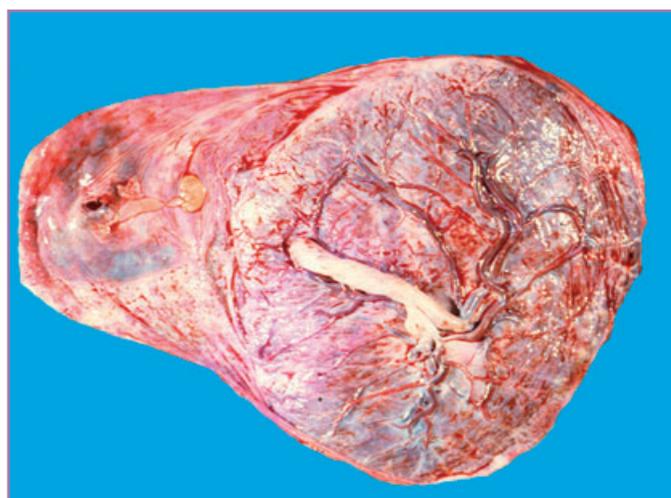

FIGURE 4-23 Placenta of a 35-year-old woman thought to have abruptio placentae. Diamniotic dichorionic separate twin placentas. Fetus papyraceus is attached to cord. Embryo was golden-yellow, about 1 cm. Surviving twin associated with this pregnancy had aplasia cutis.

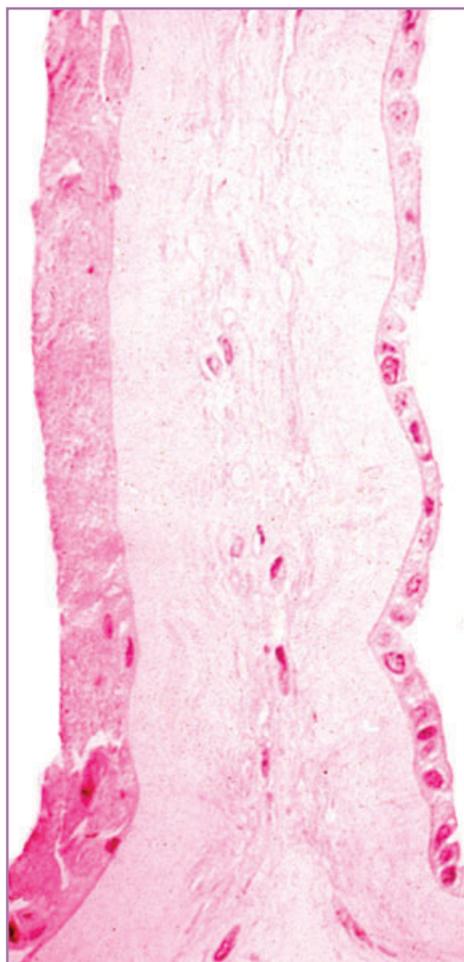

FIGURE 4-24 Cross section of diamniotic dividing membranes. The left twin had died and with it the entire amniotic epithelium.

therefore reversed, and most authors have assumed that this reversal of circulation may also be the cause of the malformation.⁷⁰ This concept is challenged by the occasional observation of an acardiac twin with different chromosomal constitution from that of the always diploid normal twin. Two trisomic acardiac fetuses and one triploid acardiac have been described, findings that suggest major errors in fertilization.^{22,71} Genetic study in the case of Bieber and colleagues indicated the likelihood of origin by fertilization of a polar body for the triploid embryo. It is then remarkable that for every acardiac twin for which adequate placental examination has been made, a monoamniotic (usually monoamniotic) placenta has been found, thought to be diagnostic of monozygosity.

Occasionally, an acardiac fetus is also a fetus papyraceus (Fig. 4-25), and only radiographs disclose its identity. Acardiac fetuses usually have no heart, as the name implies. Occasionally, however, a misshapen heart is found, commonly two chambered. The wide range of sizes and shapes among acardiac twins has led to a complex taxonomy. Most often, acardiac twins possess legs but lack arms and often have no head or have a head that is markedly abnormal. An acardiac fetus may look like an inside-out teratomatous mass (Fig. 4-26), although the fetus can be distinguished from a teratoma by the presence of an umbilical cord. The cord is almost invariably short, betraying the immobility of the acardiac fetus, and it usually possesses only one artery. Occasion-

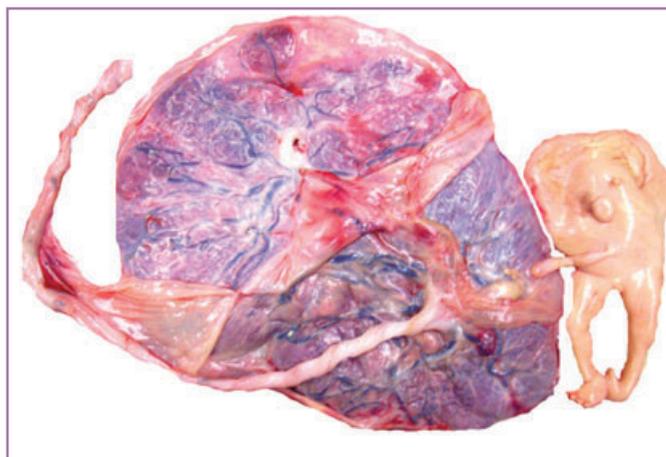

FIGURE 4-25 Triplet pregnancy with two survivors and one macerated acardiac fetus. This is a triamniotic dichorionic placenta, and the umbilical cord of the acardiac fetus had been interrupted by laser ablation 3 months earlier.

FIGURE 4-26 Diamniotic monochorionic term twin placenta. The (amorphous) acardiac twin is at right. It was a skin-covered ball of fat with few bones. The umbilical cord was very short. (Courtesy of the late N. Eastman, Johns Hopkins School of Medicine, Baltimore.)

ally, however, acardiac fetuses have been witnessed to move, and then their cord may be quite long (Fig. 4-27).

Acardiac fetuses are often referred to as representing the twin reversed arterial perfusion syndrome; they can now be detected prenatally by the absence of cardiac activity and reversal of flow by Doppler sonography.⁷² Because the normal twin perfuses this acardiac fetus in a reversed fashion, cardiac hypertrophy and failure may develop in the donor. Healey⁷³ identified a 35% mortality rate for the so-called pump twin, and prenatal removal, cord ligation, and other therapies have been advocated.

Other Anomalies

It has long been known that malformations occur more commonly in twins than in singletons; this increase results from the higher incidence of structural defects in MZ twins.⁷⁴ These anomalies may be concor-

FIGURE 4-27 Monoamniotic twin pregnancy with plethoric acardiac fetus. The acardiac fetus has an unusually long umbilical cord. It had been seen to move sonographically; it had a spinal cord but no brain.

dant but more frequently are discordant, even in MZ twins. The reasons for the genesis of some anomalies are more readily comprehended than for others, such as the discordant development of conjoined twins and perhaps the acardiac anomaly and aplasia cutis that may be associated with sudden drops in blood pressure before birth. It is plausible that some other disruptions, such as porencephaly, occur as a result of interfetal vascular embolization or coagulation, and that other deformations are caused by crowding. In a large number of structural defects, however, the pathogenesis appears to be linked in some way to the twinning process itself. Thus, anencephaly and sirenomelia occur inexplicably commonly as discordant anomalies in MZ twins. These data suggest that further studies may provide significant insight into not only the poorly understood twinning process itself but also the pathogenesis of many congenital anomalies.⁷⁵

Perhaps the most perplexing discordance occurs in the so-called heterokaryotic MZ twins (i.e., MZ twins with different karyotypes and phenotypes). On first impression, the idea of MZ twins with different karyotypes appears to be contradictory. If chromosomal nondisjunction of cells occurs just before or at the time of twinning, however, the process that causes mosaicism in a singleton may lead to MZ twins with different chromosome sets. Most often this has been described for the sex chromosomes, and XO/XXX, XO/XX, and even XO/XY twins

have been reported with appropriate divergence of phenotypes. Sixteen such cases of divergence in gonadal dysgenesis were described by Pedersen and colleagues,⁷⁶ to which cases of discordance for trisomy 21 and some cases of acardiac twins must be added. These are the exceptional events, but they indicate the complexities of the twinning process.

“Disappearance” of a Twin

A word may be said about the apparent frequency of twins detected in early pregnancy by ultrasonography and their “disappearance” in later development. Figure 4-23 clearly indicates that even early embryonic death can be recognized in term placentas. A relevant inquiry resulted in the following findings—spontaneous reduction in twin pregnancies observed sonographically occurred in 36%, of triplets in 53%, and of quadruplets in 65%.⁷⁷

Another reason for a vanishing twin, of course, is the selective fetal reduction of multifetal pregnancies. These multiple pregnancies are often hormonally induced, and selective reduction from triplets to twins improves the outcome of pregnancy.⁷⁸ The “reduced” twin may be detected in the placental membranes, but more often it is represented merely by a small amount of necrotic tissue. The many complications of selective reduction have been summarized by Berkovitz and associates.⁷⁹

Chimeras

On rare occasions, blood grouping or lymphocyte karyotype examination of fraternal twins has shown the coexistence of two genetically dissimilar cell types. This state is referred to as blood chimerism because the solid tissues may not participate in the admixture of genotypes. Blood chimerism is best explained by the existence of transplacental anastomoses in fraternal twins that allowed migration of the bone marrow–like blood cell precursors, circulating in one embryo, to settle in the other twin. Because blood chimerism happens so early in embryonic life, this graft is tolerated as “self” and survives permanently without any ill effect. Although blood chimerism occurs with regularity in marmosets and frequently in twin cattle, where it may cause freemartinism, it must be very uncommon in humans, in whom such anastomoses between the presumably dichorionic twins have been identified only rarely.

Identification of Twin Zygosity

The zygosity of twins is of interest to the twins, their parents, physicians who may treat the children in the future, and to scientists. An attempt should be made to establish the zygosity at birth and to register the objective findings in the chart. Performing this task at the birth is particularly appropriate because of the availability of the placenta, examination of which can aid materially in the process. A good example for this need was provided by St. Clair and colleagues,⁸⁰ who treated presumed DZ twins for renal transplantation. DNA tests established “identity” only 15 years later when the transplant had been successful; immunosuppressive therapy was discontinued only then.

The most efficient way to identify zygosity is as follows: Gender examination allows the classification of male–female pairs as fraternal or DZ. The twins should also have a dichorionic placenta that may be separated or fused. Next, the placenta is studied in detail, and twins

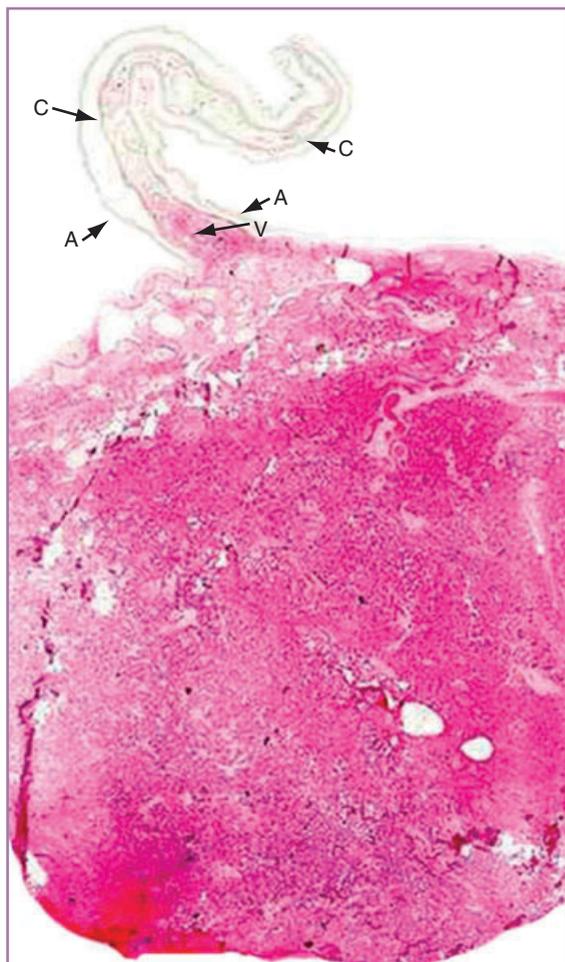

FIGURE 4-28 Fused twin placenta. Transverse-section at point of dividing membranes in diamniotic (A) dichorionic (C) fused twin placenta showing degenerated villi (V) and trophoblast (dark area) between the membranes. Inflammation of the chorial vessel is present (left).

with a monochorionic placenta (monoamniotic or diamniotic) can be set aside as being of MZ (“identical”) origin, whether or not they have dissimilar phenotypes. If doubt exists on gross examination of the dividing membranes, a transverse section (see Figs. 4-2 and 4-28) should be studied histologically. There then remain the like-sex twins with dichorionic placental membranes whose zygosity cannot instantly be known. They must be studied genetically, and the study of DNA polymorphism is currently the best way to approach these difficult problems.³⁸⁻⁴⁰ Cameron⁸¹ examined sex, placentas, and genotypes of 668 consecutive twin pairs in Birmingham, England, and found the following distribution:

- 35% DZ, because they were male and female
- 20% MZ, because they were monochorionic (and had the same sex)
- 45% of the same sex but with dichorionic membranes; when these last were genotyped, 36% were DZ because of genetic differences
- 8% MZ, because of genetic identity

Chapter 5

Biology of Parturition

Errol R. Norwitz, MD, PhD, and Stephen J. Lye, PhD

Labor is the physiologic process by which the products of conception are passed from the uterus to the outside world, and it is common to all viviparous species. The timely onset of labor and birth is an important determinant of perinatal outcome. Considerable evidence suggests that the fetus is in control of the timing of labor, although maternal factors are also involved. Our progress in understanding of the molecular and cellular mechanisms responsible for the onset of labor is slow primarily because of the lack of an adequate animal model and because of the autocrine and paracrine nature of the parturition cascade in humans, which precludes direct investigation. This chapter summarizes the current state of knowledge on the biologic mechanisms responsible for the onset of labor at term in the human.

Morphologic Changes in the Reproductive Tract during Pregnancy

Pregnancy is associated with gestational age–dependent morphologic changes in all tissues of the reproductive tract. The most important changes occur in the uterus and cervix.

The Uterus

The uterus undergoes a dramatic increase in weight (from 4 to 70 g in the nonpregnant state to 1100 to 1200 g at term) and volume (from 10 mL to 5 L) during pregnancy. The number of myometrial cells increases in early pregnancy (referred to as myometrial hyperplasia), but thereafter it remains stable. Myometrial growth in the latter half of pregnancy results primarily from the increase in cell size (hypertrophy) that occurs under the influence of the sex steroids, especially estrogen.¹ This is accompanied by an increase in fibrous and connective tissue as well as blood vessels and lymphatics. In the latter half of pregnancy, distention leads to gradual thinning of the uterine wall. However, this thinning is not uniform throughout the uterus. For example, the lower portion of the uterus (the isthmus) does not undergo hypertrophy and becomes increasingly thin and distensible as pregnancy progresses, thereby forming the lower uterine segment.²

The increase in size of the uterus is accompanied by a 10-fold increase in uterine blood flow—from 2% of cardiac output in the nonpregnant state to 17% at term.^{3,4} Moreover, pregnancy is associated with a redistribution of blood flow within the uterus. In the nonpregnant state, uterine blood flow is equally divided between myometrium

and endometrium. As pregnancy progresses, 80% to 90% of uterine blood flow goes to the placenta, with the remainder distributed equally between the endometrium and myometrium.⁵ Although the cellular mechanisms responsible for the increase in uteroplacental blood flow in pregnancy are not fully understood, the increase in flow parallels the increase in placental size and decrease in placental vascular resistance, most likely related to the sensitivity of the uterine vasculature to circulating levels of estrogen.⁶ However, a number of other biologically active hormones may be involved at the level of the uterine arteries, including vascular endothelial growth factor,⁷ angiotensin II,^{8,9} nitric oxide,⁹⁻¹¹ and prostacyclin (also known as prostaglandin I₂ [PGI₂]).^{11,12}

The Cervix

In contrast to the uterus, which is made up primarily of smooth muscle cells, the cervix is composed of fibrous connective tissue containing an extracellular matrix (collagen, elastin, and proteoglycans) and a number of different cell types (smooth muscle cells, fibroblasts, blood vessels, and epithelial cells). The cervix undergoes extensive remodeling during pregnancy. The amount of collagen decreases progressively, and the collagen fibrils become increasingly dispersed and disorganized, probably because of an increase in the amount of decorin, a low-molecular-weight dermatan sulfate proteoglycan, which coats and separates collagen fibrils.¹³ Ongoing pregnancy is associated with enzymatic degradation of the cervical extracellular matrix caused by the increased activity of matrix metalloproteinases and elastases. Finally, the hormonal influence of estrogen, progesterone, and relaxin may result in increased collagenase activity as well as increased glycosaminoglycan content of the cervix.¹⁴⁻¹⁶

For several weeks before delivery, the connective tissues of the cervix undergo biochemical modifications in preparation for labor that result in changes to its elasticity and tensile strength. These include alterations in water, collagen, elastin, and proteoglycan composition. Advancing gestational age is associated with an increase in hyaluronic acid content within the cervix, which leads to increased water content and loosening and dispersal of collagen fibers.^{16,17} These changes are mediated through the coordinated effort of a number of mechanical factors (such as cervical stretch and pressure of the fetal presenting part) and hormones, including oxytocin, relaxin, nitric oxide, and prostaglandins.¹⁶ Thus, the factors responsible for cervical effacement (softening and shortening) and dilation during labor are most likely a combination of biochemical changes, the mechanical forces of traction caused by myometrial contractions, and pressure resulting from descent of the fetal head.¹⁶

Diagnosis of Labor

Labor is a clinical diagnosis. It is characterized clinically by regular, painful uterine contractions increasing in frequency and intensity and associated with progressive cervical effacement and dilation, leading, ultimately, to expulsion of the products of conception. In normal labor, there appears to be a time-dependent relationship between these factors. Biochemical connective tissue changes in the cervix usually precede uterine contractions and cervical dilation, which, in turn, occur before spontaneous rupture of the fetal membranes. Similarly, pro-contractional biochemical changes in the uterus precede active and effective uterine contractions. Cervical dilation in the absence of uterine contractions is seen most commonly in the second trimester and is suggestive of cervical insufficiency. Similarly, the presence of uterine contractions in the absence of cervical change does not meet criteria for the diagnosis of labor and should be referred to as preterm contractions.

Timing of Labor

The timely onset of labor and birth is an important determinant of perinatal outcome. The mean duration of a human singleton pregnancy is 280 days (40 weeks) from the first day of the last menstrual period. *Term* is defined as the period from 37 weeks of gestation to 42 weeks of gestation. Both preterm (defined as delivery before 37 weeks of gestation¹⁸) and post-term births (delivery after 42 weeks of gestation¹⁹) are associated with increased neonatal morbidity and mortality.

Considerable evidence suggests that, in most viviparous animals, the fetus is in control of the timing of labor.²⁰⁻²⁷ During the time of Hippocrates, it was believed that the fetus presented head first so that it could kick its legs up against the fundus of the uterus and propel itself through the birth canal. We have moved away from this simple and mechanical view of labor, but the factors responsible for the initiation and maintenance of labor at term are still not well understood. The past few decades have seen a marked change in the nature of the hypotheses to explain the onset of labor. Initial investigations centered on changes in the profile of circulating hormone levels in the maternal and fetal circulations (endocrine events). More recent studies have focused on the biochemical dialog that occurs at the fetal-maternal interface (paracrine and autocrine events) in an attempt to understand in detail the molecular mechanisms that regulate parturition.

Genetic Influences on the Timing of Labor

Horse-donkey crossbreeding experiments performed in the 1950s resulted in a gestational length intermediate between that of horses (340 days) and that of donkeys (365 days), suggesting an important role for the *fetal* genotype in the initiation of labor.^{22,23} Moreover, fetuses who fail to trigger labor at the appropriate gestational age, thereby allowing the pregnancy to continue after term, have an increased risk of both antepartum stillbirth and of unexplained death in the first year of life,²⁸⁻³⁰ suggesting that such fetuses may have subtle abnormalities in their hypothalamic-pituitary-adrenal (HPA) axis.

Familial clustering,^{31,32} racial disparities,³³⁻³⁷ and the high incidence of recurrent preterm birth^{38,39} all suggest an important role for *maternal* genetic factors in the timing of labor. For example, black (including African-American, African, and Afro-Caribbean) women in the United

States have a preterm birth rate that is twofold higher than that observed in whites.³³⁻³⁷ Even after adjusting for potential confounding demographic and behavioral variables, the rate of premature deliveries in black women remains higher than that in white women, and this is especially true of extremely premature deliveries before 28 weeks' gestation.^{35,36} Interestingly, the risk of preterm birth in interracial (black-white) couples is significantly different and intermediate between that of white-white (8.6%) and black-black (14.8%) couples.⁴⁰

Taken together, these data suggest that genetic influences of both the mother and the fetus may be involved in the timing of labor. More recent studies suggest that genetic factors—or more correctly, gene-environment factors—may account for up to 20% of preterm births.⁴¹⁻⁴³ For example, maternal carriage of the 308(G>A) polymorphism in the promoter region of the tumor necrosis factor α (TNF- α) gene is associated with an increased risk of spontaneous preterm birth (odds ratio [OR] = 2.7; 95% confidence interval [CI], 1.7 to 4.5),^{44,45} which is further increased in the presence of bacterial vaginosis (OR = 6.1; 95% CI, 1.9 to 21.0).⁴⁴⁻⁴⁶ Interestingly, the risk of spontaneous preterm birth is increased even further if the woman with the TNF α gene promoter polymorphism and bacterial vaginosis also happens to be black (OR = 17).⁴⁶

The Hormonal Control of Labor

The hypothesis that the fetus is in control of the timing of labor has been elegantly demonstrated in domestic ruminants, such as sheep and cows, and involves activation at term of the fetal HPA axis.⁴⁷ In such animals, a sharp rise in the concentration of adrenocorticotropic hormone (ACTH) and cortisol in the fetal circulation 15 to 20 days before delivery⁴⁸ results in an increased expression in the ruminant placenta of the trophoblast cytochrome P450 enzyme 17 α -hydroxylase/C_{17,20}-lyase, which catalyzes the conversion of pregnenolone to 17 α -hydroxypregnenolone and dehydroepiandrosterone. The resultant fall in progesterone and rise in estrone and 17 β -estradiol levels in the maternal circulation stimulate the uterus to produce prostaglandin F_{2 α} (PGF_{2 α}), which provides the impetus for labor.^{25,48-50} Human placentas, however, lack the glucocorticoid-inducible 17 α -hydroxylase/17,20-lyase enzyme,²³ and thus this mechanism does not apply. Despite these observations, recent data suggest that there may be more similarities than differences between these species. In both species, fetal adrenal C19 precursors are used to form estrogens. Androstenedione and dehydroepiandrosterone sulfate (DHEAS) are secreted by the fetal adrenal gland, and their secretion is stimulated by ACTH and hypoxia; DHEAS and androstenedione infused into the fetus can be metabolized into estrone and estradiol, respectively. The result is a progressive increase in conjugated estrogens in maternal plasma during the latter part of gestation, which precedes the sharp rise in estrogen that occurs just before delivery in response to cortisol-mediated induction of the cytochrome P450 enzyme in ruminants and other nonprimate species.

Recent studies in mice suggest that surfactant protein-A (SP-A) secreted from the lungs of near-term pups may provide an additional trigger for parturition in that species.⁵¹ Whether SP-A has a comparable role in humans remains to be determined. As explained in the first paragraph of this chapter, we lack an adequate animal model for study of these events in humans.

It is likely that a parturition cascade (Fig. 5-1) exists in humans that is responsible for the removal of mechanisms maintaining uterine

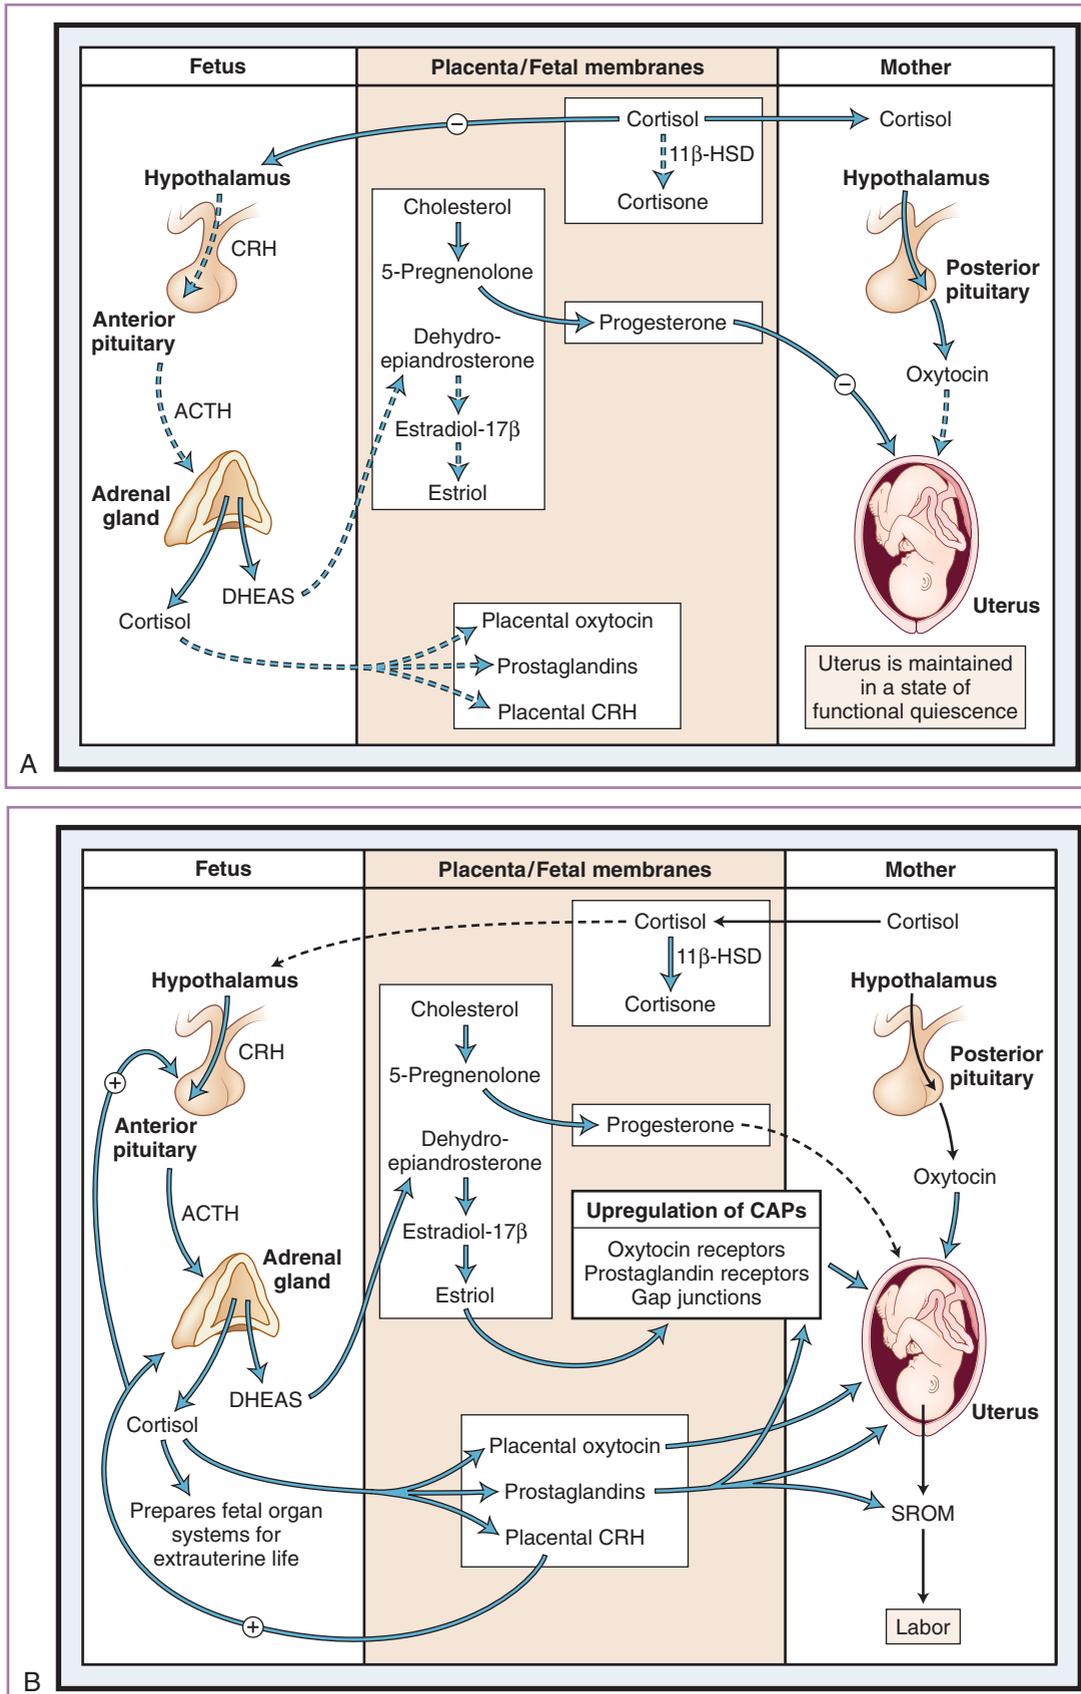

FIGURE 5-1 Proposed parturition cascade for labor induction at term. The spontaneous induction of labor at term in the human is regulated by a series of paracrine and autocrine hormones acting in an integrated parturition cascade. **A**, The factors responsible for maintaining uterine quiescence throughout gestation are shown. **B**, The factors responsible for the onset of labor are shown. They include the withdrawal of the inhibitory effects of progesterone on uterine contractility and the recruitment of cascades that promote estrogen (estriol) production and lead to upregulation of the contraction-associated proteins in the uterus. ACTH, adrenocorticotropic hormone (corticotropin); CAPs, contraction-associated proteins; CRH, corticotropin-releasing hormone; DHEAS, dehydroepiandrosterone; 11β-HSD, 11β-hydroxysteroid dehydrogenase; SROM, spontaneous rupture of membranes.

quiescence and for the recruitment of factors acting to promote uterine activity.²⁶ Given its teleologic importance, such a cascade is likely to have multiple redundant loops to ensure a fail-safe system of securing pregnancy success and ultimately the preservation of the species. In such a model, each element is connected to the next in a sequential fashion, and many of the elements demonstrate positive feed-forward characteristics typical of a cascade mechanism. The sequential recruitment of signals that serve to augment the labor process suggest that it may not be possible to identify any one signaling mechanism as being uniquely responsible for the initiation of labor. It may therefore be prudent to describe such mechanisms as being responsible for *promoting*, rather than *initiating*, the process of labor.⁵²

In brief, human labor is a multifactorial physiologic event involving an integrated set of changes within the maternal tissues of the uterus (myometrium, decidua, and uterine cervix) and fetal membranes, which occur gradually over a period of days to weeks. Such changes include, but are not limited to, an increase in prostaglandin synthesis and release within the uterus, an increase in myometrial gap junction formation, and upregulation of myometrial oxytocin receptors (i.e., uterine activation). Once the myometrium and cervix are prepared, endocrine and/or paracrine/autocrine factors from the fetal membranes and placenta bring about a switch in the pattern of myometrial activity from irregular contractures to regular contractions (i.e., uterine stimulation).⁵³ The fetus may coordinate this switch in myometrial activity through its influence on placental steroid hormone production, through mechanical distention of the uterus, and through secretion of neurohypophyseal hormones and other stimulators of prostaglandin synthesis. The roles of several specific hormones and pathways involved in the timing of labor will now be discussed further.

Fetal Hypothalamic-Pituitary-Adrenal Axis

In virtually every animal species studied, there is an increase in the concentration of the major adrenal glucocorticoid product in the fetal circulation in late gestation (cortisol in the sheep and human; corticosterone in the rat and mouse). As in other viviparous species, the final common pathway toward parturition in the human appears to be maturation and activation of the fetal HPA axis. The result is a dramatic increase in the production of the C19 steroid DHEAS from the intermediate (fetal) zone of the fetal adrenal. As noted, DHEAS is directly aromatized in the placenta to estrone, and it can also be 16-hydroxylated in the fetal liver and converted in the placenta to estriol (16-hydroxy-17 β -estradiol) (see Fig. 5-1). This is because the human placenta is an incomplete steroidogenic organ, and estrogen synthesis by the placenta requires C19 as a steroid precursor.^{25,54,55}

The cellular and molecular factors responsible for the maturation of the fetal HPA axis, although not completely understood, are associated with the gestational age-dependent upregulation of a number of critical genes within each component of the HPA axis: corticotropin-releasing hormone (CRH) in the fetal hypothalamus, proopiomelanocortin in the fetal pituitary, and ACTH receptor and steroidogenic enzymes in the fetal adrenal gland. Animal studies have shown that undernutrition of the mother around the time of conception leads to precocious activation of the fetal HPA and preterm birth,^{56,57} suggesting that—although maturation of the fetal HPA axis is developmentally regulated and the timing of parturition may be determined by a “placental clock” set shortly after implantation—stress may accelerate this clock.⁵⁸ Thus, the length of gestation for any individual pregnancy appears to be established early in gestation, but some degree of flexibility may be possible. For example, rapid and profound activation of the fetal HPA axis has been demonstrated in the setting of experimentally

induced fetal hypoxemia in the sheep, probably representing a functional adaptation and an effort by the fetus to escape a hostile intra-uterine environment.⁴⁸

Levels of CRH in the maternal circulation increase from between 10 and 100 pg/mL in nonpregnant women to between 500 and 3000 pg/mL in the third trimester of pregnancy, and then they decrease precipitously after delivery.⁵⁹ The source of this excess CRH is the placenta, and—in contrast to the situation in the hypothalamus, where corticosteroids suppress CRH expression in a classic endocrine feedback inhibition loop—the production of CRH by the placenta is upregulated by corticosteroids produced primarily by the fetal adrenal glands at the end of pregnancy.⁶⁰ Under the influence of estrogen, hepatic-derived CRH-binding protein (CRH-BP) concentrations also increase in pregnancy. CRH-BP binds and maintains CRH in an inactive form. Importantly, circulating CRH levels increase and CRH-BP levels decrease before the onset of both term and preterm labor, resulting in a marked increase in free (biologically active) CRH.⁶¹ In addition to stimulating the production of ACTH by the fetal pituitary, CRH may also act directly on the fetal adrenal glands to promote the production of C19 steroid precursor (DHEAS).^{62,63} For these reasons, some authorities have proposed that CRH may prime the placental clock that controls the duration of pregnancy, and that measurements of plasma CRH levels in the late second trimester may predict the onset of labor.⁵⁸ In support of this hypothesis, circulating levels of CRH have been shown to be increased in pregnant women with anxiety and depression, which may account for the increased incidence of preterm birth in such women.⁶⁴ However, recent studies have shown that measurements of maternal CRH are not clinically useful because of substantial inpatient and outpatient variability,⁶⁵⁻⁶⁷ which most likely reflects the mixed endocrine and paracrine role of placental, fetal membrane, and decidual CRH in the initiation of parturition.

At a molecular level, CRH acts by binding to specific nuclear receptors and affecting transcription of target genes. A number of CRH receptor isoforms have been described, and all have been identified in the myometrium, placenta, and fetal membranes.⁶⁸ During pregnancy, high-affinity CRH receptor isoforms dominate, and CRH promotes myometrial quiescence by inhibiting the production and increasing the degradation of prostaglandins, increasing intracellular cAMP, and stimulating nitric oxide synthase activity.^{68,69} At term, CRH acts primarily through its low-affinity receptor isoforms, which promote myometrial contractility by stimulating prostaglandin production from the decidua and fetal membranes⁷⁰ and potentiating the contractile effects of oxytocin and prostaglandins on the myometrium.⁷¹

In addition to preparing organ systems for extrauterine life, endogenous glucocorticoids within the fetoplacental unit have a number of important regulatory functions. They regulate the production of prostaglandin at the maternal-fetal interface by affecting the expression of the enzymes responsible for their production and degradation—amniotic prostaglandin H synthase (PGHS) and chorionic 15-hydroxyprostaglandin dehydrogenase (PGDH), respectively.^{72,73} They upregulate placental oxytocin expression⁷⁴ and interfere with progesterone signaling in the placenta.²⁷ Last, they regulate their own levels locally within the placenta and fetal membranes by affecting the expression and activity of the 11 β -hydroxysteroid dehydrogenase (11 β -HSD) enzyme. This enzyme exists in two isoforms: 11 β -HSD-1 acts principally as a reductase enzyme, converting cortisone to cortisol, and is the predominant isoform found in the fetal membranes; 11 β -HSD-2, which predominates in the placental syncytiotrophoblast, serves as a dehydrogenase that primarily oxidizes cortisol to inactive cortisone. It has been proposed that placental 11 β -HSD-2 protects the fetus from high levels of maternal glucocorticoids.⁷⁵⁻⁷⁷ Placental 11 β -HSD-2

expression and activity is reduced in the setting of hypoxemia and in placentas from preeclamptic pregnancies, leading to increased passage of maternal cortisol into the fetal compartment, which may contribute to intrauterine growth restriction as well as fetal programming of subsequent adult disease.⁷⁸

Progesterone

Progesterone is a steroid hormone that plays an integral role in each step of human pregnancy. It acts through its receptor, a member of the family of ligand-activated nuclear transcription regulators. Progesterone produced by the corpus luteum is critical to the maintenance of early pregnancy until the placenta takes over this function at 7 to 9 weeks of gestation—hence its name (progestational steroid hormone). Indeed, surgical removal of the corpus luteum⁷⁹ or the administration of a progesterone receptor (PR) antagonist such as mifepristone (RU-486)⁸⁰ readily induces abortion before 7 weeks (49 days) of gestation. The role of progesterone in later pregnancy, however, is less clear. It has been proposed that progesterone may be important in maintaining uterine quiescence in the latter half of pregnancy by limiting the production of stimulatory prostaglandins and inhibiting the expression of contraction-associated protein genes (ion channels, oxytocin and prostaglandin receptors, and gap junctions) within the myometrium.^{26,27}

In most laboratory animals (with the noted exception of the guinea pig and armadillo), systemic withdrawal of progesterone is an essential component of parturition.²⁷ In humans, however, circulating progesterone levels during labor are similar to levels measured 1 week before labor, and levels remain elevated until after delivery of the placenta,^{23,81} suggesting that systemic progesterone withdrawal is not a prerequisite for labor at term. However, circulating hormone levels do not necessarily reflect tissue levels. In the 1960s, Csapo and Pinto-Dantas put forth the idea of a “progesterone blockage,” which suggested that the myometrial quiescence of human pregnancy was maintained by steady levels of progesterone, just as in pregnancies of other species.⁸² The earliest studies looking at progesterone levels in labor were done separately in the 1970s by Csapo and colleagues⁸³ and Cousins and coworkers⁸⁴ and described a relative progesterone deficiency and an increase in the ratio of 17 β -estradiol to progesterone in patients presenting in preterm labor, regardless of etiology. These and other findings have prompted extensive research into the potential mechanisms of progesterone action on the uterus and the possibility of progesterone therapy to prevent preterm birth.

Although systemic progesterone withdrawal may not correlate directly with the onset of labor in humans, there is increasing evidence to suggest that the onset of labor may be preceded by a physiologic (functional) withdrawal of progesterone activity at the level of the uterus.^{26,27,85} The evidence in support of this hypothesis is mounting. For example, the administration of a PR antagonist (such as RU-486) at term leads to increased uterine activity and cervical ripening.⁸⁶ Moreover, antenatal supplementation with progesterone from 16 to 20 weeks through 34 to 36 weeks of gestation has been shown to reduce the rate of preterm birth in approximately one third of women judged to be at high risk by virtue of a prior spontaneous preterm birth.^{87,88}

The molecular mechanisms by which progesterone is able to maintain uterine quiescence and prevent preterm birth in some high-risk women are not clear. However, six putative mechanisms have been proposed in the literature both by us and by other investigators. These are summarized briefly under the following headings:

Functional Progesterone Withdrawal before Labor May Be Mediated by Changes in PR-A and PR-B Expression with an Increase in the PR-A/PR-B Expression Ratio. The single-copy human PR gene uses separate promoters and translational start sites

to produce two distinct isoforms, PR-A (94 kD) and PR-B (116 kD), which are identical except for an additional 165 amino acids that are present only in the amino terminus of PR-B.^{89,90} Although PR-B shares many of its structural domains with PR-A, they are two functionally distinct transcripts that mediate their own response genes and physiologic effects, with little overlap. PR-B is an activator of progesterone-responsive genes, whereas PR-A acts, in general, as a repressor of PR-B function.⁹¹ The onset of labor at term is associated with an increase in the myometrial PR-A/PR-B expression ratio, resulting in a functional withdrawal of progesterone action.⁹²⁻⁹⁶ The factors responsible for this differential expression with the onset of labor are not known, but they may include prostaglandins (both PGE₂ and PGF_{2 α}), inflammatory cytokines (such as TNF α), and estrogen activation. The changes seen in the PR-A/PR-B ratio in the myometrium are also seen in the cervix⁹⁷ and fetal membranes.⁹⁸ Recent studies indicate that there may be an additional PR isoform (PR-C) that contributes to the onset of labor by inhibiting progesterone-PR signaling in the myometrium.⁹⁹

Progesterone as an Anti-inflammatory Agent. Inflammation has a well-established role in the initiation and maintenance of parturition, both at term and preterm. Progesterone has been shown to inhibit the production and activity of key inflammatory mediators at the maternal-fetal interface, including cytokines (such as interleukin [IL]-1 β and IL-8) and prostaglandins.¹⁰⁰⁻¹⁰² Recent data suggest that progesterone may also exert an anti-inflammatory effect at the level of the myometrium. For example, expression of the chemokine, monocyte chemoattractant protein-1 (MCP-1), increases in human myometrium during labor, both at term and preterm, and in association myometrial stretch.¹⁰³ In other model systems, MCP-1 has been shown to induce an influx of peripheral monocytes that differentiate into macrophages and secrete cytokines, matrix metalloproteinases, and prostaglandins, thereby contributing to an enhanced inflammatory state. Interestingly, myometrial MCP-1 expression can be inhibited by the administration of progesterone, both in vivo and in vitro.¹⁰³

Progesterone Receptor Cofactors Mediate a Functional Withdrawal of Progesterone in the Myometrium at Term. The ability of progesterone to bind its receptor and affect transcription of target genes is reduced in uterine tissues obtained after, compared with before, the onset of labor.¹⁰⁴ Condon and colleagues¹⁰⁵ have shown that the PR coactivators cAMP-response element-binding protein (CREB)-binding protein and steroid receptor coactivators 2 and 3, as well as acetylated histone H3, are decreased in the myometrium of women in labor as compared with women not in labor. These data suggest that the decline in PR coactivator expression and histone acetylation in the uterus near term and during labor may impair progesterone-PR functioning. Progesterone-PR function may also be antagonized directly through the increased expression of PR co-repressors. Dong and coworkers¹⁰⁶ reported that polypyrimidine tract binding protein-associated splicing factor (PSF) blocked PR binding to its DNA response element, thereby preventing the progesterone-PR complex from regulating the transcription of target genes. Interestingly, PSF appears to be expressed at higher levels in myometrium collected from the fundus than myometrium from the lower uterine segment,¹⁰⁷ and, at least in the rodent model, its expression is increased before the onset of labor.¹⁰⁶ Modulation of PR function by coactivators and co-repressors may therefore explain, at least in part, how it is possible to have a functional withdrawal of progesterone action at the level of the uterus without a significant change in circulating progesterone levels.

Progesterone May Interfere with Cortisol-Mediated Regulation of Placental Gene Expression. Cortisol and progesterone appear to have antagonistic actions within the fetoplacental unit. For

example, cortisol increases, and progesterone decreases, prostaglandin⁷⁸ and CRH gene expression.¹⁰⁸ These data suggest that the cortisol-dominant environment of the fetoplacental unit just before the onset of labor may act locally through a series of autocrine and paracrine pathways to overcome the efforts of progesterone to maintain uterine quiescence and prevent myometrial contractions.

Progesterone May Act Also through Nongenomic Pathways. In addition to its well-described genomic effects, progesterone may also act through nongenomic (DNA-independent) pathways. For example, several investigators have shown that select progesterone metabolites (such as 5 β -dihydroprogesterone)—but not progesterone itself—are capable of intercalating themselves into the lipid bilayer of the cell membrane, binding directly to and distorting the heptahelical oxytocin receptor, thereby inhibiting oxytocin binding and downstream signaling.¹⁰⁹⁻¹¹¹ A functional withdrawal of this progesterone metabolite-mediated inhibition of oxytocin action on the myometrium at term would promote myometrial contractility and labor.

Possible Role for Cell Membrane-Bound PR in Myometrium. Recent studies have identified a specific membrane-bound PR in a number of human tissues, including uterine tissues, but the function of this receptor in pregnancy and labor has yet to be fully elucidated.

Estrogens

In the rhesus monkey, infusion of a C19 steroid precursor (androstenedione) leads to preterm delivery.¹¹² This effect is blocked by concurrent infusion of the aromatase inhibitor 4-hydroxyandrostenedione,¹¹³ demonstrating that conversion of C19 steroid precursors to estrogen at the level of the fetoplacental unit is important. However, systemic infusion of estrogen failed to induce delivery, suggesting that the action of estrogen is most likely paracrine or autocrine, or both.^{112,114} Levels of estrogen in the maternal circulation are significantly elevated throughout gestation and are derived primarily from the placenta. In contrast to the situation in many animal species (such as the sheep), the high circulating levels of estrogens in the human are already at the dissociation constant (K_d) for the estrogen receptor, which explains why there is no need for an additional increase in estrogen production at term.

At the cellular level, estrogens exert their effect by binding to specific nuclear receptors and effecting the transcription of target genes. Two distinct estrogen receptors are described: ER α and ER β . Each is coded by its own gene (*ESR1* and *ESR2*, respectively), and requires dimerization before binding to its ligand. At the level of the uterus, ER α appears to be dominant. Expression of ER α increases in concert with an increase in the PR-A/PR-B expression ratio with increasing gestational age in nonlaboring myometrium.^{115,116} These findings suggest that functional estrogen activation and functional progesterone withdrawal are linked. For most of pregnancy, progesterone decreases myometrial estrogen responsiveness by inhibiting ER α expression. Such an interaction would explain why the human myometrium is refractory to the high levels of circulating estrogens for most of pregnancy. At term, however, functional progesterone withdrawal removes the suppression of myometrial ER α expression, leading to an increase in myometrial estrogen responsiveness. Estrogen can then act to transform the myometrium into a contractile phenotype. This model may explain why disruption of progesterone action alone can trigger the parturition cascade. The link between functional progesterone withdrawal and functional estrogen activation may be a critical mechanism for the endocrine and paracrine control of human labor at term.

Prostaglandins

Endogenous levels of prostaglandins in the decidua are lower in pregnancy than in the endometrium at any stage of the menstrual cycle,^{101,117} primarily because of a decrease in prostaglandin synthesis.¹⁰¹ This is true also of prostaglandin production in other uterine tissues. These findings, along with the observation that the administration of exogenous prostaglandins, intravenously, intra-amniotically, or vaginally, in all species examined and at any stage of gestation, has the ability to induce abortion,¹¹⁸⁻¹²⁰ support the hypothesis that pregnancy is maintained by a mechanism that tonically suppresses prostaglandin synthesis, release, and activity throughout gestation.

Overwhelming evidence suggests a role for prostaglandins in the process of labor, both at term and preterm,^{26,27} which is probably common to all viviparous species. For example, mice lacking a functional PGF_{2 α} receptor, cytosolic phospholipase A₂ (PLA₂), or prostaglandin H₂ synthase type 1 (PGHS-1) protein all demonstrate a delay in the onset of labor.¹²¹ In the human, exogenous prostaglandins stimulate uterine contractility both in vitro and in vivo,¹²² and drugs that block prostaglandin synthesis can inhibit uterine contractility and prolong gestation.¹²³ All human uterine tissues contain receptors for the naturally occurring prostanoids and are capable of producing prostaglandins,¹²⁴ although their production is carefully regulated and compartmentalized within the uterus: the fetal membranes produce almost exclusively PGE₂, the decidua synthesizes mainly PGF_{2 α} but also small amounts of PGE₂ and PGD₂, and the myometrium mainly produces prostacyclin (PGI₂). This is because, although these compounds are structurally similar, they can have different and often antagonistic actions. For example, PGF_{2 α} , thromboxane, PGE₁, and PGE₃ promote myometrial contractility by increasing calcium influx into myometrial cells and enhancing gap junction formation,¹²⁴⁻¹²⁶ whereas PGE₂, PGD₂, and PGI₂ have the opposite effect and inhibit contractions.¹²⁴

Prostaglandin levels increase in maternal plasma, urine, and amniotic fluid before the onset of uterine contractions,^{124,127,128} suggesting that it is a cause and not a consequence of labor. Regulation of prostaglandin synthesis occurs at several different levels of the arachidonic acid cascade (Fig. 5-2). Prostaglandins are synthesized from unesterified (free) arachidonic acid released from membrane phospholipids through the action of a series of phospholipase enzymes, the most important of which appears to be phospholipase A₂ (PLA₂). Expression of PLA₂ increases gradually in the fetal membranes throughout gestation, but it does not appear to show further increase at the time of labor. Thereafter, arachidonic acid is metabolized to the intermediate metabolite (PGH₂) by PGHS enzymes, which have both cyclooxygenase and peroxidase activities. PGHS exists in two forms, each a product of a distinct gene: PGHS-1 (which is constitutively expressed) and PGHS-2 (also known as cyclooxygenase-2 [COX-2]), the inducible form that can be upregulated by growth factors and cytokines. Several studies have suggested that the transcription factor, nuclear factor kappa B (NF- κ B), is an important regulator of PGHS-2 expression.²⁷

PGH₂ is rapidly converted to one of the primary (biologically active) prostaglandins through different prostaglandin synthase enzymes (see Fig. 5-2). These hormones act locally in a paracrine or autocrine fashion (or both) by binding to specific prostaglandin receptors on adjacent cells. In addition, unesterified arachidonic acid can diffuse into the cell and interact directly with nuclear transcription factors to regulate the transcription of target genes, including cytokines and other hormones. The primary prostaglandins are then metabolized and excreted. The major pathway in the degradation of PGE_{2 α} and PGF_{2 α} involves the action of a nicotinamide adenine dinucleotide (NAD)⁺-dependent PGDH that oxidizes 15-hydroxy groups, resulting in the formation of 15-keto and 13,14-dihydro-15-keto compounds

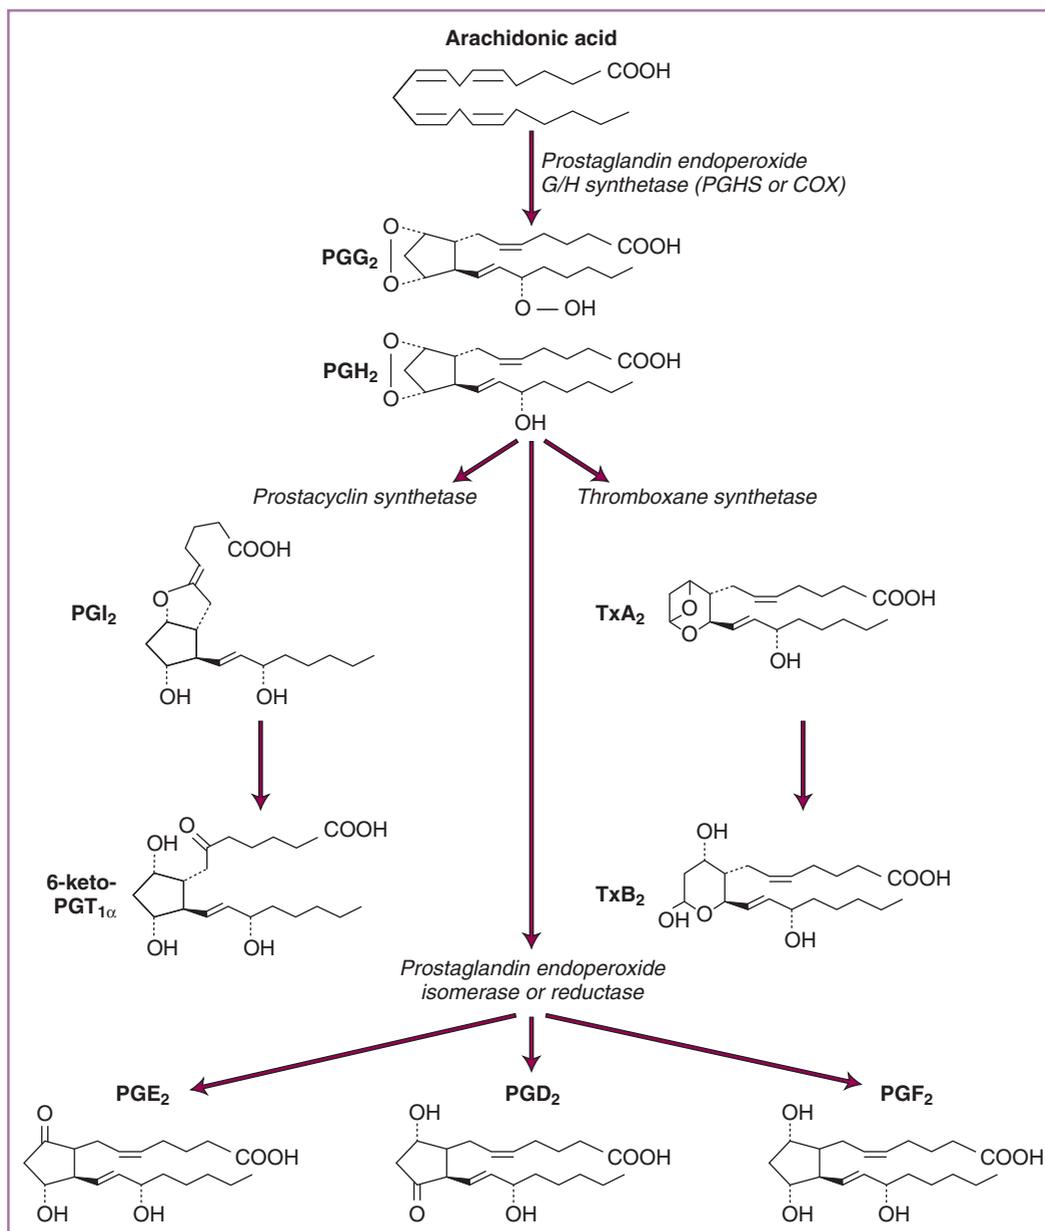

FIGURE 5-2 Schematic representation of the eicosanoid cascade. Dietary linoleic acid (18:3 ω -6) is lengthened and desaturated to form arachidonic acid, which is then esterified and incorporated into phospholipid within cell membranes. In response to a number of hormonal and inflammatory stimuli, phospholipase (PL) enzymes (primarily PLA₂) release free (unesterified) arachidonic acid from membrane phospholipid, which can then be enzymically converted to one of the eicosanoid metabolites. COX, cyclooxygenase; PG, prostaglandin; PGHS, prostaglandin H synthase.

with markedly reduced biologic activity. PGDH is abundantly expressed in the human chorion. In this way, the chorion serves as a protective barrier, preventing the transfer of the primary prostaglandins from the fetoplacental unit to the underlying decidua and myometrium.¹²⁹ Interestingly, the cells that express PGDH (chorionic trophoblasts) are decreased in preterm labor associated with chorioamnionitis resulting in a loss of this metabolic barrier.¹³⁰ The expression of PGDH is regulated by a variety of factors, including cytokines and steroid hormones. For example, progesterone tonically stimulates PGDH expression,⁷² whereas cortisol increases prostaglandin production by the placenta and fetal membranes by upregulating PGHS-2 expression (in amnion

and chorion) and downregulating PGDH expression (in chorionic trophoblast), thereby promoting cervical ripening and uterine contractions.^{67,69,70} In the myometrium, the onset of labor, both at term and preterm, is associated with a significant decrease in PGDH but no change in PGHS-1 or -2 expression, suggesting that levels of prostaglandins in the myometrium may depend largely on catabolism rather than synthesis.¹³¹

Oxytocin

Maternally derived oxytocin is synthesized in the hypothalamus and released from the posterior pituitary in a pulsatile fashion. It is rapidly

inactivated in the liver and kidney, resulting in a biologic half-life of 3 to 4 minutes in the maternal circulation. During pregnancy, oxytocin is degraded primarily by placental oxytocinase. Concentrations of oxytocin in the maternal circulation do not change significantly during pregnancy or before the onset of labor, but they do rise late in the second stage of labor.^{132,133} Studies on fetal pituitary oxytocin production, the umbilical arteriovenous difference in oxytocin concentration, amniotic fluid oxytocin levels, and fetal urinary oxytocin output demonstrate conclusively that the fetus secretes oxytocin toward the maternal side.¹³⁴ Furthermore, the calculated rate of oxytocin secretion from the fetus increases from a baseline of 1 mU/min before labor to approximately 3 mU/min after spontaneous labor, which is similar to the amount normally administered to women to induce labor at term.

Specific receptors for oxytocin are present in the myometrium, and there appear to be regional differences in oxytocin receptor distribution, with large numbers of receptors in the fundal area and few receptors in the lower uterine segment and cervix.^{135,136} Myometrial oxytocin receptor concentrations increase 50- to 100-fold in the first trimester of pregnancy compared with the nonpregnant state, and they increase an additional 200- to 300-fold during pregnancy, reaching a maximum during early labor.^{124,130,131,135-137} This is mediated primarily by the sex steroid hormones, with estrogen promoting and progesterone inhibiting myometrial oxytocin receptor expression.¹³⁰ This rise in receptor concentration is paralleled by an increase in myometrial sensitivity to circulating levels of oxytocin.^{124,130} Activation of myometrial oxytocin receptors results in interaction with the guanosine triphosphate binding proteins of the $G\alpha_{q/11}$ subfamily of G-proteins that stimulate phospholipase C activity resulting in increased production of inositol triphosphate¹³⁸ and calcium influx of calcium.¹³⁹

Specific high-affinity oxytocin binding sites have also been isolated from amnion and decidua parietalis, but not from decidua vera.^{133,140} However, neither amnion nor decidual cells are contractile, and the action of oxytocin on these tissues remains uncertain. It has been suggested that oxytocin plays a dual role in parturition. It may act directly through both oxytocin receptor-mediated and nonreceptor, voltage-mediated calcium channels to affect intracellular signal transduction pathways that promote uterine contractions. It may also act indirectly through stimulation of amniotic and decidual prostaglandin production.^{133,137,140} Indeed, induction of labor at term is successful only when the oxytocin infusion is associated with an increase in $PGF_{2\alpha}$ production, in spite of seemingly adequate uterine contractions in both induction failures and successes.¹³³

Myometrial Contractility

Regulation of Electrical Activity within the Uterus

During pregnancy, the pattern of electrical activity in the myometrium changes from irregular spikes to regular activity. As with other types of muscle, action potentials must be generated and propagated in the myometrium to effect contractions, in a process known as electromechanical coupling.^{141,142} The generation of action potentials of +12 to +25 mV from a normal resting potential of -65 to -80 mV in pregnant myometrial cells relies on the rapid shifts of ions (especially calcium) through membrane ion channels,^{143,144} the most important of which appear to be voltage-sensitive calcium channels and, at the end of pregnancy, fast sodium and potassium channels.^{138,145-149} Autonomous pacemaker cells exist in the uterus. These cells have a higher resting

transmembrane potential and spontaneously initiate action potentials.¹⁵⁰ Action potentials in the uterus occur in bursts, and the strength of contractions relies on their frequency and duration. This, in turn, determines the number of myometrial cells recruited for action. The action potential results in a rapid rise in intracellular calcium derived from both extracellular and intracellular sources, which trigger myometrial contractions by encouraging the relative movement of thick (myosin) and thin (actin) filaments within the contractile apparatus, resulting in shortening of the contractile unit. In this way, the electrical activity is translated into mechanical forces that are exerted on the intrauterine contents (Fig. 5-3).

The frequency of contractions correlates with the frequency of action potentials; the force of contractions correlates with the number of spikes in the action potential and the number of cells activated together; and the duration of contractions correlates with the duration of the action potentials. As labor progresses, electrical activity becomes more organized and increases in amplitude and duration. The strength of contractions, which is best measured as intrauterine pressure in millimeters of mercury (mm Hg), depends on the stage of labor. Early labor contractions have a peak intensity of +25 to +30 mm Hg, and this increases to +60 to +65 mm Hg during active labor.¹⁵¹ A number of factors influence the strength of the uterine contractions, including parity, cervical status, exogenous oxytocin, and labor analgesia (especially epidural analgesia). For example, the more rapid labor observed in multiparous than in nulliparous women is caused not by increased intrauterine pressures during labor (indeed, multiparous women have lower intrauterine pressures than nulliparas)¹⁵² but to a reduction in the resistance of the pelvic floor.

Mechanics of Myometrial Contractions

The structural basis for contractions is the relative movement of thick and thin filaments in the contractile apparatus, which allows them to slide over each other with resultant shortening of the myocyte. Although this movement is similar in all muscles, several structural and regulatory features are unique to smooth muscle including the myometrium.^{153,154} In smooth muscle, the sarcomere arrangement of thick and thin filaments seen in striated muscle is present on a much smaller scale, and intermediate filaments of the cytoskeletal network maintain the structural integrity of these mini-sarcomeres. The thin filaments insert into dense bands linked by the cytoskeletal network, thereby allowing the generation of force in any direction within the cell. This allows smooth muscle cells to generate greater force (greater shortening) than striated muscle cells, and with relatively little energy expenditure.

Myosin makes up the thick filaments of the contractile apparatus. Smooth muscle myosin is a hexamer consisting of two heavy chain subunits (~200 kDa) and two pairs each of 20- and 17-kDa light chains (Fig. 5-4). Each heavy chain has a globular head that contains actin binding sites and sites with adenosine triphosphate (ATP) hydrolysis (ATPase) activity. A neck region connects the globular head to the α -helical tail, which interacts with the tail of the other heavy-chain subunits. In this way, multiple myosin molecules interact through their α -helical tails to make a coiled-coil rod, which forms the thick filament. Thin filaments are composed of actin, which polymerizes into a double-helical strand in association with a number of proteins. When the myosin head interacts with actin, the ATPase activity in the myosin head is activated. The energy generated from the hydrolysis of ATP allows the myosin head to move in the neck region, thereby changing the relative position of the thick and thin filaments with shortening of the contractile unit. The myosin head then detaches

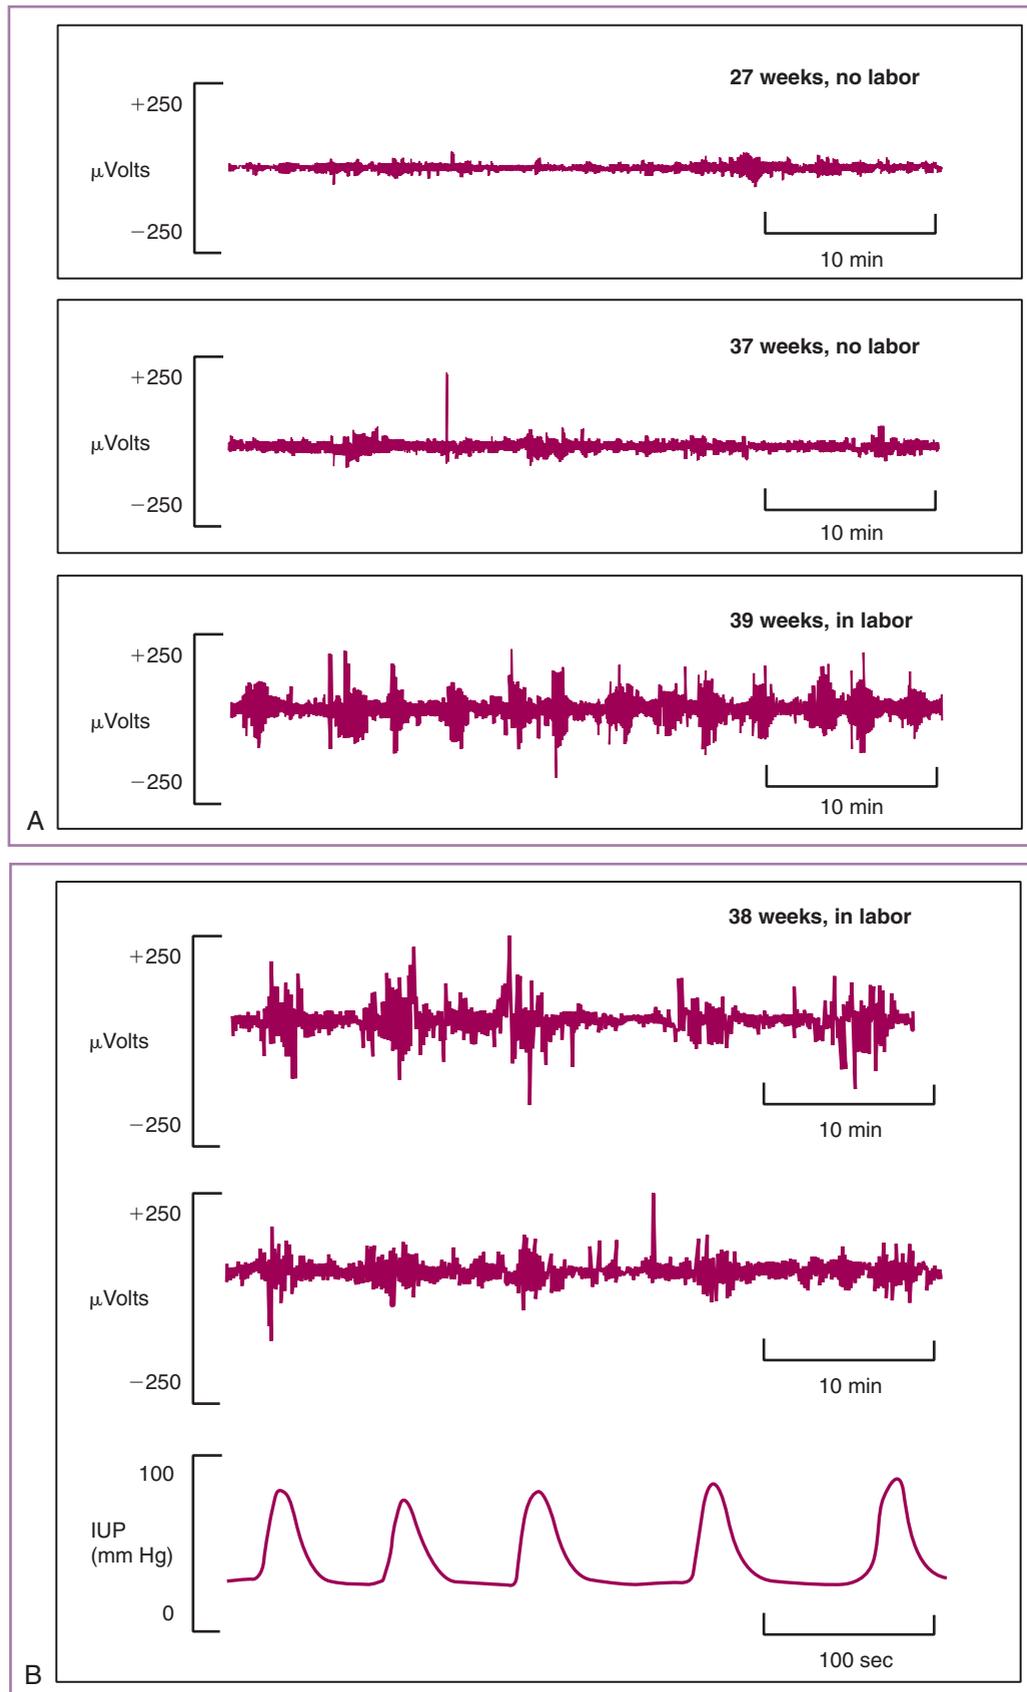

FIGURE 5-3 Uterine electrical activity during pregnancy and labor. **A**, During pregnancy, the pattern of electrical activity in the myometrium changes from irregular spikes to regular activity. Labor is associated with a further increase in the frequency, amplitude, and duration of action potential pulses. **B**, Electrical activity recorded noninvasively from two separate sites on the maternal abdomen is shown, which confirms electrical synchrony within the myometrium during labor. These electrical pulses correlate with uterine contractions as measured using an intrauterine pressure (IUP) catheter. (Modified from Buhimschi C, Buhimschi IA, Malinow AM, et al: The forces of labour. *Fetal Matern Med Rev* 14:273-307, 2003.)

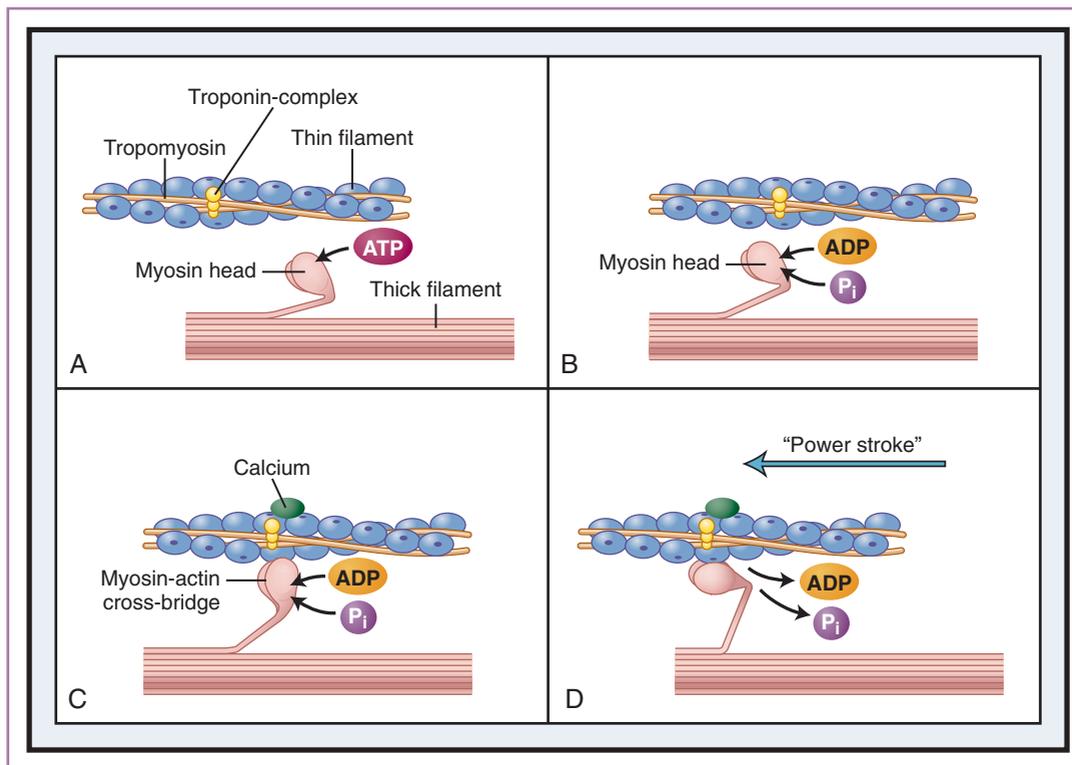

FIGURE 5-4 Mechanics of muscle contraction. **A**, The appearance of the contractile unit is illustrated. The thick filament refers to myosin; the thin filament is actin. Myosin-binding sites on the actin filaments are covered by a thin filament known as tropomyosin that obscures the myosin-binding sites, therefore preventing the myosin heads from attaching to actin and forming cross-bridges. Adenosine triphosphate (ATP) binds to the myosin head. The troponin complex is attached to the tropomyosin filament. **B**, The hydrolysis of ATP into adenosine diphosphate (ADP) and inorganic phosphate (P_i) allows the myosin head to assume its resting position. **C**, The binding of calcium to the troponin complex results in a conformational change that allows binding sites between actin and myosin to be exposed with the formation of actin-myosin cross-bridges. **D**, The formation of actin-myosin cross-bridges results in release of P_i and ADP, causing the myosin heads to bend and slide past the myosin fibers. This “power stroke” results in a shortening of the contractile unit and the generation of force within the muscle. At the end of the power stroke, the myosin head releases the actin-binding site, is cocked back to its furthest position, and binds to a new molecule of ATP in preparation for another contraction. The binding of myosin heads occurs asynchronously (i.e., some myosin heads are binding actin filaments while other heads are releasing them), which allows the muscle to generate a continuous smooth force. Cross-bridge formations must therefore form repeatedly during a single muscle contraction.

and, when reactivated, can reattach at another site on the actin filament.

Actin-myosin interaction is regulated by the intracellular calcium concentration, which is mediated through the calcium-binding protein calmodulin (CaM).^{138,155,156} The calcium-CaM complex binds to and increases the activity of myosin light-chain kinase (MLCK), an enzyme responsible for phosphorylating the 20-kDa myosin light chain on a serine residue near the N-terminus.^{156,157} This results in an increase in myosin ATPase activity, thereby increasing flexibility of the head-neck junction and increasing uterine contractility.¹⁵³ A further increase in intracellular calcium concentration triggers a negative-feedback loop with activation of calcium-CaM-dependent kinase II, an enzyme that phosphorylates MLCK, leading to a decrease in affinity of MLCK for calcium-CaM, a decrease in MLCK activity, and thereby a decrease in myometrial contractility.^{156,158}

A number of intracellular proteins interact with actin and further regulate actin-myosin interactions. Tropomyosin does so by binding to calcium-CaM, making it less available for binding to MLCK; calponin directly inhibits myosin ATPase activity; and caldesmon acts through

both of these mechanisms. The phosphatase group of enzymes also plays an important role in determining the sensitivity of the contractile apparatus to electrical stimuli and changes in intracellular calcium concentrations.¹⁵⁹⁻¹⁶² Phosphatases can be regulated by direct effects on catalytic subunits or by targeting regulatory proteins.^{160,161,163} For example, MLCK phosphatase is responsible for dephosphorylating and thus inactivating MLCK; phosphatases also remove phosphate groups from and relieve the inhibitory actions of the actin-associated regulatory proteins calponin and caldesmon.^{159,163} A number of external stimuli also affect myometrial contractility. For example, myometrial stretch (tension) leads to an increase in intracellular calcium concentration and MLCK phosphorylation.^{155,159} The increase in intracellular calcium concentration typically precedes MLCK phosphorylation, and maximal phosphorylation is evident before maximal force is achieved. For the same amount of tension, less phosphorylation occurs in myometrium from late pregnant than from nonpregnant myometrium,¹⁶⁴ and this effect is seen without an increase in actin-myosin or phosphatase protein content with increasing gestational age.¹⁵⁵

Multiple mechanisms are therefore responsible for the spontaneous contraction-relaxation cycles in human myometrium, including changes in intracellular calcium concentrations, alteration in membrane potential, phosphorylation and dephosphorylation (activation and inhibition) of MLCK, activation of phosphatases, and recruitment of a number of distinct intracellular signal transduction pathways.^{138,149,154,155,158,162} This may explain why smooth muscle contractions can occur in response to external stimuli without a change in membrane potential or intracellular calcium concentration.^{153,154}

Hormonal Regulation of Myometrial Contractility

As in other smooth muscles, myometrial contractions are mediated through the ATP-dependent binding of myosin to actin. In contrast to vascular smooth muscle cells, however, myometrial cells have a sparse innervation that is further reduced during pregnancy.¹⁶⁵ The regulation of the contractile mechanism of the uterus is therefore largely humoral or dependent on intrinsic factors within myometrial cells (or both). During pregnancy, the contractile activity of the uterus is maintained in a state of functional quiescence through the action of various putative inhibitors including, but not limited to, progesterone, prostacyclin (PGI₂), relaxin, parathyroid hormone-related peptide, nitric oxide, calcitonin gene-related peptide, adrenomedullin, and vasoactive intestinal peptide. The onset of uterine contractions at term is a consequence of release from the inhibitory effects of pregnancy on the myometrium as well as recruitment of uterine stimulants such as oxytocin and stimulatory prostaglandins (e.g., PGF_{2α}, PGE₂).¹⁶⁶

Not surprisingly, investigation of the control of myometrial contractility during pregnancy has focused on the physiologic, endocrine, and molecular events that occur a few days before the onset of labor, both at term and before term. Traditionally it was thought that, during the majority of pregnancy, the myometrium was a relatively inert organ whose role was limited to growing and protecting the products of conception. However, recent studies, primarily on rats, have challenged this notion and suggested that the myometrium undergoes a tightly regulated program of differentiation throughout pregnancy. In this model, labor can be viewed as the terminal differentiation state of the myometrium, with downregulation of inhibitory pathways and activation of contractile processes. This model explains why tocolysis in the setting of active preterm labor is largely ineffective.²⁶

The program of myometrial differentiation includes four distinct states or phenotypes: proliferative, synthetic, contractile, and labor. In early pregnancy, uterine myocytes exhibit a high level of proliferation, as evidenced by increased expression of cell cycle markers and anti-apoptotic factors such as BCL2.¹⁶⁷ Myocyte proliferation during this phase is mediated in large part by estrogen-induced expression of insulin-like growth factor-1 (IGF-1).¹⁶⁸ In the rat, the proliferative phenotype ends abruptly on day 14 of 23 of gestation, and the myocytes differentiate to a synthetic phenotype. The switch from a proliferative to a synthetic phenotype most likely results from stretch-induced hypoxic injury to the myometrium that induces expression of stress-activated caspases.¹⁶⁷ The synthetic phase of myometrial differentiation is maintained by progesterone and tension on the uterine wall exerted by the expanding conception. During this phase, the myometrium expresses contractile protein isoforms typical of undifferentiated cells¹⁶⁹ and there is extensive tissue remodeling leading to loss of focal cell-matrix adhesion.¹⁷⁰ Growth of the myometrium during the synthetic period results not from cell proliferation but from myocyte hypertrophy and secretion of interstitial matrix proteins such as collagen I and fibronectin.¹⁷¹

At around day 19 of 23 in the rat, the myometrium switches to a contractile phenotype in preparation for labor. This change appears to be mediated by increased tension on the myometrium and a reduction in circulating progesterone levels, which together lead to an increased expression of more differentiated contractile protein isoforms in myocytes¹⁶⁹ and a switch from the synthesis of interstitial matrix proteins to basement membrane matrix proteins (such as laminin and collagen IV).¹⁷¹ This serves to stabilize focal adhesions and allows myocytes to anchor more firmly into the underlying matrix,¹⁷⁰ which is critical to enable contraction and retraction (shortening) of the myometrium during labor. The slowdown in myocyte growth and continued growth of the fetus during this phase significantly increases myometrial tension which, in the setting of low circulating levels of progesterone (or an increase in the estrogen-to-progesterone ratio), is believed to provide the signal for terminal differentiation of the myometrium.¹⁶⁸ The resultant labor phenotype of the myometrium is associated with the upregulation of a series of “labor genes” or contraction-associated proteins (CAPs) associated with contractile activity, including ion channels that increase myocyte excitability, gap junctions (connexin 43) that increase the synchronization of contractions (Fig. 5-5), and receptors for uterotonic agonists (such as oxytocin and the stimulatory prostaglandins).

At a cellular and molecular level, the upregulation of the CAPs appears to be mediated at the level of gene transcription resulting from increased expression of cFos and other members of the activating protein (AP)-1 family of transcription factors (Fra-1, Fra-2) within myometrial cells caused by uterine stretch and hormonal factors, primarily estrogen.¹⁶⁷ There also appear to be regional differences in gene expression within the myometrium. For example, genes that promote contractile activity (such as connexin 43, oxytocin receptors, and the prostaglandin receptors EP1/4 and FP) are more highly expressed in the uterine fundus, whereas genes associated with contractile inhibition (EP2/4, CRH receptor subtype 1) are expressed more highly in the

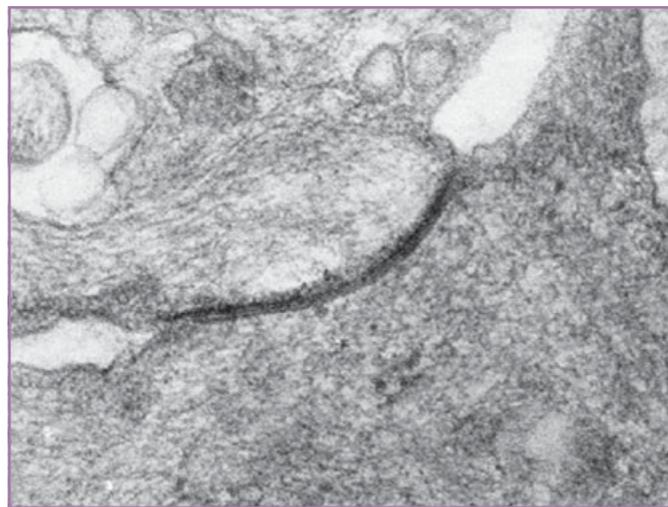

FIGURE 5-5 Electron micrograph of gap junction between adjacent myometrial cells. The transition of the uterus from a quiescent entity to a dynamic, contractile one comes through the recruitment of and communication between myometrial cells through gap junctions. An increase in gap junctions allows action potentials to be propagated between adjacent myometrial cells, thereby establishing electrical synchrony within the myometrium and allowing more effective coordination of contractions. (Reprinted from Buhimschi C, Buhimschi IA, Malinow AM, et al: The forces of labour. *Fetal Matern Med Rev* 14:273-307, 2003.)

lower uterine segment.^{172,173} The molecular mechanisms responsible for the regionalization of gene expression within the uterus have yet to be determined, although recent reports of higher levels of the PR co-repressor, PSF, in the uterine fundus suggests the possibility of regionalized differences in functional withdrawal of progesterone.¹⁰⁷

The role of a number of specific stimulants and relaxants involved in myometrial contractility during labor is discussed under the following headings:

Uterine Stimulants

Table 5-1 summarizes uterine stimulants implicated in uterine contractions during labor. *Oxytocin* is a potent endogenous uterotonic agent (discussed earlier) that is capable of stimulating uterine contractions if given exogenously at intravenous infusion rates of 1 to 2 mU/min at term. *Prostaglandins* (discussed earlier) cause uterine contractions and cervical effacement and dilation, and can be used clinically for induction of labor. A number of other less well recognized uterine factors have also been implicated in the generation of uterine contractions:

Endothelin. Endothelin is a 21–amino acid peptide with potent vasoconstrictor properties that binds to specific receptors on vascular endothelial cells to regulate vascular hemostasis. Endothelin receptors have been isolated in amnion, chorion, endometrium, and myometrium,^{124,174} and they increase in the myometrium during labor.^{174,175} Endothelin promotes uterine contractility directly by increasing intracellular calcium concentrations^{124,176} and indirectly by stimulating prostaglandin production by the decidua and fetal membranes.¹⁷⁴

Epidermal Growth Factor. Epidermal growth factor (EGF) is a ubiquitous growth factor that plays an important role in the regulation of cell growth, proliferation, and differentiation. It acts by binding to specific cell-surface tyrosine-kinase receptors that have been identified also in decidua and myometrium, and it appears to be upregulated by

estrogen.¹²⁴ EGF appears to promote uterine contractility directly by increasing intracellular calcium concentrations¹⁷⁷ and indirectly by mobilizing arachidonic acid and increasing the synthesis and release of prostaglandins by the decidua and fetal membranes.¹⁷⁴

Uterine Relaxants

A number of endogenous uterine relaxants have been described (see Table 5-1), although their role in labor and delivery are not well understood.

Relaxin. Relaxin is secreted by the corpus luteum, placenta, and myometrium, and relaxin binding sites have been identified on myometrial cells.¹⁷⁸ Relaxin acts in several ways to inhibit myometrial contractile activity: it decreases intracellular calcium concentrations by promoting calcium efflux and inhibiting agonist-mediated activation of calcium channels, and it directly inhibits MLCK phosphorylation.^{138,149,178} Unfortunately, exogenous administration of relaxin has not been shown to consistently inhibit uterine contractile activity.¹⁷⁹

Parathyroid Hormone–Related Protein. Parathyroid hormone–related protein (PTHrP) is produced by many tissues, and it has several functions both during development and in adult tissues, including regulation of vascular tone, bone remodeling, placental calcium transport, and myometrial relaxation. In rat myometrium, levels of PTHrP mRNA increase during late gestation and are higher in gravid than in nongravid myometrium.¹⁸⁰ In pregnant rats, administration of PTHrP-(1-34) inhibits spontaneous contractions in the longitudinal layer of the myometrium; in nonpregnant rats, PTHrP-(1-34) inhibits both oxytocin- and acetylcholine-stimulated uterine contractions^{181,182} and delays but does not completely abrogate the increase in connexin 43 and oxytocin receptor gene expression.¹⁸³ PTHrP-(1-34) has been shown to exert a significant relaxant effect on human myometrium collected from late gestation tissues obtained before but not after the onset of labor.¹⁸⁴ Taken together, these data suggest that the onset of labor is associated with a removal of the ability of PTHrP to exert its myometrial relaxant effect.

Calcitonin Gene-Related Peptide and Adrenomedullin.

Circulating levels of calcitonin gene–related peptide (CGRP) and adrenomedullin are increased during pregnancy, and both have been implicated in the maintenance of myometrial quiescence throughout gestation.^{185–187} CGRP has been shown to inhibit myometrial contractility in rats,¹⁸⁵ humans,¹⁸⁸ and mice¹⁸⁹ during pregnancy. However, this effect disappears after the onset of labor, suggesting that progesterone may be required to mediate CGRP activity.¹⁸⁵ Adrenomedullin has been shown to inhibit spontaneous as well as bradykinin- and galanin-induced uterine contractions in rats,^{186,190} but its role in human pregnancy is not well established.

Nitric Oxide. Nitric oxide and its substrate, L-arginine, as well as nitric oxide donors (such as sodium nitroprusside) have been shown to cause relaxation of myometrial contractile activity both in vitro and in vivo, and this effect is reversed by the nitric oxide synthase inhibitor, L-nitro-arginine methyl ester (L-NAME).¹⁹¹ Nitric oxide activates the guanylate cyclase pathway leading to the production of cyclic guanosine monophosphate (cGMP), which decreases intracellular calcium concentrations and interferes with myosin light chain phosphorylation.^{192,193}

Magnesium. Magnesium is present in the extracellular fluid of the myometrium in very high concentrations (10 nM), which results in increased intracellular magnesium levels, inhibition of calcium entry into myometrial cells via L- and T-type voltage-operated calcium channels, and enhanced sensitivity of potassium channels,^{138,149} all of which lead to hyperpolarization and myometrial cell relaxation. Moreover, because they are both cations, magnesium competes with calcium

TABLE 5-1 ENDOGENOUS AND EXOGENOUS FACTORS AFFECTING MYOMETRIAL CONTRACTILITY DURING LABOR

Uterine Stimulants

Endogenous	Exogenous
Oxytocin	Oxytocin
Prostaglandins	Prostaglandins
Endothelin	
Epidermal growth factor	

Uterine Relaxants

Endogenous	Exogenous
Relaxin	β-Adrenergic agonists (ritodrine)
Nitric oxide	hydrochloride, terbutaline sulfate, salbutamol, fenoterol)
L-Arginine	
Magnesium	Oxytocin receptor antagonist (atosiban)
Corticotropin-releasing hormone	Magnesium sulfate
Parathyroid hormone–related protein	Calcium channel blockers (nifedipine, nitrendipine, diltiazem, verapamil)
Calcitonin gene–related peptide	Prostaglandin inhibitors (indomethacin)
Adrenomedullin	Phosphodiesterase inhibitor (aminophylline)
Progesterone	Nitric oxide donor (nitroglycerin, sodium nitroprusside)

within the cell for calmodulin binding, resulting in decreased affinity of calmodulin complexes for MLCK, which further favors myometrial relaxation.¹⁹⁴

Non-naturally Occurring Uterine Relaxants. In addition to naturally occurring uterine relaxants, a number of such agents have been developed in an attempt to stop preterm labor (see Table 5-1). Unfortunately, the ability of these tocolytic agents to prevent preterm birth has been largely disappointing.²⁶

β_2 -Adrenergic receptor agonists act through specific receptors on myometrial cells to activate cAMP-dependent protein kinase A, which inhibits myosin light-chain phosphorylation¹⁹⁵ and decreases intracellular calcium concentrations,^{138,149} thereby leading to myometrial relaxation.

Synthetic competitive *oxytocin receptor antagonists* such as atosiban (which has mixed vasopressin and oxytocin receptor specificity) inhibit uterine contractility both in vitro and in vivo.¹⁹⁶⁻¹⁹⁸ The relative absence of oxytocin receptors in other organ systems suggests that such agents should have few side effects, and this has been borne out by a number of clinical trials.¹⁹⁹⁻²⁰¹

Calcium channel blockers function primarily by inhibiting the entry of calcium ions via voltage-dependent L-type calcium channels, which causes uterine relaxation but can also have adverse effects on the atrioventricular conduction pathway in the heart.

Prostaglandin synthesis inhibitors inactivate the cyclooxygenase enzyme responsible for the conversion of arachidonic acid to the intermediate metabolite (PGH₂), which is subsequently converted to PGE₂ and PGF_{2 α} . Aspirin causes irreversible acetylation of the cyclooxygenase enzyme, whereas indomethacin is a competitive (reversible) inhibitor. Although relatively effective, the adverse effects of these agents on the developing fetus (including premature closure of the ductus arteriosus and persistent pulmonary hypertension) have significantly limited their use. Moreover, these adverse effects can be seen with both nonselective cyclooxygenase inhibitors (such as indomethacin) and those that are selective for the inducible isoform, cyclooxygenase-2 (meloxicam, celecoxib).

Achieving a Successful Delivery

Labor is not a passive process in which uterine contractions push a rigid object through a fixed aperture. The ability of the fetus to successfully negotiate the pelvis during delivery depends on the complex interaction of three critical variables: the forces generated by the uterine musculature (the powers), the size and orientation of the fetus (the passenger), and the size, shape, and resistance of the bony pelvis and soft tissues of the pelvic floor (the passage). Because of the asymmetry in the shape of both the fetal head and the maternal pelvis, the fetus needs to undergo a series of orchestrated rotations (referred to as the cardinal movements) to allow it to negotiate the birth canal successfully. Further discussion of the mechanics of labor and delivery are beyond the scope of this chapter, but they have been reviewed in detail elsewhere.¹⁶⁶ Suffice it to say, the timely onset of labor does not guarantee an uneventful delivery and a healthy, undamaged child.

Conclusions

Labor is a physiologic and continuous process. The factors responsible for the onset and maintenance of normal labor at term are not com-

pletely understood and continue to be actively investigated. A better understanding of the mechanisms responsible for the onset of labor at term will further our knowledge about disorders of parturition, such as preterm and prolonged (post-term) labor, and will improve our ability to secure a successful pregnancy outcome.

Chapter 6

The Immunology of Pregnancy

Gil Mor, MD, PhD, and Vikki M. Abrahams, PhD

Pregnancy as an Allograft

Cases of recurrent abortion, preeclampsia, or hemolytic disease of the newborn raise the rhetorical question, “Why did your mother reject you?” However, considering that maternal-fetal immune interactions are complex and the number of successful pregnancies is vast, perhaps the more salient question is “Why *didn’t* your mother reject you?” More than 50 years ago, the renowned transplant immunologist Sir Peter Medawar proposed a theory as to why the fetus, a semi-allograft, is not rejected by the maternal immune system.¹ He recognized for the first time the unique immunology of the maternal-fetal interface and its potential relevance for transplantation. In his original work, he described the “fetal allograft analogy,” in which the fetus is viewed as a semi-allogeneic conceptus (made of paternal antigens and therefore foreign to the maternal immune system) that, by unknown mechanisms, has evaded rejection by the maternal immune system. Subsequent studies demonstrated the presence of an active maternal immune system at the implantation site, and this provided evidence to support Medawar’s original notion. As a result, investigators began to pursue the mechanisms by which the fetus might escape such maternal immune surveillance. Moreover, alterations in these pathways in pregnancy complications such as recurrent abortion and preeclampsia, where the immune system is thought to play a central role, have been used as further evidence for the Medawar hypothesis of the semi-allogeneic fetus. As a consequence, since Medawar’s original observation, numerous studies have been performed to explain this paradox, many of which have centered on how the fetus and placenta suppress an active and aggressive maternal immune system. The objective of this chapter is to review some of the significant events involved in human implantation as they relate to the interaction between the maternal immune system and the fetus, to challenge some traditional concepts, and to propose a new perspective for the role of the immune system in pregnancy.

Defining the Immunology of Pregnancy

In 1991, Colbern and Main redefined the conceptual framework of reproductive immunology as maternal-placental tolerance rather than a maternal-fetal tolerance, focusing on the interaction between the maternal immune system and the placenta rather than the fetus.² The blastocyst in early development divides into two groups of cells: the internal, inner cell mass, which gives rise to the embryo, and the

external embryonic trophectoderm, which ultimately produces the placenta and fetal membranes. Cells from the placenta directly interact with the mother’s uterine cells and, therefore, the maternal immune system, and these placental cells are able to evade immune rejection. The fetus itself has no direct contact with maternal cells. Moreover, the fetus is known to express paternal major histocompatibility complex (MHC) antigens. Thus, as postulated by Medawar, the fetus would be rejected as a true allograft if removed from its external trophoblast-embedded placental and chorionic “cocoon” and transplanted into the thigh muscle or kidney capsule of the mother.

General Concepts of Immunology

Types of Immune Responses

The immune system eliminates foreign material in two ways: through natural or innate immunity and through adaptive immunity. Innate immunity produces a relatively unsophisticated response that prevents access to the body by potential pathogens. This is a primitive, evolutionarily preserved system that does not require prior exposure to similar pathogens. The primary cell types involved in these responses are phagocytic cells, such as macrophages and granulocytes. These cells express pattern recognition receptors (PRRs) that sense conserved sequences on the surface of microbes, triggering an immune response. As a result, phagocytic cells produce proinflammatory cytokines, release degradative enzymes, generate intense respiratory bursts of free radicals, and ultimately engulf and destroy the invading microorganisms. Thus, the innate immune system provides the first line of defense against invading microbes, and it is critical for priming the adaptive immune response.

Adaptive immunity is an additional, more sophisticated response found in higher forms of species, including humans. Cells of the innate immune system process phagocytosed foreign material and present derived antigens to cells of the adaptive immune system to initiate possible reactions. This immune response is highly specific and normally is potentiated by repeated antigenic encounters. Adaptive immunity consists of two types of immune responses: humoral immunity, in which antibodies are produced; and cellular immunity, which involves infected or foreign cells being lysed by specialized lymphocytes (cytolytic T cells). Adaptive immunity is characterized by an anamnestic response that enables the immune cells to remember the

foreign antigenic encounter and react to further exposures to the same antigen faster and more vigorously.

Cytokines and the Immune Response

Immune cells mediate their effects by releasing cytokines, and through these secreted factors, they establish particular microenvironments. In other words, immune cells through their cytokine production may create either a proinflammatory or anti-inflammatory environment. Moreover, the cytokine profile created by immune cells can shape the characteristics of subsequent immune responses. For example, naive T helper lymphocytes (T_H0) originate in the thymus and play a major role in creating specific microenvironments within the periphery, depending on their differentiation status. If a T_H0 cell then differentiates into a T_H1 cell, it secretes interleukin-2 (IL-2) and interferon- γ (INF- γ), setting the scene for a cellular, cytotoxic immune response. On the other hand, T_H2 lymphocytes secrete cytokines, such as IL-4, IL-6, and IL-10, which are predominantly involved in antibody production. Furthermore, the actions of T_H1 and T_H2 cells are closely intertwined, both acting in concert and responding to counter-regulatory effects of their cytokines. Thus, T_H1 cytokines produce proinflammatory cytokines that, although they act to reinforce the cytolytic immune response, also downregulate the production of T_H2 -type cytokines.

As will be discussed, the pregnant endometrium is populated by maternal immune cells, both during implantation and throughout gestation. Furthermore, the maternal immune system interacts, at different stages and under various circumstances, with the invading trophoblast. Our objective is to understand the types of interactions that occur and their role in the support of a normal pregnancy. We will summarize some of the main hypotheses proposed to explain the trophoblast-maternal immune interaction.

Maternal Immune Response to the Trophoblast: The Pregnant Uterus as an Immune Privileged Site

Implantation is the process by which the blastocyst becomes intimately connected with the maternal gestational endometrium (i.e., the decidua). During this period, the semi-allogeneic trophoblast comes in direct contact with the maternal uterine and blood-borne immune cells. However, as mentioned, in most cases, fetal rejection by the maternal immune system is prevented by a mechanism or mechanisms as yet undefined, but several have been proposed. We will discuss five of the main ones that endeavor to account for the immune privileged state of the decidua: (1) a mechanical barrier effect of the placenta, (2) systemic suppression of the maternal immune system during pregnancy, (3) a local and systemic cytokine shift from a T_H1 to a T_H2 cytokine profile, (4) the absence of MHC class I molecules on the trophoblast, and (5) (a more recent proposal) local immune suppression mediated by the Fas/FasL system.

The Placenta as a Mechanical Barrier

Until the late 1980s, the most popular of the five theories was that a mechanical barrier formed by the placenta prevented the movement of immune cells in both directions across the maternal-fetal interface.

The barrier thus created a state of immunologic ignorance in which fetal antigens were never presented to, and thus never detected by, the maternal immune system. Scientists believed that the barrier, which is formed in the pregnant uterus by the trophoblast and the decidua, prevents the movement of activated, alloreactive, immune cells from the maternal circulation to the fetal side. Similarly, this barrier would isolate the fetus and prevent the escape of fetal cells into the maternal circulation.³

Challenging the mechanical barrier theory are studies showing that the trophoblast-decidual interface is less inert or impermeable than first envisioned. Evidence for bidirectional trafficking across the maternal-fetus interface includes the migration of maternal cells into the fetus³ and the presence of fetal cells in the maternal circulation.⁴ This is now known to be the case in most of the body's other immune privileged tissues, including the brain's blood-brain barrier.⁴ Indeed, fetal cells are observed in the mother decades after the pregnancy.⁵ These cells, like stem cells, have the potential to infiltrate maternal tissues and differentiate into liver cells, muscle, skin, and so on, transforming the mother into a chimera. Originally it was thought that these fetal cells were responsible for triggering autoimmune diseases that more often afflict women.⁶ However, more recent studies have demonstrated that the fetal cells may play a role in repairing maternal tissues that are damaged by a pathologic process. In one case study, a woman suffering from hepatitis stopped treatment (against medical advice), yet, despite this, she did well clinically and her disease abated. Moreover, her liver specimen was found to contain male cells that had originated from her previous pregnancies, suggesting that these leftover fetal cells in the mother's circulation produced new liver cells and were, at least in part, responsible for her recovery.^{5,7,8}

Systemic Immune Suppression

The second theory postulates that pregnancy is a state of systemic immune suppression, and therefore the maternal immune cells are unable to reject the fetus. This concept has been studied by numerous investigators and has become the conventional wisdom. Indeed, a wide array of factors in human serum have been found to have profound *in vitro* immunosuppressive activities.⁹ However, if we carefully analyze this hypothesis, it is difficult to imagine how, from an evolutionary point of view, pregnancy involves a stage of profound immune suppression. Early humans were not able to wash their hands or clean their food, and were continually exposed to bacteria, parasites, and other microorganisms. If pregnant women were systemically immunosuppressed, they would not have survived, and the human species would have become extinct. Even today, in many parts of the world, pregnant women are continually exposed to harsh, unsanitary conditions, and a suppressed immune system would make it impossible for the mother and fetus to survive. Where human immunodeficiency virus (HIV) is pandemic, such as in Africa, HIV-positive women do not develop acquired immunodeficiency syndrome (AIDS) during pregnancy. In fact, recent studies clearly demonstrate that the maternal antiviral immunity is not affected by pregnancy.¹⁰ Together, these observations argue against the existence of such nonspecific immune suppression.

Cytokine Shift

As the definition of pregnancy as a T_H2 or anti-inflammatory state was enthusiastically embraced, numerous studies attempted to prove and support this hypothesis, which postulates that pregnancy is

an anti-inflammatory condition,¹¹ and that a shift in the type of cytokines produced would lead to abortion or pregnancy complications. Many studies supported this hypothesis, but a similar number argued against it.^{12,13} The reason for these contradictory results may have been oversimplification of the disparate observations made during pregnancy. Pregnancy was viewed as a single continuous event. However, it appears to have three distinct immunologic phases characterized by distinct biologic processes that mirror how the pregnant woman feels.

Implantation and placentation in the first trimester and early second trimester of pregnancy resemble an open wound and require a strong inflammatory response. During this first stage, the embryo has to break through the epithelial lining of the uterus to implant; it must damage the underlying endometrial tissue to invade; and it must replace the endothelium and vascular smooth muscle of the maternal blood vessels to secure an adequate blood supply. These activities create a veritable battleground of invading cells, dying cells, and repairing cells. An inflammatory environment is required to secure the adequate repair of the uterine epithelium and the removal of cellular debris. During this period, the mother's well-being is affected: if she feels terrible, it is because her whole body is struggling to adapt to the presence of the fetus. The resultant immune response and attendant hormonal changes (e.g., human chorionic gonadotropin production) are responsible for morning sickness. Thus, the first trimester of pregnancy is a proinflammatory phase (Fig. 6-1).

The second immunologic phase of pregnancy, a period of rapid fetal growth and development, is in many ways the optimal time for the mother. The mother, placenta, and fetus are symbiotic, and the predominant immunologic feature is induction of an anti-inflammatory state. The woman no longer suffers the nausea, extreme fatigue, and inflammatory symptoms that she did in the first phase, in part because the immune response is no longer the predominant endocrine feature.

During the last immunologic phase of pregnancy, the fetus has completed its development; its organs are functional and ready to deal with the external world. Now the mother needs to deliver the infant and this can be achieved only through renewed inflammation. Parturi-

tion is characterized by an influx of immune cells into the myometrium to promote recrudescence of an inflammatory process. This proinflammatory environment promotes the contraction of the uterus, expulsion of the infant, and rejection of the placenta. In conclusion, pregnancy is a proinflammatory and anti-inflammatory condition, depending on the stage of gestation (see Fig. 6-1).¹⁴

Lack of Expression of HLA Antigens

A more recently postulated theory is based on the fact that polymorphic class I and II molecules have not been detected on the trophoblast.¹⁵ MHC class I antigens are expressed on the surface of most nucleated cells and serve as important recognition molecules. In humans, these antigens are also known as human leukocyte antigens (HLA). HLA class I genes, located on chromosomal region 6p.21.3, have been subdivided into two groups—the HLA class Ia and the HLA class Ib genes, according to their polymorphism, tissue distribution, and function. HLA-A, -B, and -C class Ia genes exhibit a very high level of polymorphism, they are almost ubiquitously expressed in somatic tissue, and their immunologic functions are well established. They modulate antiviral and antitumoral immune responses through their interaction with T and natural killer (NK) cell receptors. In contrast, HLA-E, F, and G class Ib genes are characterized by their limited polymorphism and their restricted tissue distribution, and their roles are poorly understood.

The statement that the human placenta does not express polymorphic MHC class I molecules is not entirely accurate. The human placenta does not express the polymorphic HLA-A and HLA-B class I antigens, but it does express HLA-C molecules. In addition, HLA-G and HLA-E molecules are also expressed by the human placenta.^{16,17} Using immunostaining with antibodies against the class I molecule, King and colleagues divided the human trophoblast into two distinct populations: the villous trophoblast in contact with maternal blood at the intervillous interface, which is class I negative, and the extravillous trophoblast invading the uterine decidua, which is class I positive.^{18,19} On the basis of these findings, it was suggested that there are two fetal-maternal interfaces in human reproduction and that they

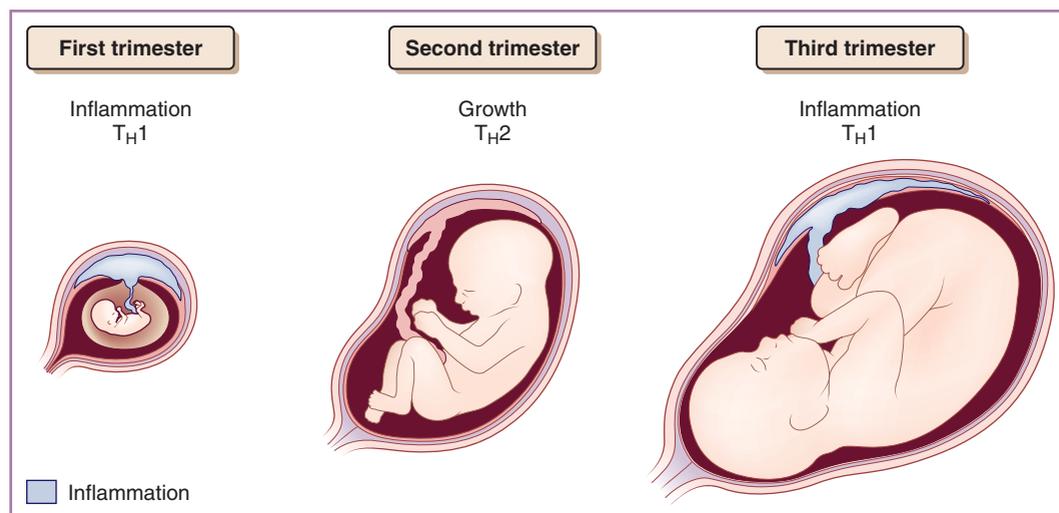

FIGURE 6-1 Inflammation and pregnancy. Each stage of pregnancy is characterized by a unique inflammatory environment. The first and third trimesters are proinflammatory (T_H1), whereas the second trimester represents an anti-inflammatory phase also known as T_H2 environment.

differ immunologically: a trophoblast population that is immunologically neutral in contact with the systemic maternal immune system, and a local immunologically active population of trophoblast cells migrating into the decidua, which can be stimulated by HLA class I.²⁰

HLA-G was originally cloned in 1987, and it was demonstrated to be present in abundant amounts at the maternal-fetal interface.^{21,22} On the basis of what was thought to be an almost exclusive expression of HLA-G at the maternal-fetal interface, it was suggested that this molecule maintains a very specialized role in this environment. Another unique feature of the HLA-G genes, which was postulated to be a prerequisite for maintenance of maternal immune tolerance, is the lack of polymorphism of the HLA-G nucleotide sequence.²³ However, new data have shown that this may not be the case. Thus, alternative splicing of the HLA-G mRNA yields different membrane-bound and soluble variants of the HLA-G protein and a limited number of variable sites in the DNA sequence of the HLA-G gene.²⁴⁻²⁸ Therefore, the hypothesis that HLA-G is the mediator of fetal-maternal tolerance because of its monomorphism and immunologic neutrality needed to be revised.^{23,29,30} In animal studies, it has been shown that murine trophoblast cells express MHC class I genes and alloantigens at high levels early in gestation. During those times, MHC class I is barely detectable on fetal tissues.^{31,32} Therefore, it has been suggested by several investigators that it is highly unlikely that maternal T cells circulating through the murine maternal-fetal interface do not encounter cells of fetal origin. Thus, this pattern of MHC class I expression at the maternal-fetal interface is incompatible with the hypothesis that fetal tissues at the interface are antigenically immature and therefore do not provoke maternal T-cell responses.

In conclusion, although the apparent lack of classic MHC gene expression suggests that the preimplantation embryo is protected from direct immunologic attack by MHC-restricted T cells, the preimplantation embryo could still be vulnerable to a delayed-type hypersensitivity reaction, as well as to adverse effects of antibodies and cytokines by non-MHC-restricted effector cells.

Local Immune Suppression

The last main hypothesis is that there is a specific immune suppressor or regulatory mechanism during pregnancy. According to this hypothesis, immune cells that specifically recognize paternal alloantigens are deleted from the maternal immune system. This elimination process is thought to be achieved through either deletion of these alloreactive cells or through the suppression of their activity. One mechanism by which paternal antigen-recognizing T cells may be deleted is through the induction of cell death (apoptosis) by the Fas/Fas ligand (FasL) system (Fig. 6-2).³³⁻³⁵ Our recent studies indicate that the proapoptotic protein FasL is not expressed at the cell surface membrane of trophoblast cells but instead is secreted via microvesicles and can then act on activated Fas receptor-expressing immune cells at locations away from the implantation site.³⁶ However, the role of this functional, secreted FasL is not fully understood and is under investigation.

Another way in which T cells may recognize and delete paternal antigens is through the production of indolamine 2,3-dioxygenase (IDO) at the maternal-fetal interface.³⁷ IDO is an enzyme that degrades tryptophan, an amino acid that is essential for T-cell proliferation and survival.³⁸⁻⁴⁰ Most recently, studies have described a subset of lymphocytes known as T regulatory cells (Tregs) that are able to suppress the actions of alloreactive T cells to promote fetal-paternal immunotolerance.^{41,42} Together, these are all potential mechanisms for the immune escape of the fetus.

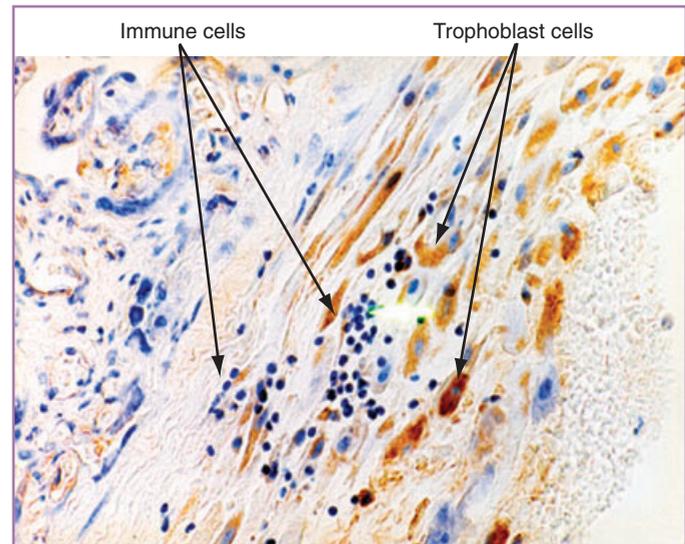

FIGURE 6-2 Expression of FasL in first-trimester trophoblast cells. The proapoptotic protein FasL is highly expressed in extravillous trophoblasts that are in close proximity to maternal immune cells present at the decidua.

The Role of the Innate Immune System in Pregnancy

During normal pregnancy, several of the cellular components of the innate immune system are found at the site of implantation. This has been taken as conclusive proof that the maternal immune system responds to the fetal allograft. During the first trimester, 70% of decidual leukocytes are NK cells, 20% to 25% are macrophages, and approximately 1.7% are dendritic cells.⁴³⁻⁴⁵ These cells infiltrate the decidua and accumulate around the invading trophoblast cells. Furthermore, from the first trimester onward, circulating monocytes, granulocytes, and NK cells increase in number and acquire an activated phenotype. This evidence suggests that the maternal innate immune system is not indifferent to the fetus. However, where once these observations were thought to support the hypothesis of an immune response *against* the fetal allograft, animal studies using cell-deletion methods have proved quite the opposite. Indeed, depletion of NK cells during pregnancy, instead of being protective, has been shown to be detrimental for pregnancy outcome.⁴⁶ Much effort was focused on the susceptibility of the trophoblast to NK cell-mediated cytotoxicity,^{20,47} until it was found that uterine NK cells are not cytotoxic.⁴⁸ Moreover, recently it was shown that uterine NK cells are important for promoting angiogenesis and trophoblast invasion, the two critical events in early pregnancy.⁴⁹ Similar findings have been observed with other immune cells. For example, macrophages within the decidua are important for clearing apoptotic and cellular debris, as well as for facilitating trophoblast migration throughout gestation,⁵⁰⁻⁵² whereas dendritic cells play an important role in the early implantation stage.⁵³ Therefore, the innate immune cells may have a critical role to play in the fetomaternal immune adjustment and in successful placentation. These findings challenge the conventional wisdom and the paradigm of pregnancy that has until now held that the maternal immune system was a threat to the developing fetus.

The field of reproductive immunology has always followed mainstream immunology, translating findings from transplantation to explain the immunology of the maternal-fetal relationship. However, these ideas have failed to conclusively prove the principle of semi-allograft acceptance by the mother and have also produced confusion over the role of the immune system during pregnancy. It is, therefore, time to reevaluate the basic underpinnings of the immunology of pregnancy: Does the fetal-placental unit truly act like an allograft that is in continual conflict with the maternal immune system?

Redefining Medawar's Hypothesis

Medawar's original observation was based on the assumption that the placenta was akin to a "piece of skin" with paternal antigens, which, under normal immunologic conditions, should be rejected. However, the placenta is more than just a transplanted organ. Our knowledge of placental biology has significantly increased over the past 50 years. We now know that the placenta is a complex organ; the original concept of it as an elaborate "egg cover" has evolved. Unlike transplanted grafts, pregnancy and implantation have been taking place for millions of years, and from an evolutionary point of view it is difficult to conceive that the placenta and the maternal immune system maintain an antagonistic status. Thus, although there should be an active mechanism preventing the potential recognition of paternal antigens

by the maternal immune system, the trophoblast and the maternal immune system have evolved to a cooperative status, helping each other against common enemies—that is, against infectious microorganisms.

Today, research is focused on understanding how the trophoblast and the maternal immune system can work together to protect the fetus against infection. The results of our studies suggest that the trophoblast functions like the conductor of a symphony where the musicians are the cells of the maternal immune system. The success of the pregnancy depends on how well the trophoblast communicates with each immune cell type and then how all of them work together. At the molecular level, researchers are trying to understand how the trophoblast recognizes what is present, and, on the basis of that information, what types of signals are sent that would then coordinate the activities of the cellular components at the implantation site.

Current studies demonstrate that, like an innate immune cell, the trophoblast expresses PRRs that function as sensors of the surrounding environment.⁵⁴⁻⁵⁸ Through these sensors, the trophoblast recognizes the presence of bacteria, viruses, dying cells, and damaged tissue. On recognition, the trophoblast often secretes a specific set of cytokines that, in turn, act on the immune cells within the decidua (e.g., macrophages, T regulatory cells, NK cells), "educating" them to work together in support of the growing fetus (Fig. 6-3).⁵⁹ Indeed, each immune cell type acquires specific properties related to implantation and placenta-

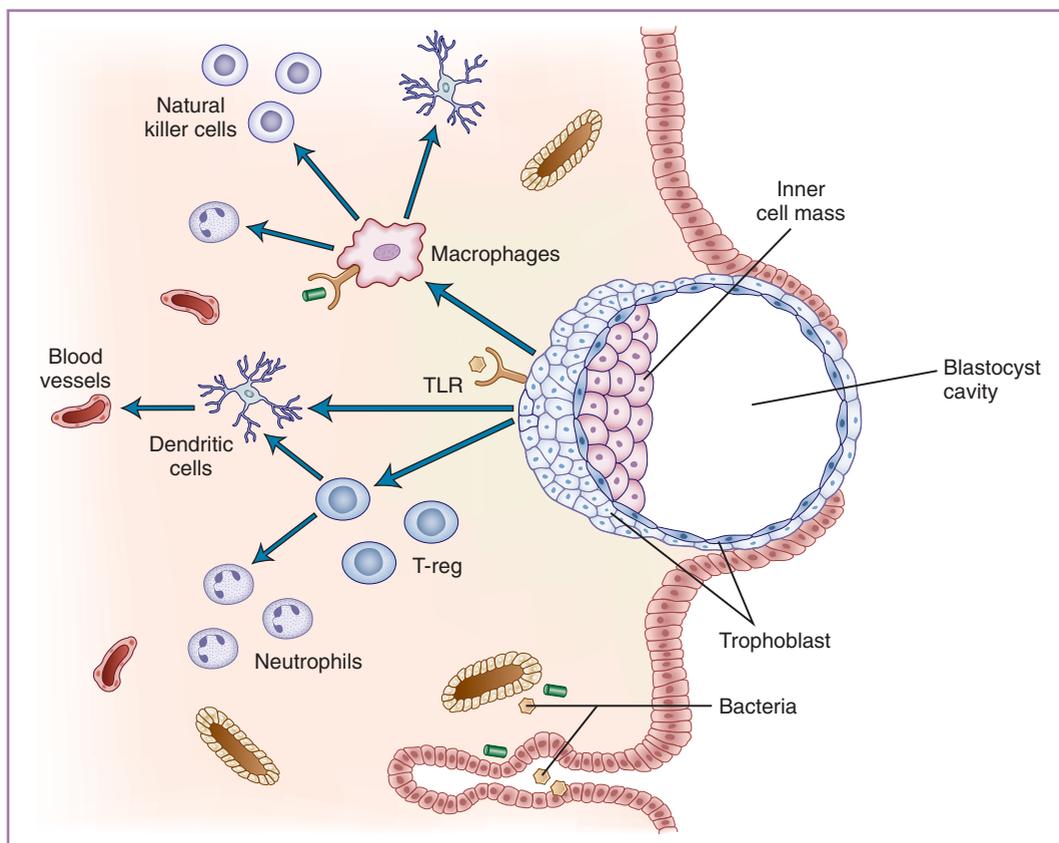

FIGURE 6-3 Trophoblast-immune interaction. The model summarizes a new perspective on trophoblast-immune interaction, in which the placenta and the maternal immune system positively interact for the success of pregnancy. The trophoblast recognizes, through Toll-like receptors (TLRs), microorganisms and the cellular components at the implantation site and responds to them with the production of cytokines and chemokines. These factors coordinate the migration, differentiation, and function of maternal immune cells.

tion, as already discussed. However, a viral or bacterial infection may perturb the harmony of these interactions.

Infection and Pregnancy

Bacterial and viral infections can pose a significant threat to a pregnancy, and to the well-being of the fetus, by gaining access to the placenta through one of three major routes: via the maternal circulation, by ascending into the uterus from the lower reproductive tract, or by descending into the uterus from the peritoneal cavity.⁶⁰ Clinical studies have established a strong association between pregnancy complications and intrauterine infections.⁶⁰⁻⁶² Indeed, infections have been reported as responsible for up to 60% of preterm delivery cases. Up to 80% of preterm deliveries occurring at less than 30 weeks of gestation have evidence of infection,⁶¹⁻⁶³ and other pregnancy complications, such as pre-eclampsia, may have an underlying infectious trigger.⁶⁴⁻⁶⁶ How can a microorganism initiate a response that can induce preterm labor or abortion, or even pre-eclampsia? Interestingly, signals promoting such fetal rejection in the presence of an infection may be initiated by the same cells that promote fetal acceptance under normal conditions—that is, the trophoblast.⁵⁵

Pattern Recognition Receptors

The innate immune system can distinguish between self and infectious nonself through a system of pattern recognition.⁶⁷⁻⁶⁹ A series of innate immune receptors, the PRRs, recognize and bind to highly conserved sequences, known as pathogen-associated molecular patterns (PAMPs), that are expressed by microorganisms. Some of these PRRs can also recognize endogenous stress proteins or damage-associated molecular patterns (DAMPs).⁷⁰ The ligation of PRR by PAMPs or DAMPs often results in an inflammatory response.⁷¹ PRRs include the large and well-defined family of Toll-like receptors (TLRs), which allow either the extracellular or lysosomal (or endosomal) recognition of a wide range of microbes,⁷² whereas the newly identified nucleotide-binding oligomerization domain (NOD) proteins are cytoplasm-based receptors that facilitate responses to invasive intracellular bacteria.⁷³

Toll-like Receptors

Toll-like receptors are transmembrane proteins that have an extracellular domain of leucine-rich repeat motifs, and the various receptors differ in specificity. So, although individually, TLRs respond to limited ligands, collectively the family of TLRs can respond to a wide range of PAMPs associated with bacteria, viruses, fungi, and parasites. Eleven mammalian TLRs have been identified (TLR1 to TLR11),^{74,75} but only TLR1 to TLR10 have been found to be expressed in humans. TLR4, the first to be identified,⁷¹ is the specific receptor for gram-negative bacterial lipopolysaccharide (LPS).⁷⁶ TLR2 has the widest specificity, recognizing bacterial lipoproteins, gram-positive bacterial peptidoglycan (PDG) and lipoteichoic acid, and fungal zymosan.⁷⁷⁻⁷⁹ Also, TLR2 is unusual in that its recognition of some microbial products appears to require the formation of heterodimers with either TLR1 or TLR6.^{80,81} Although the natural ligands for TLR7 and TLR10 are unknown, TLR3 is known to bind viral dsRNA, TLR5 recognizes bacterial flagellin, TLR8 recognizes viral ssRNA, and TLR9 binds microbial CpG DNA.⁸²⁻⁸⁴ In addition, TLR4 and TLR2 can bind DAMPs, such as heat shock protein 60, heat shock protein 70, and fibrinogen.⁸⁵

Ligation of TLRs by microbial products often results in the production of cytokines and antimicrobial factors. Such responses arise via a

common intracellular signaling pathway. On ligand recognition, the TLRs recruit an intracellular signaling adapter protein, myeloid differentiation factor-88 (MyD88), and a subsequent kinase cascade triggers activation of the nuclear factor kappa B (NF- κ B) pathway, which results in the generation of an inflammatory response.⁸⁵ However, TLR3 and TLR4 can also signal in a MyD88-independent manner.⁸⁶ Such MyD88-independent signaling occurs through another adapter protein, TRIF, which, although it can activate the NF- κ B pathway, also results in the phosphorylation of interferon regulatory factor (IRF)-3. This alternative pathway generates an antiviral response associated with the production of type I interferons and interferon-inducible genes.⁸⁷

Toll-like Receptors and Trophoblast Responses to Infection

The expression of all 10 TLRs has been described in the human placenta, and the dominant cell type expressing these TLRs is the trophoblast.⁸⁸⁻⁹⁰ However, the expression of TLRs by trophoblasts differs with their differential stage and with gestational age. For example, first-trimester trophoblasts do not express TLR6, but this receptor is expressed by third-trimester trophoblasts.^{88,91} Furthermore, in first-trimester placentas, the populations expressing TLR2 and TLR4 are the villous cytotrophoblast and the extravillous trophoblasts.^{88,92,93} In contrast, syncytiotrophoblasts do not express these receptors. The lack of TLR expression by the outer trophoblast layer suggests that the first- and second-trimester placenta responds only to a microbe that has broken through this outer layer. Thus, a microorganism poses a threat to the fetus only if the TLR-negative syncytiotrophoblast layer is breached and the pathogen has entered the placental villous compartment.⁵⁷

The term placenta, on the other hand, shows a different pattern of TLR expression, characterized by positive immunoreactivity for TLR2 and TLR4 on the cytoplasm of the syncytiotrophoblast.^{89,93} More recently, Ma and colleagues evaluated the expression of TLR2 and TLR4 in third-trimester placentas and described the expression of TLR2 in endothelial cells, macrophages, syncytiotrophoblasts, and fibroblasts, whereas TLR4 expression was prominently expressed in syncytiotrophoblast and endothelial cells.⁹⁴

In terms of function, Holmlund and coworkers first demonstrated that stimulation with zymosan and LPS induced IL-6 and IL-8 cytokine production by third-trimester placental cultures, without affecting TLR2 and TLR4 mRNA and protein expression levels,⁸⁹ suggestive of functional TLRs in the placenta. Recent studies have demonstrated that TLR-expressing first-trimester trophoblasts generate very distinct patterns of response, depending on the type of stimuli and, therefore, the specific TLR that is activated. For example, first-trimester trophoblasts respond in opposite directions to gram-negative bacterial LPS and gram-positive bacterial PDG. After ligation of TLR4 with LPS, trophoblasts generate a slow inflammatory response, characterized by a modest upregulation of chemokines.^{56,88} In contrast, PDG, which signals through TLR2 rather than generating a cytokine response, induces trophoblasts to undergo apoptosis.⁸⁸ This unusual response after TLR2 stimulation appears to depend on the cooperative receptors TLR1 and TLR6. In trophoblasts that lack TLR6, TLR1 and TLR2 heterodimers promote the proapoptotic effect in response to PDG. However, in the presence of TLR6, cell death is prevented and a cytokine response ensues.⁹⁵ Other studies reporting the induction of trophoblast apoptosis through TLR2 include ultraviolet-inactivated human cytomegalovirus⁹⁶ and a recent report using recombinant chlamydial heat shock protein 60 through TLR4.⁹⁷

In terms of their responses to viral infections, trophoblasts display some unique characteristics. TLR3 ligation by small amounts of viral dsRNA induces a rapid and highly potent inflammatory response characterized by a strong upregulation of chemokines and the production of type I interferons and interferon-inducible genes.⁹⁵ Moreover, the trophoblast has the ability to secrete antimicrobial factors that can act directly on the virus to inhibit its infectivity, suggesting that the placenta can actively prevent the transmission of certain viral infections to the fetus.

Together, these observations suggest that the trophoblast has the ability to discriminate between danger signals that jeopardize the pregnancy and microorganisms that may be necessary for the success of the pregnancy.^{57,98} Viral infections, and possibly gram-positive bacterial infections, may be more likely to pose a threat to the fetus and to pregnancy outcome than an extracellular gram-negative bacterial infection. Indeed, the majority of lower-tract commensals are in this latter group.⁶⁰

We believe that the expression of TLRs allows the trophoblast to recognize microorganisms as well as cellular debris and to coordinate a local immune response that, in principle, would not jeopardize the success of the pregnancy. Thus, the first step in our understanding of this interaction during the implantation process involves the attraction of monocytes by the invading trophoblast. Earlier work showed that trophoblasts constitutively secrete monocyte attractants, such as growth-related oncogene (GRO- α), monocyte chemoattractant protein (MCP-1), and IL-8, and that these trophoblasts are also able to recruit monocytes and macrophages.^{54,57,59} A second step in this trophoblast-immune interaction involves a process of immune cell education, in which signals originating from the trophoblast could determine the subsequent cytokine profile generated by the local decidual immune cells. Thus, we found that first-trimester trophoblast cells induce the production of chemokines (GRO- α , MCP-1, IL-8, RANTES [regulated on activation, normal T cell expressed and secreted]) and TNF- α by monocytes.⁵⁹ We believe that this trophoblast-immune cell crosstalk is characteristic and essential for a normal early pregnancy.

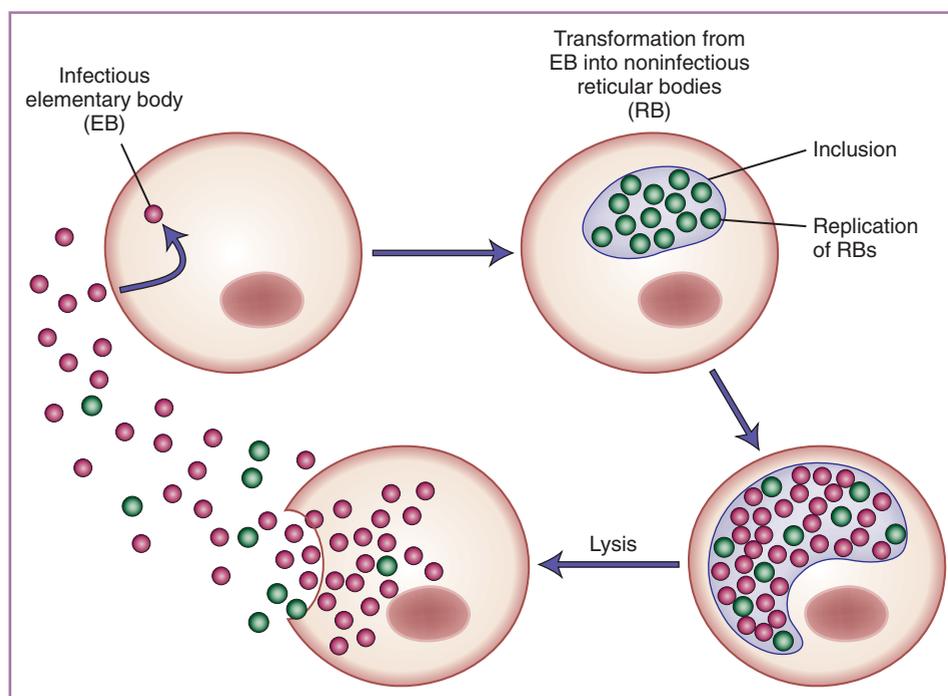

However, a placental response to an infection, if intense enough or left unresolved, may subsequently alter the normal crosstalk between the trophoblast and decidual immune cells. Thus, TLR-mediated trophoblast inflammatory or apoptotic responses to an infection may affect the resident and recruited maternal immune cells by changing them from a supportive to an aggressive phenotype.⁵⁹ This may further promote a strong proinflammatory and proapoptotic microenvironment, and it may ultimately prove detrimental to pregnancy outcome by facilitating fetal rejection.⁵¹ A number of animal models have supported this concept, as well as our *in vitro* observations. Gram-negative bacterial LPS cannot trigger prematurity in wild-type mice when delivered at low concentrations.^{99,100} However, if bacterial LPS is administered at high doses, preterm labor is observed, and this has been shown to be mediated by TLR4.^{101,102}

In vivo studies have also demonstrated that poly(I:C) promotes prematurity in a TLR3-dependent manner,^{103,104} and this is associated with a type-I interferon response.¹⁰⁵ In addition, TLR2 stimulation triggers prematurity *in vivo*.¹⁰⁵⁻¹⁰⁷ These studies, together with clinical data, make a strong case for TLRs as mediators of infection-associated prematurity. Possible therapeutic strategies are now being explored to determine whether the inhibition of TLR signaling might help prevent such pregnancy complications.

Chlamydial Infection and Pregnancy

Although no single infectious agent has been linked to poor pregnancy outcome, some bacteria (e.g., *Mycoplasma hominis*, *Ureaplasma urealyticum*, and *Gardnerella vaginalis*) are more often isolated from patients with preterm delivery than others.^{61,108} One bacterium that has proved much harder to isolate and correlate with poor clinical outcome is *Chlamydia*.^{109,110} *Chlamydia trachomatis* is the most common sexually transmitted infection in the United States¹¹¹ (Fig. 6-4). Chlamydial infection of the female genital tract can result in infertility, ectopic pregnancy, or pelvic inflammatory disease.¹¹² However, the link between chlamydial infection and pregnancy complications is more controver-

FIGURE 6-4 The life cycle of *Chlamydia*. *Chlamydia* is an obligate intracellular gram-negative bacterium. It invades the host cell as an infectious, nonreplicating extracellular elementary body (EB). Once in the cytoplasm, the EB differentiates into an intracellular reticulate body (RB), which then undergoes several rounds of binary fission. This occurs in a specialized compartment known as an inclusion. It is during this phase, if conditions are unfavorable, that a persistent infection can arise. During persistence, the RBs cease to replicate and the life cycle is arrested. However, under normal conditions, after replication, the RBs redifferentiate into infectious EBs, which are released from the host cell 2 to 3 days after infection, during a lytic process. The released EBs then infect neighboring cells.

sial. A recent study revealed that 17% of first-trimester placentas have evidence of chlamydial infection,¹¹³ suggesting that the placenta is a target. Although the concept that chlamydial infection may adversely impact pregnancy has been supported by animal models,¹¹⁴⁻¹¹⁶ clinical data are inconsistent. Studies have shown that a high proportion of spontaneous abortions are positive for *C. trachomatis*,¹¹⁷ and that women positive for antibodies against *C. trachomatis* may be at greater risk for spontaneous abortion or preterm labor.¹¹⁸⁻¹²⁰ Moreover, a recent study reported that *Chlamydia*-infected women have an increased risk of preterm delivery compared with noninfected women.¹²¹ However, other studies have reported no association between *Chlamydia* and prematurity.¹²²⁻¹²⁵

An alternative explanation for this discrepancy could be that it is not the *presence* of a chlamydial infection that defines whether a pregnancy will be negatively affected but instead the *status* of the infection, and this may be governed by the placental innate immune response. We propose that it is an *active* chlamydial infection that may adversely affect pregnancy outcome. Furthermore, it is the placenta that determines whether a chlamydial infection may lie dormant, in a state of persistence, or remain active and pose a threat to the pregnancy. A potential mechanism by which the trophoblast regulates such chlamydial infection is through the expression of a novel group of cytoplasmic receptors, the NOD proteins, which are capable of recognizing intracellular infections.

NOD Proteins and Trophoblast Responses to *Chlamydia*

The NOD proteins, NOD1 (*CARD4*) and NOD2 (*CARD15*), share some similarities with the TLRs, as both types of PRRs contain a leucine-rich repeat domain that is responsible for ligand recognition (Fig. 6-5).¹²⁶ However, unlike the TLRs, the NOD proteins lack a transmembrane domain and, therefore, their cellular localization is restricted to the cytoplasmic compartment, making them poised to respond to microbes that might otherwise escape external immune recognition by invading and replicating within a cell's cytosol. Indeed, NOD proteins have been shown to respond to intracellular pathogens, such as *Listeria*, *Shigella*, and *Chlamydia*.¹²⁷⁻¹³⁰ In addition, NOD proteins also contain a central NOD domain that facilitates self-oligomerization, and CARD domains (one for NOD1 and two for NOD2), which interact with downstream adapter molecules, such as RIP-like interacting CLARP kinase (RICK), to mediate activation of the NF- κ B and mitogen-activated protein kinase (MAPK) pathways.¹³¹⁻¹³⁴ Therefore, activation of NOD1 and NOD2 leads to a signaling cascade that generates an inflammatory response, characterized by the production of cytokines (see Fig. 6-5).^{127,130,135}

Unlike other PRRs, which recognize native microbial components, NOD proteins recognize peptides derived from the degradation of bacterial PDG. Peptidoglycan from all gram-positive and gram-negative bacteria contain the NOD2 ligand, muramyl dipeptide (MDP), making NOD2 a general cytosolic sensor of all bacteria.^{136,137} NOD1 ligand recognition, however, is more selective, as it detects diaminopimelate-containing PDG, specifically the dipeptide γ -D-glutamyl-*meso*-diaminopimelic acid (iE-DAP), which is found in gram-negative bacteria.^{127,128} The PDG motifs recognized by NOD1 and NOD2 are natural degradation products that are released during bacterial growth.¹²⁸ This is another reason why NOD proteins are thought to play a role in immune responses toward invasive intracellular bacteria that replicate in the cytoplasm of a host cell.¹²⁸ Indeed, studies have shown that *Chlamydia*, an obligate intracellular bacterium, contains the stimulatory motifs for NOD1 and NOD2.^{138,139}

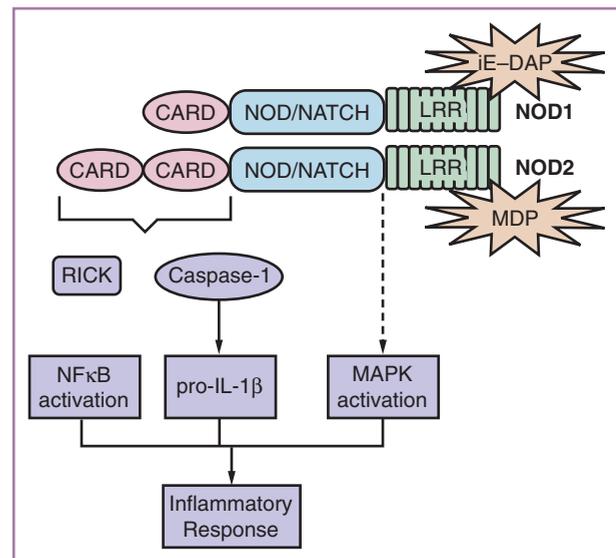

FIGURE 6-5 Structure of NOD1 and NOD2 and their signaling pathways. NOD1 and NOD2 contain a leucine-rich repeat (LRR) domain that is responsible for ligand recognition, and a central NOD/NATCH domain that facilitates self-oligomerization. NOD1 contains a single CARD domain, and NOD2 contains two CARD domains. After recognition of their specific ligands, NOD1 and NOD2 recruit RICK to their CARD domains, and RICK in turn activates the nuclear factor (NF)- κ B pathway, resulting in the induction of an inflammatory response. NOD1 and NOD2 also have the capacity to bind and activate procaspase-1 through their CARD domains. Caspase-1 activation results in the processing of pro-interleukin-1 beta (IL-1 β) into active IL-1 β . NOD1 and NOD2 can also activate the mitogen-activated protein kinase (MAPK) pathway, although the upstream molecular mechanism of this is unknown at present. iE-DAP, γ -D-glutamyl-*meso*-diaminopimelic acid; MDP, muramyl dipeptide.

NOD1 and NOD2 are expressed in first-trimester placenta and are localized to the villous cytotrophoblast and syncytiotrophoblast cells (Fig. 6-6).⁵⁸ In addition, isolated first-trimester trophoblast cells express NOD1 and NOD2 as well as the signaling effector protein RICK.⁵⁸ That the syncytiotrophoblast layer expresses these intracellular receptors is important because, as mentioned earlier, these cells lack the transmembrane TLRs.⁸⁸ This further supports the concept that the placenta responds only to a bacterium that has either breached this protective cell layer or gained access to the placenta via the decidua and/or intervillous space. Bacterial MDP through NOD2 triggers first-trimester trophoblasts to produce elevated levels of cytokines and chemokines,⁵⁸ as does NOD1 in response to iE-DAP (unpublished observations). Therefore, the trophoblast appears to be fully equipped to respond to the PDG derivatives that might be generated in the cytosol by a replicating intracellular bacterium such as *Chlamydia* (see Fig. 6-4). Indeed, we find that trophoblast cells mount an inflammatory response only when infected with an active chlamydial infection; ultraviolet-inactivated *Chlamydia* has no effect on these cells (unpublished observations).

Therefore, it is plausible that the response triggered by the trophoblast, through NOD proteins in response to a chlamydial infection, may change the infection from an active state into one of persistence. One of the mechanisms by which this process may be mediated involves the subsequent upregulation of IDO production.³⁷ A chlamydial infection in this persistent state would not be detrimental to the pregnancy (Fig. 6-7). However, should this infection remain active or become

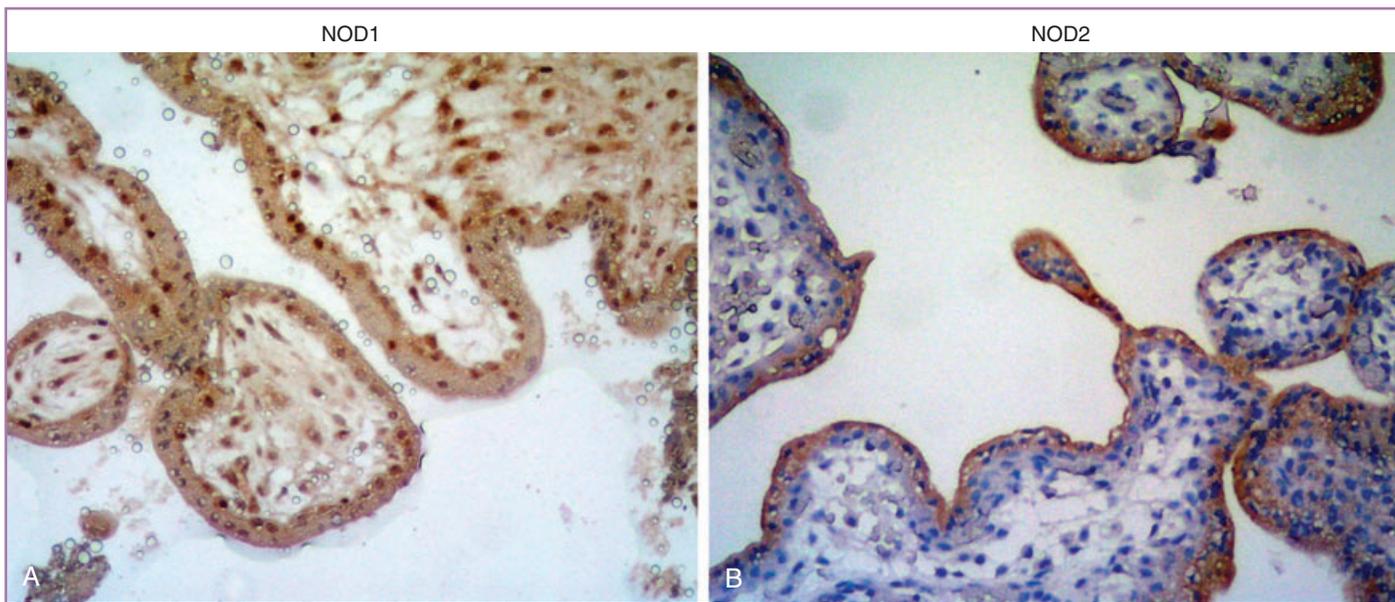

FIGURE 6-6 Expression of NOD1 and NOD2 by first-trimester placenta. NOD1 and NOD2 expression in first-trimester placental villous tissue was determined by immunohistochemistry. Tissue sections of first-trimester placental villi were stained for NOD1 and NOD2. **A**, Villous cytotrophoblast and syncytiotrophoblast cells both displayed strong positive staining for NOD1. **B**, Strong NOD2 expression is localized to the syncytiotrophoblast cells, with weaker NOD2 staining of the cytotrophoblast cells.

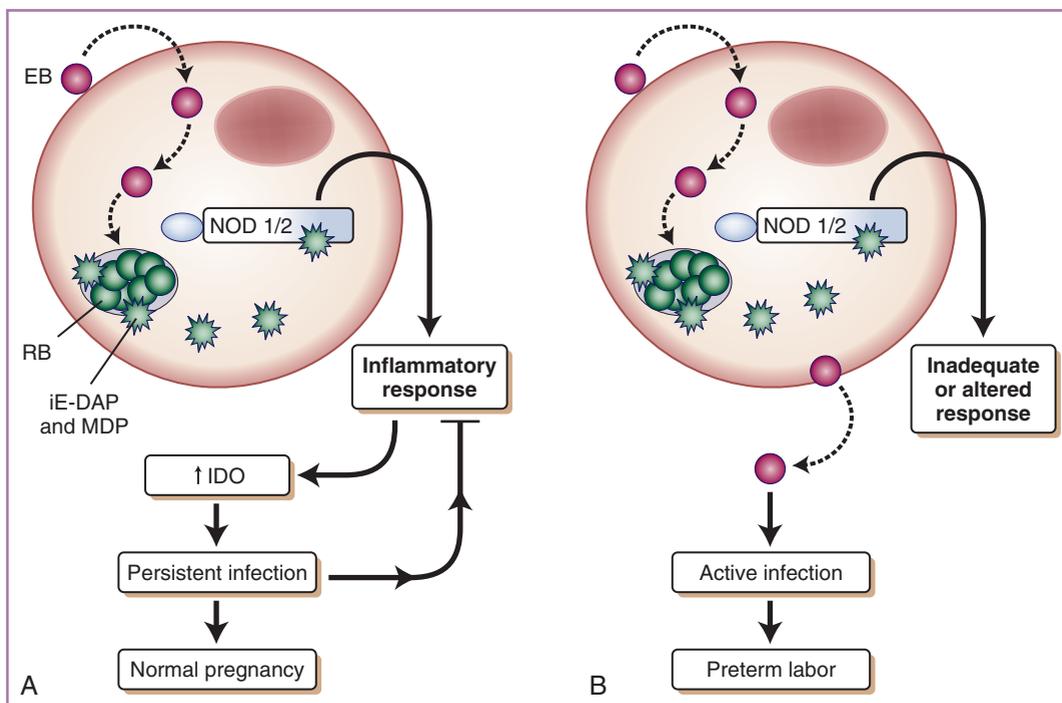

FIGURE 6-7 Trophoblast responses to *Chlamydia*. **A**, Infectious chlamydial elementary bodies (EBs) target the trophoblast. Once in the cell's cytosol, chlamydial EBs differentiate into replicating reticulate bodies (RBs), which undergo binary fission. During this replication stage, the dividing RBs generate the peptidoglycan-degradation products muramyl dipeptide (MDP) and γ -D-glutamyl-meso-diaminopimelic acid (iE-DAP). MDP and iE-DAP produced by the invasive bacterium are then recognized by the cytoplasmic NOD proteins (NOD1 or NOD2), which, in turn, activate the trophoblast to produce cytokines and chemokines. This inflammatory response then upregulates indoleamine 2,3-dioxygenase (IDO) production, which can promote a persistent infection. Once in a state of persistence, *Chlamydia* does not pose a threat to the pregnancy. **B**, Should the trophoblast response to the chlamydial infection be insufficient to upregulate IDO, or should it become altered in a way that results in a changed microenvironment, then the infection may remain active or become reactivated. An active *Chlamydia* infection may result in an adverse pregnancy outcome, such as preterm labor.

reactivated because of an inadequate response of the trophoblast, an adverse pregnancy outcome, such as preterm delivery, could occur (see Fig. 6-7).

Thus, although the prevalence of a chlamydial infection in placentas from normal and pathologic pregnancies may be the same, the *status* of the chlamydial infection may define whether a pregnancy is negatively affected, and the response by the trophoblast through NOD proteins may play an important role.

Summary

Together, our studies provide an alternative perspective on the role of the maternal innate immune system and its interactions with the trophoblast during pregnancy. The trophoblast and the maternal immune system act jointly to protect against infectious microorganisms. When the trophoblast identifies potentially dangerous molecular signatures, the maternal immune system responds with coordinate actions. Therefore, pregnancy might resemble an orchestra in which the trophoblast is the conductor and each immune cell type represents a different musical instrument. The success of the pregnancy depends on how well the trophoblast communicates and works together with each immune cell.

What was originally proposed to be only a graft-host interaction should now include a supportive regulatory interaction between the trophoblast and the maternal immune system. As we learn more about the regulation of the expression and function of TLRs and NOD proteins during pregnancy, we will better understand the cellular crosstalk existing at the maternal-fetal interface.

Chapter 7

Maternal Cardiovascular, Respiratory, and Renal Adaptation to Pregnancy

Manju Monga, MD

Profound changes occur in the cardiovascular, respiratory, and renal systems during pregnancy. These remarkable adaptations begin early after conception and continue as gestation advances, yet most are almost totally reversible within weeks to months after delivery. These physiologic adaptations are usually well tolerated by the pregnant patient, but they must be understood so that normal can be distinguished from abnormal.

Cardiovascular System

Blood Volume

Plasma volume increases from 6 to 8 weeks of gestation, reaching a maximal volume of 4700 to 5200 mL at 32 weeks, an increase of 45% (1200 to 1600 mL) above nonpregnant values.^{1,2} The mechanism of this plasma volume expansion is unclear, but it may be related to nitric oxide-mediated vasodilation, which induces the renin-angiotensin-aldosterone system and stimulates sodium and water retention, protecting the pregnant woman from hemodynamic instability after blood loss.³ As maternal hypervolemia is present with hydatidiform mole, it is unlikely that the presence of a fetus is necessary for this volume expansion to occur.⁴

Red blood cell mass increases by 250 to 450 mL, an increase of 20% to 30% by term compared with prepregnancy values. This rise reflects increased production of red blood cells rather than prolongation of red blood cell life.¹ Placental chorionic somatomammotropin, progesterone, and perhaps prolactin are responsible for increased erythropoiesis,⁵ which increases maternal demand for iron by 500 mg during pregnancy. In addition, 300 mg of iron is transferred from maternal stores to the fetus, and 200 mg of iron is required to compensate for normal daily losses during pregnancy. Erythrocyte 2,3-diphosphoglycerate concentration increases in pregnancy, lowering the affinity of maternal hemoglobin for oxygen. This facilitates dissociation of oxygen from hemoglobin, enhancing oxygen transfer to the fetus.⁶

Because plasma volume increases disproportionately to the increase in red blood cell mass, physiologic hemodilution occurs, resulting in a mild decrease in maternal hematocrit, which is maximal in the middle of the third trimester. This may have a protective function by decreasing blood viscosity to counter the predisposition to throm-

boembolic events in pregnancy and may be beneficial for intervillous perfusion.⁷

Anatomic Changes

Histologic and echocardiographic studies indicate that ventricular wall muscle mass and end-diastolic volume increase in pregnancy without an associated increase in end-systolic volume or end-diastolic pressure.^{8,9} Ventricular mass increases in the first trimester, whereas end-diastolic volume increases in the second and early third trimesters.^{8,10} This increases cardiac compliance (resulting in a physiologically dilated heart) without a concomitant reduction in ejection fraction, implying that myocardial contractility must also increase. This is supported by studies of systolic time intervals in pregnancy^{11,12} and echocardiographic demonstration of a decreased ratio of the load-independent wall stress to the velocity of circumferential fiber shortening.¹³ A recent echocardiographic study of left ventricular function during pregnancy suggests that changes in long-axis performance occur earlier than changes in transverse function and challenges the notion of dominance of circumferential fiber shortening.¹⁴ Left atrial diameter increases in parallel with the rise in blood volume, starting early in pregnancy and plateauing by 30 weeks.¹⁵

A general softening of collagen occurs in the entire vascular system, associated with hypertrophy of the smooth muscle component. This results in increased compliance of capacitive (predominantly elastic wall) and conductive (predominantly muscular wall) arteries and veins that is evident as early as at 5 weeks of the beginning of amenorrhea.¹⁶

Cardiac Output

Cardiac output, the product of heart rate and stroke volume, is a measure of the functional capacity of the heart. Cardiac output may be calculated by invasive heart catheterization using dye dilution or thermodilution, or by noninvasive methods such as impedance cardiography and echocardiography. Limited data have been obtained from normal pregnant women by means of an invasive method.¹⁷⁻¹⁹ M-mode echocardiography²⁰ and Doppler studies²¹⁻²³ have demonstrated good correlation with thermodilution methods. These validation studies have not been performed in healthy pregnant women, and reports are

limited to critically ill patients. Yet to be determined is the most appropriate echocardiographic technique (pulsed-wave or continuous Doppler) and the most reproducible site through which to measure blood flow.²⁴ In contrast, thoracic electrical bioimpedance, which is influenced by intrathoracic fluid volume, hemoglobin, and chest configuration (all of which change in pregnancy), has had poor correlation with thermodilution techniques, with underestimation of cardiac output during pregnancy.^{22,25,26}

Cardiac output increases by 30% to 50% during pregnancy,^{13,17-19,23,27,28} and 50% of this increase occurs by 8 weeks of gestation.²⁸ A small decline in cardiac output at term results from a fall in stroke volume.^{8,29-31}

Increased maternal cardiac output is caused by an increase in both stroke volume and heart rate. Stroke volume is primarily responsible for the early increase in cardiac output,^{27,32} probably reflecting the increase in ventricular muscle mass and end-diastolic volume. Stroke volume declines toward term.²⁹ In contrast, maternal heart rate, which rises from 5 weeks' gestation to a maximal increment of 15 to 20 beats/min by 32 weeks' gestation, is maintained (Fig. 7-1).^{27,29,33} Therefore, in the late third trimester, maternal tachycardia is primarily responsible for maintaining cardiac output.

Maternal posture significantly affects cardiac output. Turning from the left lateral recumbent to the supine position at term can result in a drop in cardiac output by as much as 25% to 30%.²⁹ This is the result of caval compression by the gravid uterus, which diminishes venous return from the lower extremities, decreasing stroke volume and cardiac output. Although most women do not become hypotensive with this maneuver, up to 8% of women do demonstrate the supine hypotensive syndrome, which is manifested by a sudden drop in blood pressure, bradycardia, and syncope.³⁴ This may result from inadequacy of the paravertebral collateral blood supply in these women, because symptomatic supine hypotensive syndrome does not appear to be associated with a decrease in baroreceptor response.³⁵

This physiologic increase in cardiac output has a selective regional distribution. Uterine blood flow increases 10-fold to between 500 and

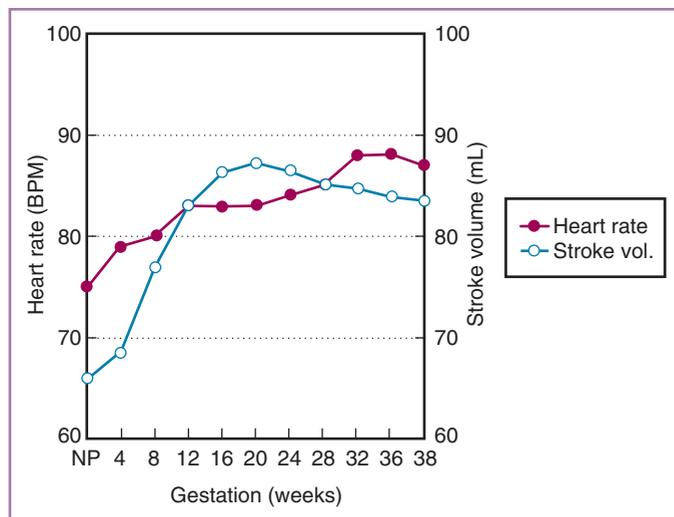

FIGURE 7-1 Alteration in stroke volume and heart rate during pregnancy. Stroke volume increases maximally during the first half of gestation. There is a slight decrease in stroke volume toward term. A mild increase in heart rate begins early in gestation and continues until term. (Adapted from Robson SC, Hunter S, Boys RJ, et al: Serial study of factors influencing changes in cardiac output during human pregnancy. *Am J Physiol* 256:H1060, 1989.)

800 mL/min,³⁶ a shift from 2% of total cardiac output in the nonpregnant state to 17% at term. Renal blood flow increases significantly (by 50%) during pregnancy,³⁷ as does perfusion of the breasts and skin.^{38,39} There does not appear to be any major alteration in blood flow to the brain or liver.

Blood Pressure

Arterial blood pressure decreases in pregnancy beginning as early as the 7th week.³² This early drop probably represents incomplete compensation for the decrease in peripheral vascular resistance by the increase in cardiac output. When measured in the sitting or standing positions, systolic blood pressure remains relatively stable throughout pregnancy, whereas diastolic blood pressure decreases by a maximum of 10 mm Hg at 28 weeks and then increases toward nonpregnant levels by term.⁴⁰ In contrast, when measured in the left lateral recumbent position, both systolic and diastolic blood pressures decrease to a level 5 to 10 mm Hg and 10 to 15 mm Hg, respectively, below nonpregnant values. This nadir occurs at 24 to 32 weeks' gestation and is followed by a rise toward nonpregnant values at term (Fig. 7-2).⁴⁰ Because diastolic pressures decrease to a greater extent than systolic pressures, there is a slight increase in pulse pressure in the early third trimester. Arterial blood pressures are approximately 10 mm Hg higher in the standing or sitting positions than in the lateral or supine positions; consistency in position during successive blood pressure measurements is essential for the accurate documentation of a trend during pregnancy.

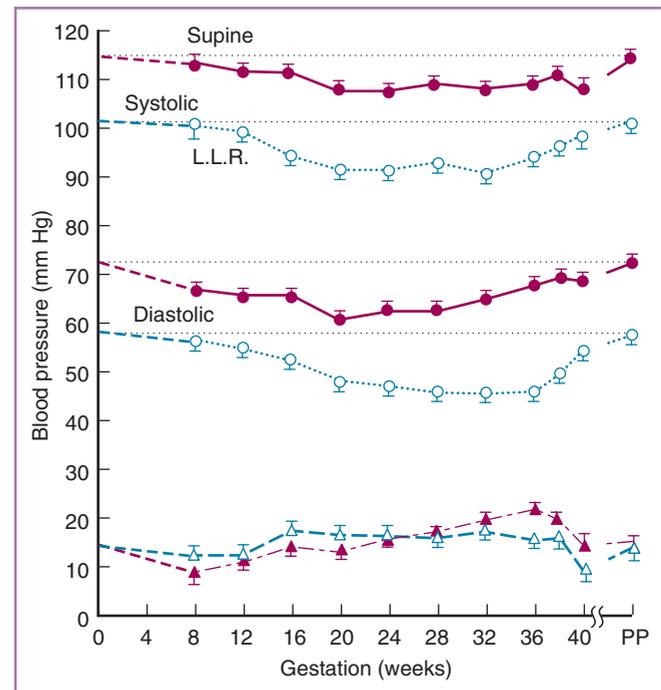

FIGURE 7-2 Sequential changes in blood pressures throughout pregnancy. The subjects were in supine (closed circles) or left lateral recumbent (L.L.R.) (open circles) positions. At the bottom of the graph, the changes in systolic (open triangles) and diastolic (closed triangles) blood pressures produced by movement from the left lateral recumbent to the supine position are shown. (From Wilson M, Morganti AA, Zervoudakis I, et al: Blood pressure, the renin-aldosterone system and sex steroids throughout normal pregnancy. *Am J Med* 68:97, 1980.)

Confusion has arisen with regard to the definition of diastolic blood pressure in pregnancy. Measurement of Korotkoff phase 4 (the point of muffling) results in mean diastolic pressures 13 mm Hg higher than measurement of Korotkoff phase 5 (the point of disappearance).⁴¹ Use of Korotkoff phase 4 may be less reproducible.⁴² Intra-arterial measurements of diastolic pressures may be 15 mm Hg lower than manual determinations,⁴³ whereas they may be significantly higher than automated cuff diastolic measurements.⁴⁴

The use of ambulatory blood pressure monitoring has been validated in pregnancy.⁴⁵ Monitoring over a period of 24 hours has shown measurements that are either significantly lower⁴⁶ or higher⁴⁷ than office measurements. These differences cannot be explained by activity level, although work and job-related stress have been shown to increase blood pressure in late pregnancy.^{47,48} Ambulatory blood pressure monitoring has shown marked circadian variation in blood pressure during pregnancy, with a nadir of systolic and diastolic blood pressures in the early morning hours and a peak in late afternoon and evening.⁴⁹

Systemic Vascular Resistance

Systemic vascular resistance is calculated by the following equation:

$$\frac{(\text{Mean arterial pressure} - \text{central venous pressure}) \times 80 \text{ dyne-sec cm}^{-5}}{\text{cardiac output}}$$

Systemic vascular resistance decreases from as early as at 5 weeks of pregnancy as a result of the vasodilatory effect of progesterone and prostaglandins and perhaps the arteriovenous fistula-like function of the low-resistance uteroplacental circulation.^{13,50-52} Alternatively, it has been proposed that increased production of endothelium-derived relaxant factors, such as nitric oxide, initiates vasodilation and a drop in systemic vascular resistance.^{3,53} This decrease in systemic vascular tone may be the primary trigger for increasing heart rate, stroke volume, and cardiac output in the first few weeks of pregnancy.^{3,52} The fall in systemic vascular resistance is paralleled by an increase in vascular compliance, which reaches a nadir at 14 to 24 weeks' gestation and then rises progressively toward term.^{16,17}

Venous Vascular Bed

Venous compliance increases progressively during pregnancy as a result of the relaxant effect of progesterone or endothelium-derived relaxant factors on blood vessel smooth muscle, or as a result of altered elastic properties of the venous wall. This results in a decrease in flow velocity and leads to stasis.⁵⁴ Pregnant women are therefore more sensitive to autonomic blockade, which results in further venous pooling, decreased venous return, and a fall in cardiac output manifested as a sudden drop in arterial blood pressure. This may be seen in response to conduction anesthesia and ganglionic blockade.

Antepartum Hemodynamics

Clark and colleagues studied the effect of pregnancy on central hemodynamics by placing Swan-Ganz catheters and arterial lines in 10 normal primiparous women at 35 to 38 weeks' gestation and again at 11 to 13 postpartum weeks (Table 7-1).¹⁹ Late pregnancy was characterized by significant elevations in heart rate, stroke volume, and cardiac output, in concert with significant decreases in systemic and pulmonary vascular resistance and serum colloid osmotic pressure. There was no significant alteration in pulmonary capillary wedge

TABLE 7-1 HEMODYNAMIC PROFILES FOR NONPREGNANT AND PREGNANT PATIENTS IN THE THIRD TRIMESTER

	Nonpregnant	Pregnant	Change
Cardiac output (L/min)	4.3 ± 0.9	6.2 ± 1.0	+43%
Heart rate (beats/min)	71 ± 10	83 ± 10	+17%
SVR (dyne-sec cm ⁻⁵)	1530 ± 520	1210 ± 266	-21%
PVR (dyne-sec cm ⁻⁵)	119 ± 47	78 ± 22	-34%
CVP (mm Hg)	3.7 ± 2.6	3.6 ± 2.5	NS
COP (mm Hg)	20.8 ± 1.0	18.0 ± 1.5	-14%
PCWP (mm Hg)	6.3 ± 2.1	7.5 ± 1.8	NS
COP-PCWP (mm Hg)	14.5 ± 2.5	10.5 ± 2.7	-28%

COP, colloid osmotic pressure; COP-PCWP, gradient between COP and PCWP; CVP, central venous pressure; nonpregnant, at 11 to 13 weeks postpartum; NS, not significant; PCWP, pulmonary capillary wedge pressure; pregnant, at 36 to 38 weeks' gestation; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

Adapted with permission from Clark SL, Cotton DB, Lee W, et al: Central hemodynamic assessment of normal term pregnancy. *Am J Obstet Gynecol* 161:1439, 1989.

pressure, central venous pressure, or mean arterial blood pressure. The authors suggested that pulmonary capillary wedge pressure does not increase, despite significant increases in blood volume and stroke volume, because of ventricular dilation and the fall in pulmonary vascular resistance. They noted, however, that pregnant women were still at higher risk for pulmonary edema because of the significantly decreased gradient between colloid osmotic pressure and pulmonary capillary wedge pressure (gradient of 10.5 ± 2.7 mm Hg) compared with the nonpregnant state (gradient of 14.5 ± 2.5 mm Hg).

Circulation time demonstrates a slight but progressive decline during pregnancy, reaching a minimal value of 10.2 seconds in the third trimester.⁵⁵ These findings have been interpreted to mean that blood flow velocity increases slightly in pregnancy.

Autonomic cardiovascular control in pregnancy has also been investigated. Although earlier studies indicated a blunted heart rate and blood pressure response to the Valsalva maneuver, possibly because of decreased vagal control of the heart,^{33,56} a study of baroreceptor sensitivity using power spectral analysis of heart rate and blood pressure variability between 28 and 28 weeks' gestation indicated a significant negative correlation between baroreceptor sensitivity and cardiac output, and a positive correlation with total peripheral resistance. This suggests that baroreceptors respond to changes in cardiac output and peripheral vascular resistance to maintain blood pressure during pregnancy.⁵⁷

Symptoms and Signs of Normal Pregnancy

Pregnant women report dyspnea with increased frequency as gestation advances (15% in the first trimester compared with 75% by the third).⁵⁸ The mechanism for this is unclear, but it may relate to the exaggerated ventilatory response (perhaps progesterone mediated) in response to increased metabolic demand. Easy fatigability and decreased exercise tolerance are also commonly reported, although mild to moderate exercise is well tolerated under normal circumstances.^{59,60} Increased lower extremity venous pressure, caused by compression by the gravid

uterus and lower colloid osmotic pressure, is commonly manifested as dependent edema—most often found in the distal lower extremities at term. High-high support stockings significantly increase systemic vascular resistance by preventing venous pooling in the lower extremities and may be effective in decreasing peripheral edema in pregnancy.⁶¹

Cutforth and MacDonald documented clearly the alterations in heart sounds in pregnancy by a phonocardiographic study of 50 normal primigravid women.⁶² Briefly, the first heart sound increased in loudness and was more widely split in approximately 90% of women (30 to 45 msec compared with 15 msec in the nonpregnant state). This results from early closure of the mitral valve, as demonstrated by the shortened interval between the Q wave of the electrocardiogram and the first heart sound. There was no significant change in the second heart sound until 30 weeks' gestation, when persistent splitting that does not vary with respiration may occur. A loud third heart sound was heard in up to 90% of pregnant women, whereas less than 5% had an audible fourth heart sound.

Systolic murmurs develop in more than 95% of pregnant women. These are heard best along the left sternal border and are most often either aortic or pulmonary in origin. Doppler echocardiography demonstrates an increased incidence of functional tricuspid regurgitation during pregnancy that may also lead to a systolic precordial murmur.⁶³ Although most of these changes in heart sounds are first audible between 12 and 20 weeks' gestation and regress by 1 week after the birth, nearly 20% have a persistent systolic murmur beyond the 4th week after delivery. Systolic murmurs louder than grade 2/4 and diastolic murmurs of any intensity are considered abnormal during pregnancy. However, 14% of women may have a continuous murmur of mammary vessel origin, which is heard maximally in the second intercostal space.⁶²

Uterine growth results in upward displacement of the diaphragm, which is associated with superior, lateral, and anterior displacement of the heart within the thorax. This leads to lateral displacement of the point of maximal impulse and may suggest cardiomegaly on chest radiographs. This appearance is further enhanced by straightening of the left heart border and by prominence of the pulmonary outflow tracts; however, the cardiothoracic ratio is only slightly increased, if at all, in normal pregnancy.⁶⁴

Intrapartum Hemodynamic Changes

Labor results in significant alteration in the cardiovascular measurements. The first stage of labor is associated with a 12% to 31% rise in cardiac output, primarily because of a 22% increase in stroke volume.^{65,66} The second stage of labor is associated with an even greater increase in cardiac output (49%). Laboring in the left lateral decubitus position or analgesia decreases the magnitude of this increment. The increase in cardiac output is not completely abolished by relief of pain, because contractions result in the transfer of 300 to 500 mL of blood from the uterus to the general circulation.^{67,68} Systolic and diastolic blood pressures transiently increase by 35 and 25 mm Hg, respectively, during labor.⁶⁶ For these reasons, women who have cardiovascular compromise may experience decompensation with labor, especially during the second stage.

Postpartum Hemodynamic Changes

Pregnant women with cardiac disease are perhaps at greatest risk for pulmonary edema in the immediate postpartum period. The immediate puerperium is associated with an 80% increase in cardiac output

within 10 to 15 minutes after vaginal delivery with local anesthesia compared with 60% with caudal anesthesia.^{69,70} Whole-body impedance cardiography was used to continuously study maternal hemodynamics and cardiovascular responses in 10 women having cesarean section under spinal analgesia.⁷¹ Within 2 minutes of delivery, there was a 47% increase in cardiac index and a 39% decrease in systemic vascular index without appreciable change in mean arterial pressure. This immediate increase in cardiac output is caused by release of venacaval obstruction by the gravid uterus, autotransfusion of uteroplacental blood, and rapid mobilization of extravascular fluid. All these changes result in increased venous return to the heart and increased stroke volume. Cardiac output returns to prelabor values 1 hour after delivery.⁷⁰

Vaginal delivery is associated with a blood loss of approximately 500 mL, whereas cesarean section may cause a loss of 1000 mL.⁷² The pregnant woman is protected from postpartum blood loss in part by the expansion of blood volume associated with pregnancy.

M-mode echocardiographic studies have shown that left atrial dimensions increase 1 to 3 days after the birth, perhaps because of mobilization of excessive body fluids and increased venous return.⁷⁰ Atrial natriuretic levels also increase in the immediate postpartum period, which may stimulate diuresis and natriuresis in the early puerperium.⁷³

Whereas left atrial dimensions and heart rate normalize within the first 10 postpartum days, left ventricular dimensions decrease gradually for 4 to 6 months. Cardiovascular measurements, such as stroke volume, cardiac output, and systemic vascular resistance, as measured by M-mode echocardiography, do not completely return to prepregnancy values by 12 postpartum weeks and may continue to decrease for 24 weeks before stabilizing.^{28,70} Therefore, the early postpartum period may not accurately reflect the nonpregnant state in studies of pregnancy-related hemodynamic changes.

Respiratory System

There is a moderate decrease in functional residual capacity during pregnancy, attributed to a decrease in both expiratory reserve volume and residual volume (Table 7-2). This is primarily the result of upward displacement of the maternal diaphragm. Maternal tidal volume increases by 40% in pregnancy, and this increase results in maternal hyperventilation and hypocapnia.⁷⁴ Because maternal respiratory rate does not change during pregnancy, the 30% to 50% increase in minute ventilation that is noted as early as the first trimester is attributed to this increase in tidal volume alone.⁷⁵ Increased minute ventilation may be the result of increased progesterone and an increase in basal metabolic rate.

There is a decrease in the partial pressure of carbon dioxide from a pre-pregnancy level of 39 mm Hg to approximately 28 to 31 mm Hg at term. This hyperventilation facilitates the transfer of carbon dioxide from the fetus to the mother and is partially compensated for by an increased renal secretion of hydrogen ions, with a resultant serum bicarbonate level of 18 to 22 mEq/L. A mild respiratory alkalosis is therefore normal in pregnancy, with an arterial pH of 7.44, compared with 7.40 in the nonpregnant state. This mild respiratory alkalosis results in a shift to the left of the oxygen dissociation curve, increasing the affinity of maternal hemoglobin for oxygen (the Bohr effect) and reducing oxygen release to the fetus. This is compensated for by an alkalosis-stimulated increase in 2,3-diphosphoglycerate in maternal erythrocytes, which shifts the oxygen dissociation curve to the right, facilitating oxygen transfer to the fetus.⁷⁶

TABLE 7-2 RESPIRATORY CHANGES DURING PREGNANCY

Lung Volume (mL)	Nonpregnant	Pregnant	Change
Total lung capacity (vital capacity + residual volume)	4200	4000	-4%
Vital capacity (total lung capacity – residual volume)	3200	3200	No change
Inspiratory capacity (vital capacity – expiratory reserve volume)	2500	2650	+6%
Tidal volume	450	600	+33%
Expiratory reserve volume (vital capacity – inspiratory capacity)	700	550	-20%
Inspiratory reserve volume (inspiratory capacity – tidal volume)	2050	2050	No change
Residual volume (result: decrease in total lung capacity)	1000	800	-20%
Functional residual capacity (residual volume + expiratory reserve volume)	1700	1350	-20%

Concomitant with the increase in maternal minute ventilation is a 20% to 40% increase in maternal oxygen consumption caused by increased oxygen requirements of the fetus, placenta, and maternal organs.⁷⁷ Because of the increase in maternal oxygen consumption and the decrease in functional residual capacity, pregnant women with asthma, pneumonia, or other respiratory pathology may be more susceptible to early decompensation.

Kidneys and Lower Urinary Tract

Dramatic changes in renal structure, dynamics, and function occur during pregnancy. These have recently been reviewed.⁷⁸

Structure and Dynamics

Renal size and weight increase during pregnancy as a result of an increase in renal vascular and interstitial volume. Kidney length increases by approximately 1 cm,⁷⁹ and renal volume, as determined by computed nephrosonography, increases by approximately 30%.⁸⁰ More dramatic, however, is dilation of the urinary collecting system, which occurs in more than 80% of gravidas by mid-gestation.⁸¹ Caliceal and ureteral dilation are more common on the right side than the left,^{82,83} and the degree of caliceal dilation is more pronounced on the right than on the left (15 versus 5 mm).⁸⁴ The prominence of these changes on the right side may result from dextrorotation of the pregnant uterus, the location of the right ovarian vein that crosses the ureter, or the protective “cushion” effect of the sigmoid colon on the left side, or any combination of these. Ureteral dilation is rarely present below the level of the pelvic brim, and sonographic visualization demonstrates tapering of the ureters as they cross the common iliac artery.⁸⁵ Although obstruction plays a role in the physiologic pyelectasis of pregnancy, an associated increase in renal arterial resistance has not been consistently documented.⁸³ One reason for this may be the poor reproducibility of pulsed Doppler measurements in the maternal renal circulation as a result of high interobserver and intraobserver variability.⁸⁶ Progesterone, relaxin, and the nitric oxide pathway may play a concomitant role in ureteral smooth muscle relaxation, but there is no consensus on the influence of hormones on these anatomic alterations.^{78,87}

The dilation of the urinary collecting system has several important clinical consequences, including an increase in ascending urinary tract infection, perhaps related to urinary stasis; difficulty in interpreting radiologic examinations of the urinary tract; and interference with evaluation of glomerular and tubular function, because these tests require high urine flow rates. Renal volume returns to normal within

the first week of delivery,⁸⁰ but hydronephrosis and hydroureter may persist for 3 to 4 months after the birth.⁸⁴ This fact should be considered when radiologic or renal function studies on postpartum women are being interpreted. Ureteral peristalsis does not change in pregnancy; however, ureteral tone progressively increases, possibly as a result of mechanical obstruction, and then returns to normal shortly after delivery.⁸⁸ Controversy exists with regard to changes in urinary bladder pressures and capacity. In one study, urinary bladder pressure doubled between the first and third trimesters of pregnancy, implying a decrease in bladder capacity.⁸⁹ Previous studies demonstrated a relatively hypotonic bladder, with decreased pressure and increased capacity near term.⁹⁰ Urethral length and intraurethral closure pressure in pregnancy have also been determined by urodynamic studies and have been found to increase by 20%.⁸⁹ The latter may counter the increase in bladder pressure in an attempt to reduce stress incontinence, which is more common in pregnancy, occurring in 29% to 41% at term.⁹¹

Renal Function

Renal plasma flow, as estimated by para-aminohippurate clearance, increases by 60% to 80% over nonpregnant values by the middle of the second trimester and then falls to 50% above prepregnancy values in the third trimester.⁹² Renal plasma flow, like cardiac output, is significantly higher when the patient is in the left lateral recumbent position than when she is sitting, standing, or supine. This reflects maximal venous return in the left lateral position.^{93,94}

Glomerular filtration rate (GFR) is estimated by determination of inulin, iothexol, or creatinine clearance. Creatinine clearance, although most commonly used, is the least precise of the determinations because creatinine is secreted by the tubules in addition to being cleared by the glomeruli. Creatinine clearance can be calculated by dividing the total amount of urinary creatinine (in milligrams) by the duration of collection (in minutes). This value is then divided by the creatinine concentration in serum (in mg/mL). This yields a creatinine clearance in mL/min.

GFR begins to increase by as early as 6 weeks' gestation, with a peak of 50% over nonpregnant values by the end of the first trimester.⁹⁴ Although there are few data on the measurement of GFR after 36 weeks of gestation, GFR does not appear to decrease at term. Creatinine clearance is thus moderately increased in pregnancy (110 to 150 mL/min). This rate has a circadian variation of 80% to 125%, with maximal creatinine excretion between 2 PM and 10 PM and lowest excretion rates between 2 AM and 10 AM.⁹⁵

The mechanisms behind the changes in renal hemodynamics are unclear, although study of pregnant rats suggests that GFR rises secondary to vasodilation of preglomerular and postglomerular resistance vessels without any alteration in glomerular capillary pressure.⁹⁶ This

is further supported by the lack of continued increase in GFR after the first trimester of pregnancy despite decreasing serum albumin, implying independence from changes in oncotic pressure.⁵²

Because the increase in renal plasma flow is initially greater than the rise in GFR, the filtration fraction (GFR divided by renal plasma flow) decreases until the third trimester of pregnancy, when a fall in renal plasma flow results in the return of the filtration fraction to a prepregnancy value of 1/5.⁹⁴ This alteration in filtration fraction parallels the change in mean arterial pressure described previously and may be related to circulating progesterone levels.^{92,97}

Filtration capacity, which is estimated by the maximal GFR in response to a vasodilator stimulus, appears to be intact in pregnancy, as documented by studies of amino acid administration in rats⁹⁶ and protein loading in pregnant women.⁹⁸ As the resting GFR rises during pregnancy, the functional renal reserve (the difference between the filtration capacity and the resting GFR) decreases. One can therefore accurately assess renal function in pregnant patients with early renal disease by determining filtration capacity, but not by functional renal reserve.⁹⁸

The pregnancy-associated rise in GFR (which normally occurs without any concomitant increase in production of urea or creatinine) results in decreased serum creatinine and urea concentrations in pregnancy.⁹⁷ Serum creatinine falls from prepregnancy values of 0.83 mg/dL to 0.7, 0.6, and 0.5 mg/dL in successive trimesters. Blood urea nitrogen decreases from 12 mg/dL in the nonpregnant state to 11, 9, and 10 mg/dL in the first, second, and third trimesters, respectively.

Renal Tubular Function

Sodium

Several factors promote sodium excretion in pregnancy. There is an increase in the filtered load of sodium from approximately 20,000 to 30,000 mEq/day as a result of the 50% rise in GFR. Hormones that favor sodium excretion include the following:

Progesterone, a competitive inhibitor of aldosterone⁹⁹
Vasodilatory prostaglandins⁹⁴

Atrial natriuretic factor (although increased pregnancy-related production of atrial natriuretic factor has not been universally demonstrated)^{100,101}

Despite these forces, there is a cumulative retention of approximately 950 mg of sodium during pregnancy. This is distributed between the maternal intravascular and interstitial compartments, the fetus, and the placenta.¹⁰² The net reabsorption of sodium is one of the most remarkable adaptations of renal tubular function to pregnancy.

Factors that promote this sodium reabsorption include the increased production and secretion of aldosterone, deoxycorticosterone, and estrogen (Fig. 7-3).⁹⁹ These hormones may be regulated, in part, by the rise in plasma progesterone and vasodilatory prostaglandins, but they are also mediated by stimulation of the renin-angiotensin system. All components of the renin-angiotensin-aldosterone system increase in the first trimester of pregnancy and peak at 30 to 32 weeks' gestation.³ Hepatic renin substrate is stimulated by estrogens and results in elevated renal production of renin. Renin stimulates increased conversion of angiotensinogen to angiotensins I and II. Sodium retention is also favored by postural changes in pregnancy; the supine and upright positions are associated with a marked decrease in sodium excretion.³⁷

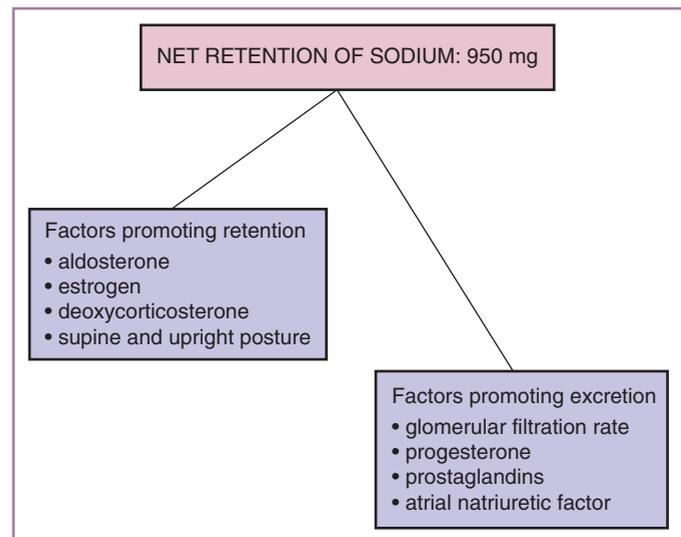

FIGURE 7-3 Factors influencing the regulation of sodium excretion in pregnancy.

Potassium

Although the pregnancy-associated increase in plasma aldosterone would favor potassium excretion, a net retention of 300 to 350 mEq of potassium actually occurs. Increased kaliuresis may be prevented by the influence of progesterone on renal potassium excretion.¹⁰³ Because potassium reabsorption from the distal tubule and the loop of Henle decreases with pregnancy, it has been deduced that a significant increase in proximal tubular reabsorption occurs.¹⁰⁴

Calcium

Urinary calcium excretion increases as a result of increased calcium clearance.¹⁰⁵ This is balanced by increased absorption of calcium from the small intestine, and therefore serum ionic (unbound) calcium levels remain stable. Total calcium levels fall in pregnancy from 4.75 mEq/L in the first trimester to 4.3 mEq/L at term because of a decrease in plasma albumin.¹⁰⁶ A rise in calcitriol in early pregnancy is paralleled by suppression of the parathyroid hormone and an increase in renal tubular phosphorus reabsorption.¹⁰⁷ This increase in calcitriol promotes reabsorption of calcium and phosphorus from the intestine and may facilitate bone mineralization in the fetus.

Glucose

Glucose excretion increases in pregnant women 10-fold to 100-fold over nonpregnant values of 100 mg/day.¹⁰⁸ This glycosuria, which occurs despite increased plasma insulin and decreased plasma glucose levels, is the result of impaired collecting tubule and loop of Henle reabsorption of the 5% of the filtered glucose that normally escapes proximal convoluted tubular reabsorption.¹⁰⁹ The clinical significance of this is that glycosuria cannot be accurately used to monitor pregnant women with diabetes mellitus.

Uric Acid

Plasma uric acid levels decrease by 25% as early as 8 weeks' gestation, reaching a nadir of 2 to 3 mg/dL at 24 weeks' gestation, and then increase toward nonpregnant levels at term.¹¹⁰ This may result from increased GFR and reduced proximal tubular reabsorption.¹¹¹ Conditions that lead to volume contraction, such as preeclampsia, may be

associated with decreased uric acid clearance and increased plasma levels.

Amino Acids

The fractional excretion of alanine, glycine, histidine, serine, and threonine increases in pregnancy.¹¹² Cystine, leucine, lysine, phenylalanine, taurine, and tyrosine excretion increases early in pregnancy but then decreases in the second half of gestation. The excretion of arginine, asparagine, glutamic acid, isoleucine, methionine, and ornithine does not change. The mechanism of this selective amino aciduria is unknown. It is unclear whether renal excretion of albumin increases, decreases, or remains stable¹¹³⁻¹¹⁵ in normal pregnancy. Urinary protein excretion does not normally exceed 300 mg per 24 hours.

Volume Homeostasis

Bodyweight increases by an average of 30 to 35 pounds in pregnancy.¹¹⁶ Two thirds of this gain may be accounted for by an increase in total body water, with 6 to 7 L gained in the extracellular space and approximately 2 L gained in the intracellular space. Plasma volume expansion, as outlined previously, accounts for 25% of the increase in extracellular water, with the rest of the increment appearing as interstitial fluid.¹⁰² As water is retained, plasma sodium and urea levels fall slightly, from 140.3 ± 1.7 to 136.6 ± 1.5 mM/L, and from 4.9 ± 0.9 to 2.9 ± 0.5 mM/L, respectively.¹¹⁷ By 4 weeks after conception, plasma osmolality has decreased from 289 to 280.9. Because water deprivation in pregnant women leads to an appropriate increase in vasopressin and urine osmolality, and water loading results in a proportional decrease, it appears that the osmoregulation system is functioning normally but is “reset” at a lower threshold.¹¹⁸ Further evidence to support this conclusion is that the osmotic threshold for thirst is decreased by 10 mOsm/kg in pregnancy.¹⁰³ The mechanism for this readjustment of the osmoregulatory system is unclear but may involve placental secretion of human chorionic gonadotropin.¹¹⁹

Chapter 8

Endocrinology of Pregnancy

James H. Liu, MD

The concept of the fetus, the placenta, and the mother as a functional unit originated in the 1950s. More recent is the recognition that the placenta itself is an endocrine organ capable of synthesizing virtually every hormone, growth factor, and cytokine thus far identified. The premise that the placenta, composed chiefly of two cell types (syncytiotrophoblast and cytotrophoblast), can synthesize and secrete a vast array of active substances could not even be contemplated until it was recognized in the 1970s that a single cell can, in fact, synthesize peptide and protein factors. This concept is even more remarkable because the placenta has no neural connections to either the mother or the fetus and is expelled after childbirth. Yet the placenta, an integral part of the fetal-placental-maternal unit, can be viewed as the most amazing endocrine organ of all. In this chapter, I review the hormonal interactions of the fetal-placental-maternal unit and the neuroendocrine and metabolic changes that occur in the mother and in the fetus during pregnancy and at parturition.

Implantation

Although early studies showed that the process of embryo implantation took place between 6 and 7 days after ovulation,^{1,2} more contemporary results suggest that in most successful human pregnancies, the embryo implants approximately 8 to 10 days after ovulation.³ This event involves a series of complex steps: (1) orientation of the blastocyst with respect to the endometrial surface, (2) initial adhesion of the blastocyst to the endometrium, (3) meeting of the microvilli on the surface of trophoblast with pinopodes (microprotrusions from the apical end of the uterine epithelium), (4) trophoblastic migration through the endometrial surface epithelium, (5) embryonic invasion with localized disruption of the endometrial capillary beds, and finally (6) remodeling of the capillary bed and formation of trophoblastic lacunae.^{4,5} By day 10, the blastocyst is completely encased in the uterine stromal tissue. A diagrammatic representation of this process is shown in Figure 8-1.

Although recent work with in vitro fertilization (IVF)-related techniques such as embryo donation and frozen embryo transfer has contributed significantly to our understanding of this process, much of our present physiologic information is derived from other mammalian species, because human tissue experiments are limited by ethical constraints. The implantation process has been reviewed by Norwitz and colleagues.⁵

Results from assisted reproductive technologies suggest a window for implantation in which the endometrium is “receptive” to embryo implantation. In this concept, synchronization between embryonic and

uterine receptivity is required for successful nidation. IVF-generated data suggest that implantation is successful usually after embryo transfer into the uterus, between 3 and 5 days after fertilization. The embryo is at the 6-8-cell to blastocyst stage of development. If the embryo is transferred outside this window or is in a different location, the likelihood of embryo demise or ectopic pregnancy increases. Although the process of embryo implantation requires a receptive endometrium, the process is not exclusive to the endometrium, because advanced ectopic (e.g., abdominal) pregnancies have been reported with a viable fetus.

During a typical IVF cycle, embryos are transferred to the uterus on day 3 or day 5 after fertilization. By day 3 of embryo culture, embryo development is at the six- to eight-cell stage. Embryos placed back into the uterus at this stage remain unattached to the endometrium and continue developing to the blastocyst stage, “hatch” or escape from the zona pellucida, and implant by day 6 or 7 of embryo life. In IVF programs that transfer on day 3, the chance of each embryo implanting is approximately 12% to 25%. Thus, to achieve a reasonable chance of overall pregnancy, most women undergoing IVF will have two to three good-quality embryos placed back into the uterus to achieve clinical pregnancy rates of 35% to 45% per IVF cycle. Because the implantation potential for each embryo is affected by the age of the mother, embryo morphology alone is imprecise in predicting likelihood of implantation. Transfer of multiple embryos can result in higher-order multiple pregnancies such as twins, triplets, or occasionally quadruplets. In 1997, the use of assisted reproductive technologies accounted for more than 40% of all triplets born in the United States.⁶

Many IVF programs have the capability to culture embryos for up to 5 days. Embryos at this stage are at the blastocyst or morula stage. The overall implantation rate for each good-quality embryo at this stage is between 30% and 50% per embryo. Thus, to achieve a reasonable chance of pregnancy, most women have only one or two good-quality blastocyst-staged embryos transferred to the uterus, reducing the chances of higher-order multiple pregnancies. A study from population-based control data indicates that the use of assisted reproductive technology accounts for a disproportionate number of low-birth-weight and very low birth weight infants partly because of multiple pregnancies and partly because even singleton infants conceived with this technology have lower birth weights.⁷

The cellular differentiation and remodeling of the endometrium induced by sequential exposure to estradiol and progesterone may play a major role in endometrial receptivity. The beginning of endometrial receptivity coincides with the downregulation of progesterone and estrogen receptors induced by the production of progesterone in the corpus luteum. It was thought that this process involved tight regulation, so that the morphologic development of microvilli (pinopodes)

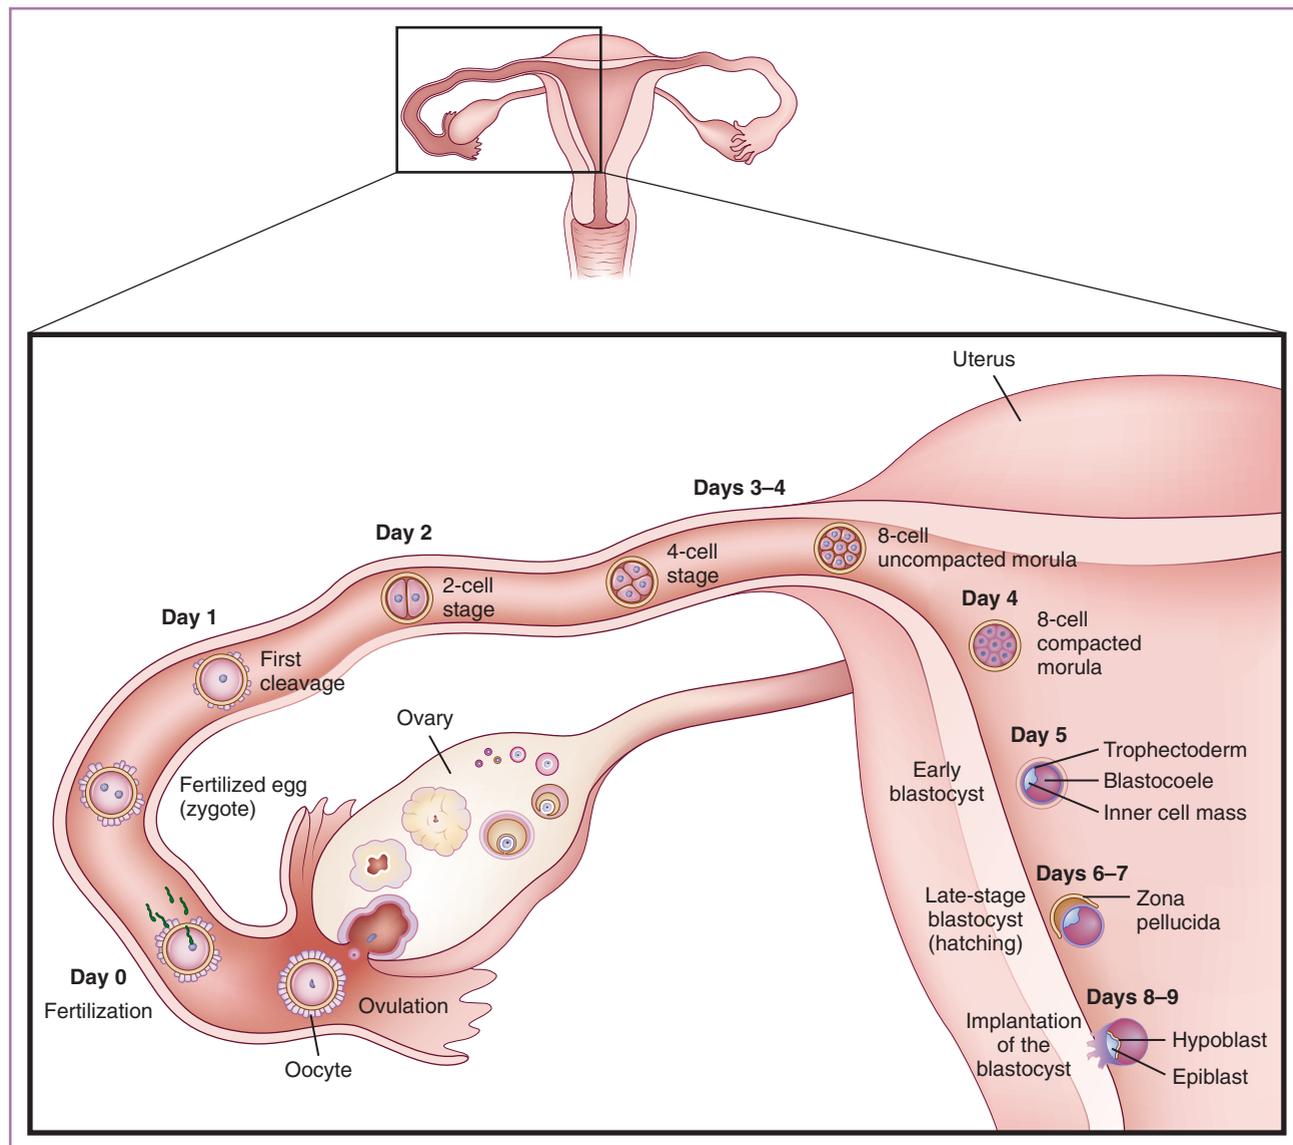

FIGURE 8-1 Diagrammatic sequence of embryo development from ovulation through the blastocyst stage of implantation in the human.

in glandular epithelium⁸ and increased angiogenesis were required for successful embryo nidation. Experience with IVF techniques, however, suggests marked differences in endometrial morphology between different women at the same point in their cycle, as well as in the same woman from cycle to cycle.⁹ Nevertheless, the current concept is that expression of factors produced by the blastocyst and the endometrium allows cell-to-cell communication so that successful nidation can take place.

Reviews of embryo implantation have identified an increasing number of factors, such as integrins, mucins, L-selectin, cytokines, proteinases, and glycoproteins, that are localized to either the embryo or the endometrium during the window of implantation.¹⁰ Much information is derived from animal studies, and its application to human implantation is primarily circumstantial. Table 8-1 lists several of the factors believed to mediate embryo implantation.

Ultrasound studies of early human gestation show that most implantation sites are localized to the upper two thirds of the uterus

and are closer to the side of the corpus luteum.¹¹ A growing body of literature suggests that the integrins, a class of adhesion molecules, are involved in implantation. Integrins are also essential components of the extracellular matrix and function as receptors that anchor extracellular adhesion proteins to cytoskeletal components.¹²

Integrins are a family of heterodimers composed of different α subunits and a common β subunit. At present, the integrin receptor family is composed of at least 14 distinct α subunits and more than nine β subunits,¹³ making up to 20 integrin heterodimers.¹⁴ Integrins are cell-surface receptors for fibrinogen, fibronectin, collagen, and laminin. These receptors recognize a common amino acid tripeptide, Arg-Gly-Asp (RGD), present in extracellular matrix proteins such as fibronectin. Integrins have been localized to sperm, oocyte, blastocyst, and endometrium.

One particular integrin, $\alpha_v\beta_3$, is expressed on endometrial cells after day 19 of the menstrual cycle. This integrin appears to be a marker for the implantation window. Integrin $\alpha_v\beta_3$ is also localized to trophoblast

TABLE 8-1 GROWTH FACTORS AND PROTEINS WITH A SIGNIFICANT ROLE IN EMBRYO IMPLANTATION

Factor	Putative Role	Reference
Leukemia inhibitory factor	Cytokine involved in implantation	Cullinan et al, 1996
Integrins	Cell-to-cell interactions	Sueoka et al, 1997
Transforming growth factor- β	Inhibits trophoblast invasion, stimulates syncytium formation	Graham et al, 1992
Epidermal growth factor	Mediates trophoblast invasion	Bass et al, 1994

Interleukin-10	Mediates implantation	Stewart et al, 1997
Matrix metalloproteinases	Mediates implantation	Stewart et al, 1997
Vascular endothelial growth factor	Mediates implantation	Stewart et al, 1997
L-selectin	Mediates implantation	Genbacev et al, 2003

cells, suggesting that it may participate in cell-to-cell interactions between the trophoblast and the endometrium, acting through a common bridging ligand. It is postulated that after hatching, the blastocyst, through its trophoblastic integrin receptors, attaches to the endometrial surface. Mouse primary trophoblast cells appear to interact with the fibronectin exclusively through the RGD recognition site.¹⁵ The appearance of the β_3 integrin subunit depends on the downregulation of progesterone and estrogen receptors in the endometrial glands.¹⁶ Subsequent changes in trophoblast adhesive and migratory behavior appear to stem from alterations in the expression of various integrin receptors. Antibodies to α , or β -integrins inhibit the attachment activity of intact blastocysts.¹⁷

The role of integrins in trophoblast migration is not clear, but the expression of β_1 -integrins appears to promote this phenomenon.¹⁸ Work in the rhesus monkey suggests that the trophoblast migrates into the endometrium directly beneath the implantation site, invading small arterioles (but not veins).¹⁹ L-selectins have recently been identified at the maternal-fetal interface, and they are postulated to function as an adhesion molecule necessary for successful implantation.²⁰

Controlled invasion of the maternal vascular system by the trophoblast is necessary for the establishment of the hemochorial placenta. Studies with human placental villous explants suggest that chorionic villous cytotrophoblasts can differentiate along two distinct pathways: by fusing to form the syncytiotrophoblast layer and as extravillous trophoblasts that have the potential to invade the inner basalis layer of endometrium and the myometrium to reach the spiral arteries. Once trophoblasts have breached the endometrial blood vessels, decidualized stromal cells are believed to promote endometrial hemostasis by release of tissue factor and by thrombin generation.²¹

Three growth factors have been implicated in the regulation of this process. Epidermal growth factor (EGF)²² and interleukin-1 β ²³ stimulate invasion by the extravillous trophoblast, whereas transforming growth factor β appears to inhibit the differentiation toward the invasive phenotype and serves to limit the invasiveness of extravillous trophoblast and to induce syncytium formation.²⁴ The process of invasion appears to peak by 12 weeks' gestation.²⁵ These trophoblasts proceed to form the chorionic villi, the functional units of the placenta, which consist of a central core of loose connective tissue and abundant capillaries connecting them with the fetal circulation. Around this core are the outer syncytiotrophoblast layer and the inner layer of cytotrophoblast. In general, both cytotrophoblast and syncytiotrophoblast produce peptide hormones, whereas the syncytiotrophoblast produces all of the steroid hormones.

Human Chorionic Gonadotropin Production

Human chorionic gonadotropin (hCG) is one of the earliest products of the cells forming the embryo, and it should be viewed as one of the first embryonic signals elaborated by the embryo, even before implantation.²⁶ This glycoprotein is a heterodimer (36 to 40 kDa). It is composed of a 92-amino acid α subunit that is homologous to thyroid-stimulating hormone, luteinizing hormone (LH), and follicle-stimulating hormone, and a 145-amino acid β subunit that is similar to LH. The α subunit gene for hCG has been localized to chromosome 6; the β subunit gene is located on chromosome 19, fairly close to the LH- β gene.

The presence of sialic acid residues on hCG- β accounts for its prolonged half-life in the circulation (longer than the half-life of LH). After implantation, hCG is produced principally by the syncytiotrophoblast layer of the chorionic villus and is secreted into the intervillous space. Cytotrophoblasts are also able to produce hCG.

Clinically, hCG can be detected in either the serum or the urine 7 to 8 days before expected menses, and it is the earliest biochemical marker for pregnancy (Fig. 8-2). In studies during IVF cycles in which embryos were transferred 2 days after fertilization, β -hCG was detected as early as the eight-cell stage, whereas intact hCG was not detectable until 8 days after egg retrieval. The increase in hCG levels between days 5 and 9 after ovum collection is principally the result of free β -hCG production, whereas by day 22 most of the circulating hCG is in the dimer form.

These observations correspond to *in vitro* studies that indicate a two-phase control of dimer hCG synthesis mediated principally through a supply of subunits. In contrast to LH secretion in the pituitary gland, hCG is secreted constitutively as the subunits become available, and it is not stored in secretory granules.²⁷ Initially, the immature syncytiotrophoblast produces free β -hCG subunits, and the cytotrophoblast's ability to produce the α subunit appears to lag by several days.²⁸ As the trophoblast matures, the ratio of α subunits to β subunits reaches 1:1, and the concentration of hCG reaches a peak of approximately 100,000 mU/mL by the 9th or 10th week of gestation (Fig. 8-3). By 22 weeks' gestation, the placenta produces more α subunit than β -hCG. At term gestation, the ratio of the release of α subunits to the release of hCG is approximately 10:1.²⁹

The exponential rise of hCG after implantation is characterized by a doubling time of 30.9 ± 3.7 hours.³⁰ The hCG doubling time has been used as a marker by clinicians to differentiate normal from abnormal gestations (i.e., ectopic pregnancy). The inability to detect

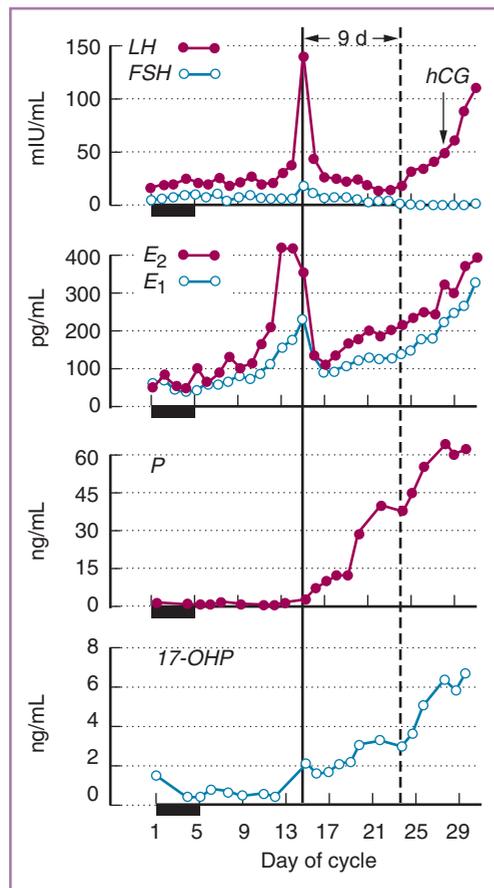

FIGURE 8-2 Hormone patterns during conception. Patterns of levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol (E₂), estrone (E₁), progesterone (P), and 17 α -hydroxyprogesterone (17-OHP) during a conception cycle. Human chorionic gonadotropin (hCG) becomes detectable on cycle days 26 and 27.

an intrauterine pregnancy (i.e., a gestational sac) by endovaginal ultrasound when serum hCG levels reach 1100 to 1500 mU/mL strongly suggests an abnormal gestation or ectopic pregnancy. Higher-than-normal hCG levels may indicate a molar pregnancy or multiple-gestational pregnancies. Levels of hCG in combination with maternal α -fetoprotein, unconjugated estriol, and inhibin have been used as a screening test for detection of fetal anomalies (see Chapter 17).

Maintenance of Early Pregnancy: Human Chorionic Gonadotropin and Corpus Luteum of Pregnancy

The major biologic role of hCG during early pregnancy is to “rescue” corpus luteum from its premature demise while maintaining progesterone production. Although the secretory pattern of hCG is not well characterized, hCG is required for rescue and maintenance of the corpus luteum until the luteal-placental shift in progesterone synthesis occurs. This concept is supported by observations that immunoneutralization of hCG results in early pregnancy loss.^{31,32}

Copyright © by the Endocrine Society.)

Studies in early pregnancy show that secretion of hCG and progesterone from the corpus luteum appears to be irregularly episodic with varying frequencies and peaks.^{33,34} In first-trimester explant experiments, intermittent gonadotropin-releasing hormone administration enhances the pulse-like secretion of hCG from these explants, indirectly implicating placental gonadotropin-releasing hormone as a paracrine regulator of hCG secretion.³⁵ During nonconception cycles, the corpus luteum is preprogrammed to undergo luteolysis, a process that is not well understood. Acting through the LH receptor, hCG is also able to stimulate parallel production of estradiol, 17-hydroxyprogesterone, and other peptides such as relaxin and inhibin, from the corpus luteum.

Timing of the Luteal-Placental Shift

Ovarian progesterone production is essential for maintenance of early pregnancy. If progesterone action is blocked by a competitive progesterone antagonist, such as mifepristone, pregnancy termination results. During later gestation, placental production of progesterone is sufficient to maintain pregnancy. To uncover the timing of this luteal-placental shift, Csapo and colleagues performed corpus luteum ablation

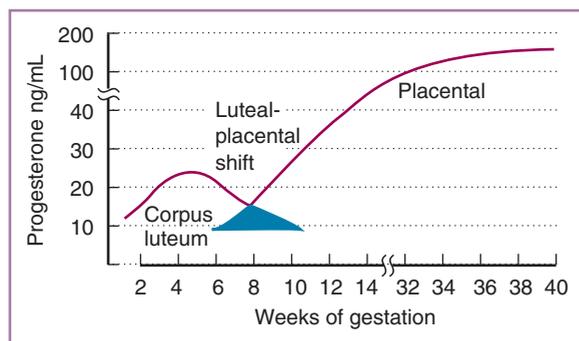

FIGURE 8-4 Shift in progesterone production. Diagrammatic representation of the shift in progesterone production from the corpus luteum to the placenta between the 7th and 9th weeks of gestation.

experiments. They demonstrated that removal of the corpus luteum before, but not after, the 7th week of gestation usually resulted in subsequent abortion.^{32,36} Removal of the corpus luteum after the 9th week appears to have little or no influence on gestation (Fig. 8-4). Thus, progesterone supplementation is required if corpus luteum function is compromised before 9 to 10 weeks of gestation.

Fetoplacental Unit as an Endocrine Organ

The fetus and placenta must function together in an integrated fashion to control the growth and development of the unit and subsequent expulsion of the fetus from the uterus. Contributing to fetal and placental activity are the changes occurring in the maternal endocrine milieu. Estrogens, androgens, and progestins are involved in pregnancy from before implantation to parturition. They are synthesized and metabolized in complex pathways involving the fetus, the placenta, and the mother.

The fetal ovary is not active and does not secrete estrogens until puberty. In contrast, the Leydig cells of the fetal testes are capable of producing such large amounts of testosterone that the circulating testosterone concentration in the first-trimester male fetus is similar to that in the adult man.³⁷ Initial stimulus of the testes is by hCG. Fetal testosterone is required for promoting differentiation and masculinization of the male external and internal genitalia. In addition, local conversion of testosterone to dihydrotestosterone by 5 α -reductase in the genital target tissues ensures final maturation of the external male genital structures. The maternal environment is protected from testosterone produced by the male fetus by the placental enzyme aromatase, which can convert testosterone to estradiol.

Progesterone

During most of pregnancy, the major source of progesterone is the placenta. For the first 6 to 10 weeks, however, the major source of progesterone is the corpus luteum. Exogenous progesterone must be administered during the first trimester to oocyte recipients who have no ovarian function.³⁸

Progesterone is synthesized in the placenta mainly from circulating maternal cholesterol.³⁹ By the end of pregnancy, the placental production of progesterone approximates 250 mg/day, with circulating levels

in the mother of about 130 to 150 ng/mL. In comparison, in the follicular phase, production of progesterone approximates 2.5 mg/day; in the luteal phase, it is about 25 mg/day. About 90% of the progesterone synthesized by the placenta enters the maternal compartment. Most of the progesterone in the maternal circulation is metabolized to pregnanediol and is excreted in the urine as a glucuronide.

During the first 6 weeks of pregnancy, 17 α -hydroxyprogesterone is also elevated in the maternal circulation, to levels comparable to those of progesterone.⁴⁰ After 6 weeks of gestation, 17 α -hydroxyprogesterone levels decrease progressively, becoming undetectable during the middle third of pregnancy, whereas progesterone levels fall transiently between 8 and 10 weeks of gestation and then increase thereafter. The decrease in 17 α -hydroxyprogesterone and the dip in progesterone levels reflect the transition of progesterone secretion from the corpus luteum to the placenta. The 17 α -hydroxyprogesterone secreted during the last third of pregnancy comes largely from the fetoplacental unit.

Estrogens

The major estrogen formed in pregnancy is estriol. Estriol is not secreted by the ovaries of nonpregnant women, but it comprises more than 90% of the known estrogen in the urine of pregnant women and is excreted as sulfate and glucuronide conjugates. Maternal serum levels of estriol increase to between 12 and 20 mg/mL by term (Fig. 8-5). Generally, circulating levels of estradiol are even higher than those of estriol. This is true because circulating estriol, in contrast to estrone and estradiol, has a very low affinity for sex hormone-binding globulin and is cleared much more rapidly from the circulation. During pregnancy, a woman produces more estrogen than a normal ovulatory woman could produce in more than 150 years.⁴⁰

The biosynthesis of estrogens demonstrates the interdependence of the fetus, the placenta, and the maternal compartment. To form estrogens, the placenta, which has active aromatizing capacity, uses circulating androgens as the precursor substrate. The major androgenic precursor to placental estrogen formation is dehydroepiandrosterone sulfate (DHEAS), which is the major androgen produced by the fetal adrenal cortex. DHEAS is transported to the placenta and then is cleaved by sulfatase, which the placenta has in abundance, to form free unconjugated dehydroepiandrosterone, which is then aromatized by placental aromatase to estrone and estradiol. Very little estrone and estradiol is converted to estriol by the placenta. Near term, about 60% of the estradiol-17 β and estrone is formed from fetal androgen precursors, and about 40% is formed from maternal DHEAS.⁴¹

The major portion of fetal DHEAS undergoes 16 α -hydroxylation, primarily in the fetal liver but also in the fetal adrenal gland (Fig. 8-6). Fetal adrenal DHEAS in the circulation is taken up by syncytiotrophoblast cells, where steroid sulfatase, a microsomal enzyme, converts it back to DHEA that is then aromatized to estriol.⁴² Estriol is then secreted into the maternal circulation and conjugated in the maternal liver to form estriol sulfate, estriol glucosiduronate, and mixed conjugates and is excreted in the maternal urine.

Estetrol is an estrogen unique to pregnancy. It is the 15 α -hydroxy derivative of estriol, and it is derived exclusively from fetal precursors. Although the measurement of estetrol in pregnancy was proposed as an aid in monitoring a fetus at risk for intrauterine death, it has not proved to be any better than measurement of urinary estriol.⁴³ Neither is currently used in the clinical setting.

Hydroxylation at the C₂ position of the phenolic A ring results in the formation of so-called catecholestrogens (2-hydroxyestrone, 2-hydroxyestradiol, and 2-hydroxyestriol) and is a major process in estrogen metabolism. 2-Hydroxyestrone is excreted in maternal urine in the

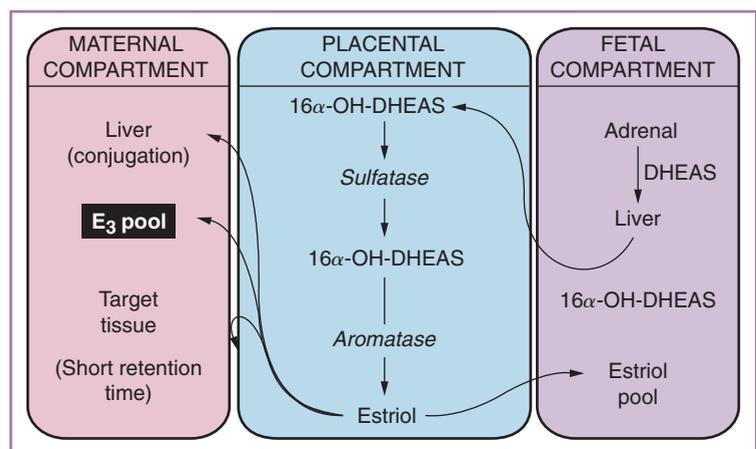

FIGURE 8-6 Roles of the maternal-placental-fetal compartments in the formation of estriol. Diagram of the roles of each compartment in the formation of estriol (E_3) from the fetal precursor 16α -hydroxydehydroepiandrosterone sulfate (16α -OH-DHEAS). DHEA, dehydroepiandrosterone.

largest amounts during pregnancy with marked individual variation (100 to 2500 mg/24 hr). Apparently, 2-hydroxyestrone levels increase during the first and second trimesters and decrease in the third trimester.⁴⁴ The physiologic significance of the catecholestrogens is unclear, particularly because they are rapidly cleared from the circulation; however, they do have the capacity to alter catecholamine synthesis and metabolism during pregnancy (inhibiting catecholamine inactivation via competition for carboxyl-*o*-methyl transferase, and reducing catecholamine synthesis via inhibition of tyrosine hydroxylase). Catecholestrogens also function as antiestrogens, competing with estrogens for receptors. Thus, catecholestrogens, when present in large quantities,

may have significant effects in pregnancy. About 90% of the estradiol- 17β and estriol secreted by the placenta enters the maternal compartment. Estrone is preferentially secreted into the fetal compartment.⁴⁴

In the past, maternal estriol measurements were often used as an index of fetoplacental function. The numerous problems that have been documented in interpreting low estriol levels have limited the use of estriol. The normal range of urinary estriol concentrations at any given stage of gestation is quite large (typically, ± 1 standard deviation). A single plasma measurement is meaningless because of moment-to-moment fluctuations. Body position (e.g., bed rest versus ambulation) affects blood flow to the uterus and kidney and therefore affects estriol

levels. Moreover, numerous drugs, including glucocorticoids and ampicillin, affect estradiol levels.

Two genetic diseases document that placental estrogen synthesis, at least at high levels, is apparently not required for maintenance of pregnancy. Human gestation proceeds to term when the fetus and placenta lack sulfatase.⁴⁵ In patients with this disorder, the gene has been localized to the distal short arm of the X chromosome, and the resulting male offspring manifest ichthyosis during the first few months of life. Pregnancies also reach term accompanied by severe fetal and placental aromatase deficiency.⁴⁶ Although pregnancy is maintained in both cases despite low placental estrogen synthesis, the changes in the reproductive tract that normally precede parturition, particularly ripening of the cervix, do not occur, revealing a significant role for placental estrogens in preparation for labor and birth. In addition, in the case of aromatase deficiency, both the fetus and the mother are virilized as a consequence of diminished aromatization of androgens.

Low levels of estrogens also occur after fetal demise and in most anencephalic pregnancies, in which fetal signals from the fetal hypothalamic-pituitary unit are diminished and do not stimulate synthesis of fetal adrenal androgens. In the absence of a fetus, as occurs in molar pregnancy and in pseudocyesis, estrogen levels are low as well.

Roles of Estrogens and Progestins during Pregnancy

Estrogens and progestins appear to play several important roles in pregnancy. They clearly induce the secretory endometrium, required for implantation. Progesterone appears to be important in maintaining uterine quiescence during pregnancy by actions on uterine smooth muscle.⁴⁷ Progesterone apparently suppresses uterine contraction by action through its two major progesterone receptor (PR) subtypes PR-A and PR-B.⁴⁸ PR-A appears to repress progesterone actions mediated by PR-B. At the time of labor, there is an increase in expression of PR-A.⁴⁹ Progesterone also inhibits uterine prostaglandin production,⁵⁰ presumably promoting uterine quiescence and delaying cervical ripening. Progesterone may also help to maintain pregnancy by inhibiting T lymphocyte-mediated processes that play a role in tissue rejection.⁵¹ Thus, the high local concentrations of progesterone appear to contribute to the immunologically privileged status of the pregnant uterus. Progesterone is important in creating a barrier to penetration of pathogens into the uterus.

Estrogens are important for parturition at the appropriate time. The stimulatory effects of estrogen on phospholipid synthesis and

turnover, prostaglandin production, and increased formation of lysosomes in the uterine endometrium, as well as estrogen modulation of adrenergic mechanisms in uterine myometrium, may be means by which estrogens act to time the onset of labor.⁵² Estrogens also increase uterine blood flow,⁵³ which ensures an adequate supply of oxygen and nutrients to the fetus. It appears that estradiol, an extremely weak estrogen, is just as effective as other estrogens in increasing uteroplacental blood flow.⁵³

Estrogens are important in preparing the breast for lactation.⁵⁴ They also affect other endocrine systems during pregnancy, such as the renin-angiotensin system,⁵⁵ and stimulate production of hormone-binding globulins in the liver. Estrogens may play a role in fetal development and organ maturation, including increasing fetal lung surfactant production.⁵⁶

The Placenta and Growth Factors

The functional roles for growth factors in the placenta can be divided into three areas:

1. Regulation of cell growth and differentiation
2. Local regulation of hormone release
3. Regulation of uterine contractility

Growth factors that are elaborated by the placenta are responsible for the following:

1. Regulation of amino acid transport
2. Increased glucose uptake
3. DNA synthesis and cell replication
4. RNA and protein synthesis

These processes may be regulated in an autocrine or paracrine manner within the placenta.

Although much of the research has been conducted in other mammalian systems and may not be directly applicable to humans, major similarities probably exist in the way growth factors operate to ensure continuing growth and development of the fetus. In the human, most of our knowledge has been limited to descriptive studies demonstrating localization of many growth factor systems. Unfortunately, our understanding of their functional roles has only begun. Table 8-2 is a partial listing of growth factors that have been identified in the

placenta. A detailed description of their respective roles is beyond the scope of this chapter. Only major growth factor systems are discussed.

Insulin-Like Growth Factor, Epidermal Growth Factor, and Transforming Growth Factor

In preimplantation embryos, the insulin-like growth factor (IGF), the transforming growth factor α , and the EGF systems have been studied extensively. In general, IGF-2/IGF-1 receptors are primarily responsible for regulation of cell proliferation, whereas cell differentiation is regulated by the transforming growth factor α and EGF-receptor systems.

IGF-1 appears to be an important modulator of fetal growth (Fig. 8-7). It is normally produced in response to pituitary growth hormone (GH) by the liver. In pregnancy, the levels of IGF-1 may be regulated in part by placental GH, a variant of pituitary GH. Fetal cord plasma IGF-1 levels are positively correlated to birth weight and length of the fetus.^{57,58}

EGF and transforming growth factor α in the placenta both interact with the EGF receptor. Both growth factors are present in cytotrophoblast and syncytiotrophoblast. In these latter cells, EGF stimulates secretion of hCG and human placental lactogen.⁵⁹ The proliferative activities induced by a number of growth factors appear to overlap. These factors include IGF, platelet-derived growth factors, EGF, and fibroblastic growth factors.

Human Chorionic Somatomammotropin

Human chorionic somatomammotropin (hCS), initially named human placental lactogen when it was isolated from the human placenta in

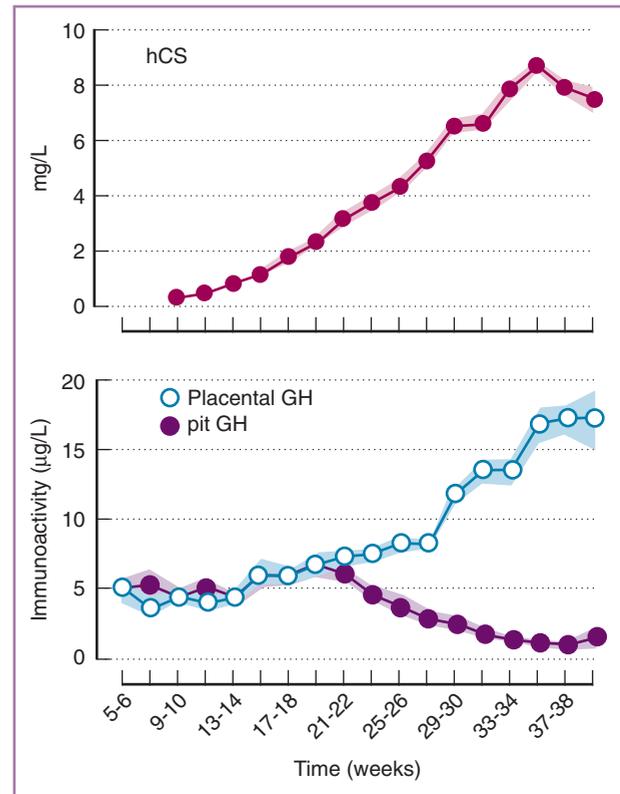

FIGURE 8-8 Comparison of serum levels of human chorionic somatomammotropin (hCS) with immunoactivity of placental growth hormone (GH) and pituitary growth hormone (pit GH) during human pregnancy. (Modified from Frankenne F, Closset J, Gomez F, et al: The physiology of growth hormones [GHs] in pregnant women and partial characterization of the placental GH variant. *J Clin Endocrinol Metab* 66:1171, 1988. Copyright © by the Endocrine Society.)

the 1960s,⁶⁰ has structural, biologic, and immunologic similarities to both pituitary human growth hormone (hGH) and prolactin. Now known to be a single-chain polypeptide (about 22 kDa) containing 191 amino acids and two disulfide bonds, hCS has up to 96% homology with GH and about 67% homology with prolactin.^{61,62} The hCS/hGH gene cluster has been localized to the long arm of chromosome 17 and consists of five genes, two coding for hGH and three for hCS.⁶³ Two of the three hCS genes are expressed at approximately equivalent rates in the term placenta and synthesize identical proteins, and the third gene appears to be a pseudogene.⁶⁴

Human chorionic somatomammotropin is produced only by syncytiotrophoblasts and appears to be transcribed at a constant rate throughout gestation.^{65,66} As a consequence, serum levels of hCS correlate very well with placental mass as the placenta increases in size during pregnancy. At term, placental production of hCS approximates 1 to 4 g/day and maternal serum levels range from 5 to 15 $\mu\text{g}/\text{mL}$ (Fig. 8-8), making it the most abundant secretory product of the placenta.

Despite the huge quantities produced during pregnancy, the function of hCS is poorly understood. It has been suggested that hCS must exert its major metabolic effects on the mother to ensure that the nutritional demands of the fetus are met, functioning as the “growth hormone” of pregnancy.⁶⁷ During pregnancy, maternal plasma glucose levels are decreased, plasma free fatty acids are increased, and insulin secretion is increased with resistance to endogenous insulin as a con-

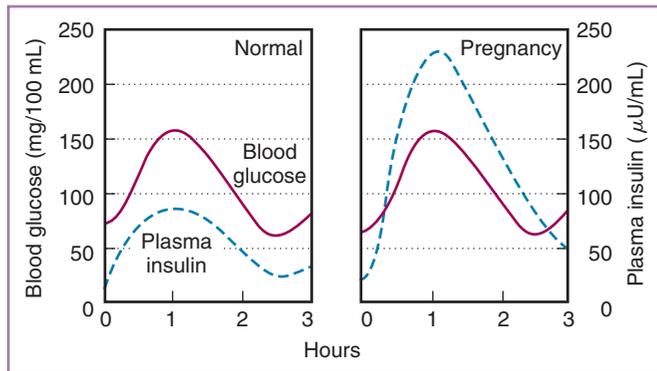

FIGURE 8-9 Insulin response to oral glucose. Comparison of the plasma insulin response to an oral glucose load (100 g) in women during late pregnancy and in nonpregnant ("normal") women.

sequence of the GH-like and contrainsulin effects of hCS (Fig. 8-9). Peripheral glucose uptake is inhibited in the mother but crosses the placenta freely. Amino acids are actively transported to the fetus against a concentration gradient, and transplacental passage of free fatty acids is slow. As a consequence, when the mother is in the fasting or starved state, glucose should be reserved largely for the fetus and free fatty acids would be used preferentially by the mother. The placenta is impermeable to insulin and other protein hormones.

Despite these presumptions, the regulation of hCS is also poorly understood. Factors that regulate pituitary GH secretion are largely ineffective in altering concentrations of hCS. In addition, despite its structural homology to GH and prolactin, hCS has very little (although definite) growth-promoting and lactogenic activity in humans.⁶⁷ Moreover, normal pregnancies resulting in delivery of healthy infants have been reported in individuals with very low to absent production of hCS.^{68,69} Thus, it is possible that hCS is not essential for pregnancy but may serve as an evolutionary redundancy for pituitary GH and prolactin. Whether pregnancies with diminished hCS production would have good outcomes in the presence of nutritional deprivation, however, remains unknown.

Human Placental Growth Hormone

Only in the past several years has the existence of a placental GH been documented. The two forms of human placental GH present include a 22-kDa form and a glycosylated 25-kDa form. Both are encoded by the *hGH-V* gene in the hCS/hGH gene cluster on chromosome 17.^{70,71} Pituitary hCG is encoded by the *hGH-N* gene in the same gene cluster.⁷²

During the first trimester, pituitary GH is measurable in maternal serum and is secreted in a pulsatile fashion.⁷³ Human placental GH levels begin to rise thereafter as pituitary GH levels decrease; human placental GH is secreted in a relatively constant (in contrast to a pulsatile) manner.⁷³ It appears that human placental GH stimulates IGF-1 production, which in turn suppresses pituitary GH secretion in the second half of pregnancy.⁷⁴

Endocrine and Metabolic Changes in Pregnancy

Pregnancy is accompanied by a series of metabolic changes, including hyperinsulinemia, insulin resistance, relative fasting hypoglycemia,

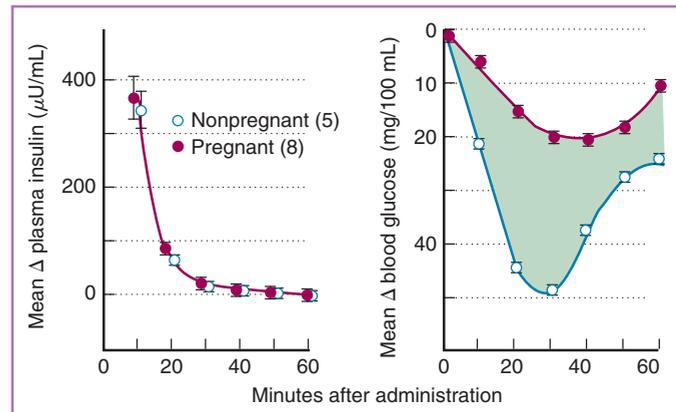

FIGURE 8-10 Disappearance of circulating insulin after injection of intravenous insulin. *Left*, Almost identical disappearance curves of circulating insulin after a bolus intravenous insulin injection (0.1 U/kg) in pregnant and nonpregnant women. *Right*, The marked decline in blood glucose in response to exogenous insulin in nonpregnant women as opposed to pregnant women suggests increased insulin resistance in the latter group. Reprinted with permission from the American College of Obstetricians and Gynecologists.)

increased circulating plasma lipids, and hypoaminoacidemia. All these changes seem intended to ensure an uninterrupted supply of metabolic fuels to the growing fetus. It is also now clear that these changes are directed by hormones elaborated by the fetoplacental unit.

The insulin resistance associated with pregnancy has been recognized for many years and is known to be accompanied by maternal islet cell hyperplasia (Fig. 8-10). The mechanism responsible for increasing insulin resistance throughout pregnancy is not entirely clear. It appears that hCS and human placental GH in particular reduce insulin receptor sites and glucose transport in insulin-sensitive tissues in the mother (Fig. 8-11).⁷⁵ There is no evidence that glucagon plays a significant role as a diabetogenic factor. The rapid return to normal glucose metabolism after delivery in women with gestational diabetes has been regarded as the best evidence that fetoplacental hormones are largely diabetogenic in the mother.⁷⁶

Total plasma lipids increase significantly and progressively after 24 weeks of gestation, with the increases in triglycerides, cholesterol, and free fatty acids being most marked (Table 8-3).⁷⁷ Pre- β -lipoprotein, a very-low-density lipoprotein that normally represents a very small percentage of total lipoprotein, is increased in pregnancy. High-density-lipoprotein cholesterol levels increase in early pregnancy, whereas low-density-lipoprotein cholesterol levels increase later in pregnancy.⁷⁸

Plasma triglyceride levels increase more in response to an oral glucose load in late pregnancy than in the nonpregnant state.⁷⁷ Because the placenta is poorly permeable to fat but readily permeable to glucose and amino acids, this mechanism helps ensure an adequate supply of glucose for the fetus.

Prolonged fasting in pregnancy is accompanied by exaggerated hypoglycemia, hypoinsulinism, and hyperketonemia.⁷⁹ Gluconeogenesis, however, is not increased, as would be expected. Thus, even though the demands of the fetus during maternal fasting are met in part by accelerated muscle breakdown, it is at the expense of the mother, in whom homeostatic mechanisms do not include sufficient gluconeogenesis to prevent maternal hypoglycemia. It is not clear whether

TABLE 8-3 BASAL VALUES FOR INSULIN, GLUCAGON, AND PLASMA METABOLIC FUELS IN YOUNG WOMEN AFTER OVERNIGHT FAST

Plasma Metabolite	Units	Nongravid	Late Pregnancy
Glucose	(mg/dL)	79 ± 2.4	68 ± 1.5*
Insulin	(μU/mL)	9.8 ± 1.1	16.2 ± 2.0*
Glucagon	(pg/mL)	126 ± 6.1	130 ± 5.2 (NS)
Amino acids	(μmol/L)	3.82 ± 0.13	3.18 ± 0.11*
Alanine	(μmol/L)	286 ± 15	225 ± 9*
Free fatty acids	(μmol/L)	626 ± 42	725 ± 21*
	(mg/dL)	76.2 ± 7.0	181 ± 10*
Cholesterol	(mg/dL)	163 ± 8.7	205 ± 5.7*

*Significant difference between nongravid and late pregnancy values. NS, not significant.

Data from Freinkel N, Metzger BE, Nitzan M, et al: Facilitated anabolism in late pregnancy: Some novel maternal compensations for accelerated starvation. In Malaisse WJ, Pirart J (eds): *Diabetes. International Series No. 312. Amsterdam, Excerpta Medica, 1973, p 474.*

normal muscle catabolism simply cannot keep up with the loss of glucose and amino acids to the fetus during fasting or whether there are additional restraints on muscle breakdown during pregnancy.

Although cortisol is a potent diabetogenic hormone, inhibiting peripheral glucose uptake and promoting insulin secretion, and serum free cortisol levels clearly increase in late pregnancy,^{80,81} it is unclear just how great a role cortisol plays in the diabetogenic nature of pregnancy. The increased circulating concentrations of estrogen and progesterone in pregnancy may also be important in the altered glucose-insulin homeostasis present during pregnancy.

Inhibin-Related Proteins

The human placenta has the capacity to synthesize inhibin, activin, and follistatin.⁸² Inhibin is a dimeric protein composed of an α subunit (18 kDa) and a β subunit (14 kDa), originally shown to have an inhibitory effect on pituitary follicle-stimulating hormone release. Two different β subunits have been characterized and have been designated as β_A and β_B . Each different β subunit can thus give rise to two different inhibins (inhibin A, $\beta_{A\alpha}$, and inhibin B, $\beta_{B\alpha}$). Activin is a closely related protein that was discovered soon after inhibin and was named because of its ability to stimulate pituitary follicle-stimulating hormone release.

Activin is composed of two β subunits. All three possible configurations of activin have been identified— $\beta_A\beta_A$, $\beta_A\beta_B$, and $\beta_B\beta_B$. Follistatin is a single-chain glycoprotein that can functionally inhibit pituitary follicle-stimulating hormone release by binding of activin. Besides the human trophoblast, the maternal decidua, amnion, and chorion have been demonstrated to express messenger RNAs and immunoreactive proteins for inhibin, activin, and follistatin.

High levels of inhibin-like proteins have been reported in patients with fetal Down syndrome⁸³ and in patients with hydatidiform mole⁸⁴; low levels have been observed in women with abnormal gestations, such as ectopic pregnancies⁸⁵ and pregnancies that end in abortion.⁸⁶ High levels of maternal activin A have been observed in pregnancies complicated by preeclampsia, diabetes, and preterm labor.⁸²

At this point, there are no in vivo models to study the functional roles of inhibin-related proteins on placental hormone secretion, and thus the biologic roles of this system have been derived from in vitro cell cultures. In cultured placental cells, activin appears to increase the release of hCG and progesterone,⁸⁷ whereas inhibins decrease hCG and progesterone levels. Follistatin has been reported to reverse the activin-induced release of hCG and progesterone. These regulatory events appear to be parallel to that of the pituitary gland, where activin increases follicle-stimulating hormone release, whereas follistatin and inhibin oppose this effect.

Corticotropin-Releasing Hormone and Corticotropin-Releasing Hormone-Binding Protein System

The placenta, chorion, amnion, and decidua are all capable of synthesizing corticotropin-releasing hormone (CRH). This 41-amino acid peptide was first isolated from the hypothalamus and is responsible for stimulation of adrenocorticotropic hormone and proopiomelanocortin peptides from the pituitary. CRH is detectable by 7 to 8 weeks' gestation,⁸⁸ and maternal plasma levels of CRH rise progressively throughout gestation.⁸⁹ Maternal CRH levels increase significantly with labor, reaching a peak at delivery; levels remain stable in the absence of labor with cesarean section.⁹⁰ In the term placenta, CRH has been localized to both the cytotrophoblast and the syncytiotrophoblast.⁹¹ The addition of CRH to human placental cells or amnion stimulates release of prostaglandin E and prostaglandin $F_{2\alpha}$, suggesting that locally elaborated CRH plays a major role in the initiation of myometrial contractility and labor.⁹²

CRH-binding protein has also been identified in the placenta and appears to be produced by the syncytiotrophoblast,⁹³ the decidua, and fetal membranes.⁹⁴ This protein conceptually functions as a CRH receptor in the circulation, reduces the biologic activity of CRH, and thus may serve a modulatory role for localized CRH action.

Oxytocin

Oxytocin, a nonapeptide produced by the supraoptic and paraventricular nuclei of the hypothalamus, has now also been localized to the syncytiotrophoblast. In placental cell cultures, increased concentrations of estradiol are associated with increased levels of oxytocin mRNA. The levels of immunoreactive oxytocin increase throughout gestation and are parallel to levels in maternal blood. The placental oxytocin content is estimated to be fivefold greater than in the posterior pituitary lobe, suggesting that the placenta may be the main source of oxytocin during pregnancy.⁹⁵

The role of maternal oxytocin in pregnancy and in parturition remains unclear. Circulating levels of oxytocin are low throughout pregnancy and increase markedly only during the second stage of labor.⁹⁶ Oxytocin receptors are present in myometrium and increase dramatically in number only shortly before the onset of labor.⁹⁷ The sensitivity of the myometrium, therefore, changes more dramatically in preparation for labor than do the circulating levels of the hormone. Oxytocin also can stimulate the production of prostaglandins by human decidua.⁹⁸ These data do not document any role for oxytocin in triggering the onset of parturition and imply that it is unlikely to be the initiator of human parturition.

Relaxin

Relaxin, a peptide hormone of approximately 6 kDa, belongs to the insulin family. It is composed of two disulfide-linked chains, A and B (see Fig. 8-7). Relaxin is produced in a number of sites, including the corpus luteum in pregnant and nonpregnant women, the decidua, the placenta, the prostate, and the atria of the heart.

Relaxin first appears in the serum of pregnant women at the same time hCG appears. Levels during pregnancy approximate 1 ng/mL. Relaxin concentrations are highest during the first trimester, peaking at about 1.2 ng/mL between the 8th and 12th weeks of pregnancy, and then gradually decrease to 1 ng/mL for the duration of pregnancy.⁹⁹ There is no evidence of any circadian rhythm, and no significant changes have been noted during labor.

The available evidence suggests that all relaxin circulating in the mother during pregnancy is of luteal origin. The relaxin concentration is highest in the blood draining the corpus luteum.¹⁰⁰ By immunohis-

tochemistry profiles, relaxin can be detected only within the corpus luteum in the ovary. Luteectomy at term results in a prompt fall in circulating relaxin, with a half-life of less than 1 hour. In the absence of luteectomy, relaxin levels fall to undetectable levels over the first 3 days after delivery, consistent with the time frame for postpartum luteolysis. Perhaps most convincing is the observation that relaxin is undetectable in the serum of women pregnant by IVF and egg donation who have no corpora lutea.^{101,102}

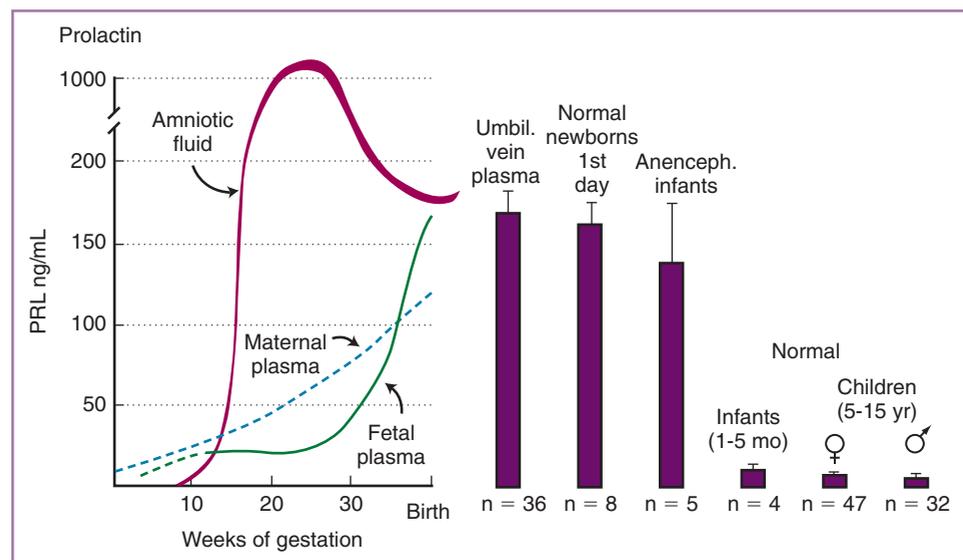

Relaxin appears to have a broad range of biologic activities. These include collagen remodeling and softening of the cervix and lower reproductive tract, and inhibition of uterine contractility.¹⁰³ However, circulating relaxin does not seem to be necessary for pregnancy maintenance or normal delivery in women. Women who become pregnant by egg donation go into labor at term and are capable of delivery vaginally.¹⁰⁴ It is possible, however, that the placenta and decidua provide sufficient relaxin for normal parturition under such circumstances.

Two conditions associated with an increase in circulating relaxin levels are multiple gestation and ovarian stimulation with the use of ovulation-inducing agents. Relaxin concentrations are higher in patients who become pregnant from IVF and exogenous gonadotropin treatment than in untreated pregnant control subjects. In both circumstances, there are multiple corpora lutea, and multiple gestations independently produce a significant increase in serum relaxin concentrations. Multiple gestations are associated with a higher risk of premature delivery, according to one group who suggested that first-trimester hyperrelaxinemia can predict the risk of preterm delivery.¹⁰⁴ This observation, potentially important, warrants further investigation.

Prolactin

During the first trimester of pregnancy, maternal serum prolactin levels rise progressively to achieve levels of approximately 125 to 180 ng/mL (Fig. 8-12).¹⁰⁵ The dramatic 10-fold increase in prolactin levels is believed to be a reflection of the estrogen-stimulated increase in size of the pituitary lactotrotes, which contributes to a twofold to threefold enlargement of pituitary volume. Despite the increased magnitude of prolactin concentrations during pregnancy, the normal sleep-associated increase in prolactin remains preserved.¹⁰⁶ At delivery, the higher level of prolactin is responsible for priming the breast tissue in preparation for lactation.

FIGURE 8-12 Prolactin levels in pregnancy. Approximate levels of prolactin (PRL) in amniotic fluid, maternal plasma, and fetal plasma during the course of pregnancy. Plasma levels in normal and anencephalic newborns are compared with levels in umbilical vein plasma and in normal infants and children. (Modified from Aubert ML, Grumbach MM, Kaplan SL: The ontogenesis of human fetal hormones: III. Prolactin. *J Clin Endocrinol Metab* 56:155, 1975. Copyright © by the Endocrine Society.)

After delivery, prolactin levels remain elevated at 200 to 250 ng/mL and fall gradually toward the normal range (<25 ng/mL) during a 3- to 4-week interval in nonbreastfeeding mothers.¹⁰⁷ In women who are breastfeeding, prolactin levels remain elevated and increase with each nursing episode. This constant hyperprolactinemic state may be partly responsible for the delay in return of ovulatory function in the breast-feeding woman.

The decidua is the major source of amniotic fluid prolactin. Decidual cells are capable of secretion of prolactin after day 23 of the menstrual cycle. Decidual prolactin is immunologically identical to the 23-kDa prolactin produced by the pituitary gland, and the complementary DNA from decidua appears virtually identical to pituitary prolactin.^{108,109} Unlike that from the pituitary gland, decidual prolactin is not regulated by dopamine or thyrotropin-releasing hormone. The decidual prolactin synthesis is coupled to progesterone-induced decidualization. Once cells are stimulated to decidualize, prolactin production continues in culture even in the absence of progesterone. Because abnormal levels of amniotic fluid prolactin levels have been found in pregnancies complicated by polyhydramnios or oligohydramnios, it is believed that the biologic role of locally produced prolactin is to regulate solute and water transport in the amniotic compartment.¹¹⁰

Prostaglandins

Although concentrations of prostaglandin precursors are high in the endometrial compartment during pregnancy, there is a marked decrease in the production of prostaglandins by the endometrial decidua. Levels of cyclooxygenase-1, the constitutively expressed cyclooxygenase enzyme, fall precipitously during the mid-luteal phase of the menstrual cycle at the time of implantation. Under the influence of progesterone, the endometrial decidua produces secretory component, an endogenous inhibitor of prostaglandin synthesis.¹¹¹ The exogenous administration of prostaglandins is capable of inducing abortion or labor in all species, including humans. Taken together, these observations suggest multiple mechanisms that inhibit prostaglandin production during pregnancy. Progesterone may be one factor that suppresses synthesis of prostaglandins.

Chapter 9

The Breast and the Physiology of Lactation

Robert M. Lawrence, MD, and Ruth A. Lawrence, MD

Universal breastfeeding is recommended by the American College of Obstetrics and Gynecology (ACOG), the World Health Organization (WHO), United Nations International Children's Emergency Fund, the American Academy of Pediatrics (AAP), and the Women, Infants and Children's Nutrition Program, but recommendations alone are not sufficient to promote breastfeeding. It is the responsibility of every physician to recommend and support breastfeeding enthusiastically. This is especially true in obstetrics, where a physician's advice can immediately influence a woman's informed decision concerning breastfeeding and create or diminish barriers to successful breastfeeding.

Benefits of Breastfeeding

Breastfeeding provides benefits for both the mother and the infant. Breast milk is species specific, made uniquely for the human infant.¹ Protein in breast milk is readily digested and is present in amounts that can be handled by the developing kidney. Various minerals (e.g., iron) and nutrients exist in a form and in conjunction with other components that make them easily absorbed to meet infants' needs during periods of rapid growth.^{1,2} Cholesterol and docosahexaenoic acid have been shown to play a role in central nervous system development and may contribute to the enhanced intelligence quotient measurements reported in breastfed infants.³⁻⁵

Protection against infections, including otitis media, croup, pneumonia, and gastrointestinal infections, is mediated by the over 50 immunologically active components found in breast milk.^{1,6} These immunologically active components include viable functioning cells (T and B lymphocytes, macrophages), T cell–secreted products, immunoglobulins (especially secretory IgA), carrier proteins such as lactoferrin and transferrin, enzymes (lysozyme and lipoprotein lipase), and nonspecific factors such as complement, bifidus factor, gangliosides, and nucleotides. Other immune factors in breast milk include hormones, hormone-like factors, and growth factors that contribute to the normal maturation of the mucosal barrier of the respiratory and gastrointestinal tracts as well as the developing infant's immune system. Breast milk is a very dynamic fluid, varying with the maternal-infant dyads' environment and needs, especially in the face of infection or stress (providing, for example, nucleotides, secretory IgA, interleukin, interferon, and cytokines).⁷⁻¹⁰ There is also evidence that breastfeeding provides protection against some noninfectious illnesses such as asthmatic wheezing, eczema, childhood lymphoma, insulin-dependent childhood-onset diabetes, and obesity^{6,10-15} in children who are exclusively breastfed for the first 4 to 6 months of life.

Cognitive and psychological benefits for breastfed infants have been suggested, including developmental performance,¹⁶ visual acuity,¹⁷⁻¹⁹ school performance,²⁰ and performance on standardized²⁰ and intelligence quotient⁴ tests. More recent articles continue to support the impact of breastfeeding on intellectual development while fostering debate over the relative contributions of nutrition, genetics, and environment to the intellectual development of infants and the possible influence on the child's or adult's future cognitive abilities as measured by intelligence quotient testing.^{21,22} The psychological benefits are more difficult to measure but are well described by Newton and Newton,²³ and indeed by most mothers who have successfully breastfed their infants. One of the most consistent findings of exclusive breastfeeding is its influence on later intelligence, with a few test point advantages to the breastfed infant.⁵ Reports questioning this effect have been based on any breastfeeding, not exclusive breastfeeding.²⁴

Potential benefits to the mother include improved postpartum recovery,²⁵ a lower incidence of subsequent obesity,²⁶ a decreased risk of osteoporosis, and reduced incidence of both breast and ovarian cancers.²⁷ Calcium and phosphorus concentrations are higher in lactating women, and the risk of osteoporosis is measurably less for women who have breastfed their infants.^{28,29} Increasing number of pregnancies, longer oral contraceptive use, and increasing duration of lactation are all protective against ovarian cancer.³⁰⁻³² The incidence of breast cancer is lower among women who have nursed.^{33,34}

It is essential that a discussion of the benefits of breastfeeding to infants, mothers, and families (fathers included) be presented alongside any potential risks or contraindications. The benefits of breastfeeding are tremendous, and the risks and contraindications are few. Summarized here are the conditions in which the risks of breastfeeding may outweigh its benefits.³⁵

- Women who take street drugs or who do not control their alcohol intake.
- A woman who has an infant with galactosemia, because both human and cow's milk exacerbate the condition. A lactose-free formula is recommended for these infants.
- Women who are infected with the human immunodeficiency virus (HIV) (see Maternal Infections during Breastfeeding, later).
- Women who have active untreated tuberculosis. Because of the increased risk of airborne transmission associated with the close contact that is typical of breastfeeding, women with active tuberculosis should not feed their infant by *any* method until treatment is initiated. However, infected women can provide their pumped milk to their infants (see later).

- Women who are known or suspected to be infected with Ebola or Marburg virus or Lassa fever (see later).
- Women who take certain medications (see Medications while Breastfeeding, later).

Medical situations that indicate a potential risk from breastfeeding must be weighed against the benefits of breastfeeding in each maternal-infant dyad's unique situation.

Role of the Obstetrician in Promoting Breastfeeding

Obstetricians have many responsibilities for breastfeeding, including the following:

- Enthusiastic promotion and support for breastfeeding, based on the published literature of its benefits advocated by the major pediatric, obstetric, and women's health organizations³⁶
- Imparting clinical information to the lactating mother about the physiology of lactogenesis³⁷ and lactation, before and after the birth
- Developing and supporting hospital policies that facilitate breastfeeding and actively remove any barriers to it
- Supporting community efforts to provide women with adequate information to make an informed decision about breastfeeding, including links to community breastfeeding resources
- Fostering a general acceptance of breastfeeding by promoting a normative portrayal of breastfeeding and supporting the provision of sufficient time and facilities in the workplace
- Performing breast examinations before and after the birth, and emphasizing lactation as the primary function of the breast
- Participating in breastfeeding education in medical and other health profession schools³⁸

The mother's plan for infant feeding should be addressed early in prenatal care, with counseling, a medical history focused on breast health and breastfeeding, and a physical examination of the breast. Counseling can be modeled after "The Best Start Three-Step Breastfeeding Counseling Strategy" (available by e-mailing Beststart@mind-spring.com),³⁹ a publication that advises beginning with open-ended questions about breastfeeding. An acknowledgment that feelings of doubt about the ability to breastfeed successfully are normal is a good place to begin. Education about breastfeeding then continues with discussion of how others have dealt with these concerns. This conversation will elucidate much about the woman's knowledge of breastfeeding, her previous experiences with breastfeeding, and her own attitudes and those of the infant's father, the extended family, and other potentially supportive persons in the mother's life.

To support breastfeeding adequately throughout the first 6 months of an infant's life, the concerns of family and friends must be addressed actively to foster support for breastfeeding on many levels. Misconceptions and potential barriers must be identified and reasonable solutions developed in partnership with the woman. These often include feelings of responsibility for every unexplained problem the infant displays; conflicts among a woman's several roles as mother, sexual partner, and worker outside the home; and, most commonly, a greater time commitment and fatigue than was expected. It is important to address these and other questions repeatedly throughout pregnancy and not just in the immediate postpartum period, working closely with the infant's pediatrician.³⁶

Examination of the Breast

The medical history related to the breasts should include their development, previous experience with breastfeeding, systemic illnesses, infections, breast surgery or trauma, medications, allergies, self-breast examinations and findings, and any anatomic or physical concerns the mother has about her breasts.

The breast examination at prenatal and postpartum visits should include careful inspection and palpation. Inspection of the breasts is most effective in the sitting position, first with the arms overhead and then with hands on the hips. Skin changes, distortions in shape or contour, and the form and size of the areola and nipple should be noted. Palpation can begin in the sitting position, looking for axillary and supraclavicular adenopathy. Palpation in the supine position is easier for the complete examination of the breast and surrounding anterolateral chest wall. Size, shape, consistency, masses, scars, tenderness, and any abnormalities can be noted in both descriptive and picture form for future comparison. Serial examinations should document maturational changes of pregnancy (size, shape, fullness, enlargement of areola) and nipple position (inversion or eversion).

The changes in the breast during pregnancy provide important prognostic data regarding successful breastfeeding. With the increased frequency of cosmetic breast surgery, it is important to be aware of the nature of any surgery and to examine carefully for the location of the surgical scars. Many women successfully breastfeed after surgery for benign breast disease, breast augmentation, or breast reduction. However, a periareolar incision or "nipple translocation technique" for breast reduction can damage nerves and ducts, making this more difficult. Nipple piercing is another increasingly common procedure, after which breastfeeding can be successful with the jewelry removed. Such surgeries do not preclude successful breastfeeding but rather remind us that additional early support should be provided to these mothers from physicians, nurses, lactation consultants, and peer support groups.

Perinatal Period

The obstetrician can make important contributions to successful breastfeeding through the conduct of the labor, delivery, and puerperium. A stressful or exhausting labor and delivery has been shown to affect lactation adversely.⁴⁰ A safe delivery for both mother and infant is, of course, the most important outcome. During the delivery and afterward, any medications used should be compatible with breastfeeding and not interfere with the bonding and first feeding. Immediate skin-to-skin contact between mother and infant, and a first feeding within 1 hour of delivery are probably the most important intrapartum steps to increase the likelihood of successful breastfeeding. Having the infant in the mother's room, feeding on demand, and early breastfeeding support (including teaching appropriate techniques) within the first 24 to 36 hours can also help. Supplementation should be avoided unless medically indicated and ordered by the pediatrician.

For the breastfeeding woman, medication choices are very important (see Table 9-6). Most women and many health professionals assume that no medication can be safely administered to a lactating woman, but the number of contraindicated drugs is in fact quite small. Before assuming a medication is unsafe, expert advice should be consulted, available in texts, via a drug information telephone service (see Suggested Readings), or at carefully selected websites.

Early follow-up (2 to 4 days after discharge) with the infant's health provider should be arranged for all breastfeeding mothers. Continued support of breastfeeding for the mother should occur through the 6-week postpartum visit. Discussions about breastfeeding should cover techniques to ensure adequate emptying of the breast, nipple soreness

or trauma, plugged duct (in the form of a small lump), mastitis, breast abscess, breast masses, and bloody nipple discharge, all of which can usually be treated without stopping breastfeeding.

The Breast

To fully understand the process of lactation, one needs to understand the anatomy and physiology of the breast as it applies to this function. The human mammary gland is the only organ that does not contain all the rudimentary tissues at birth. It experiences dramatic changes in size, shape, and function from birth through menarche, pregnancy, and lactation, and ultimately during involution. The three major phases of growth and development before pregnancy and lactation occur in utero, during the first 2 years of life, and at puberty (Fig. 9-1).

Embryonic Development

The milk streak appears in the 4th week of gestation when the embryo is approximately 2.5 mm long. It becomes the milk line, or milk ridge, during the 5th week of gestation (2.5 to 5.5 mm). The mammary gland itself begins to develop at 6 weeks of embryonic life, and proliferation of the milk ducts continues throughout embryonic growth. The process

of forming the nipple in the human embryo begins with a thickened raised area of ectoderm in the region of the future gland by the 4th week of pregnancy. This thickened ectoderm becomes depressed into the underlying mesoderm, and thus the surface of the mammary area soon becomes flat and finally sinks below the level of the surrounding epidermis. The mesoderm that is in contact with the ingrowth of the ectoderm is compressed, and its elements become arranged in concentric layers that at a later stage give rise to the gland's stroma. By dividing and branching, the ingrowing mass of ectodermal cells gives rise to the future lobes and lobules, and much later to the alveoli.

By 16 weeks' gestation in the fetus, the branching stage has produced 15 to 25 epithelial strips that represent the future secretory alveoli. By 28 weeks' gestation, placental sex hormones enter the fetal circulation and induce canalization in the fetal mammary tissue. The lactiferous ducts and their branches are developed from outgrowth in the lumen. They open into a shallow epidermal depression known as the mammary pit. The pit becomes elevated as a result of mesenchymal proliferation, forming the nipple and areola. An inverted nipple is the failure of this pit to elevate.⁴¹ At 32 weeks' gestation, the lumen has formed in the branching system, and by term there are four to 18 mammary ducts that form the fetal mammary gland.⁴² Figure 9-2 shows the hormonal regulation of mammary development in the mouse.

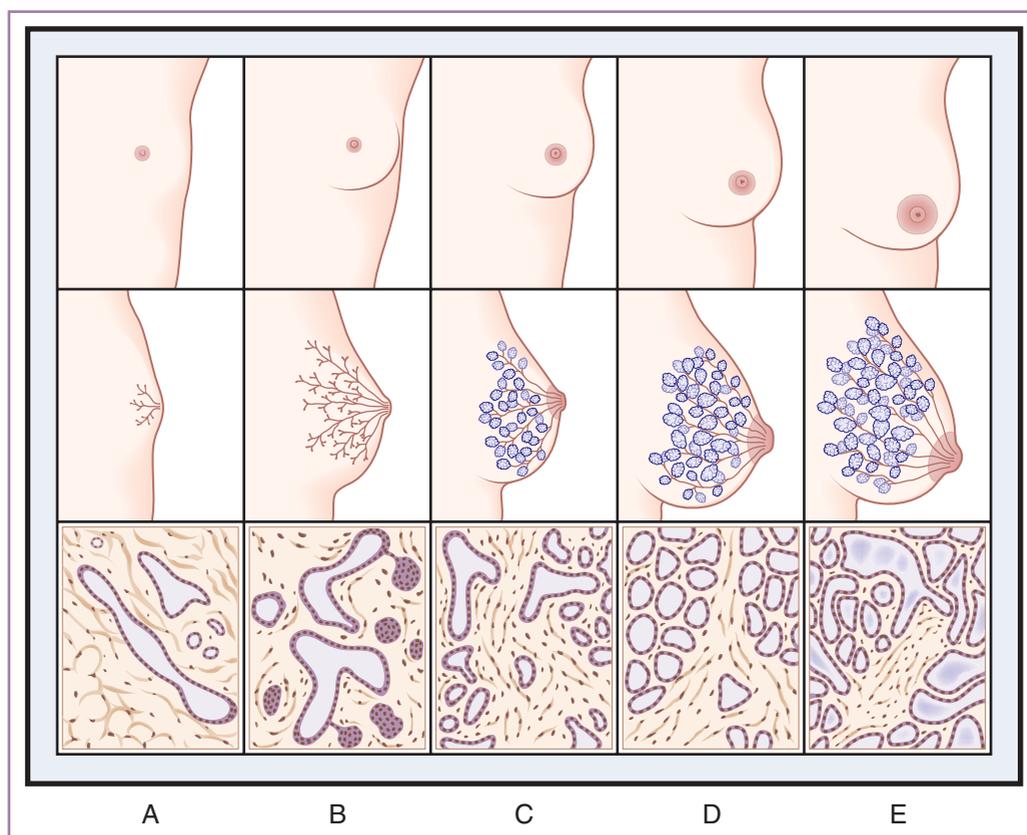

FIGURE 9-1 Female breast from infancy to lactation, with corresponding duct structure and tissue cross sections. **A, B, and C,** Gradual development of the well-differentiated ductular and peripheral lobular-alveolar system. **D,** Ductular sprouting and intensified peripheral lobular-alveolar development in pregnancy. Glandular luminal cells begin actively synthesizing milk fat and proteins near term; only small amounts are released into the lumen. **E,** With postpartum withdrawal of luteal and placental sex steroids and placental lactogen, prolactin is able to induce full secretory activity of alveolar cells and release of milk into alveoli and smaller ducts. (From Neville MC: Mammary gland biology and lactation: A short course. Presented at the annual meeting of the International Society for Research on Human Milk and Lactation. Plymouth, Mass, October 1997.)

The nipple, areola, and breast bud are important landmarks for the determination of gestational age in the newborn. At 40 weeks, the nipple and areola are clearly seen and the breast bud is up to 1.0 cm in diameter. In the first weeks after delivery, the breast bud is visible and palpable; however, the gland then regresses to a quiescent stage as maternal hormones in the infant diminish. After this, the gland grows only in proportion to the rest of the body until puberty.

Pubertal Development

With the onset of puberty in the female, further growth of the breast occurs and the areolae enlarge and become more pigmented. The further development of the breast involves two distinct processes: organogenesis and milk production. The ductal and lobular growth is organogenesis, and this is initiated before and throughout puberty, resulting in the growth of breast parenchyma with its surrounding fat pad. The formation of alveolar buds begins within 1 to 2 years of the onset of menses and continues for several years, producing alveolar lobes. This menarchial stimulus begins with the extension of the ductal tree and the generation of its branching pattern. The existing ducts elongate. The ducts can develop bulbous terminal end buds that are the forerunners of alveoli. The formation of the alveolar bud begins within 1 to 2 years of the onset of menses. During this ductal growth, the alveoli enlarge and the nipple and areola become more pigmented. This growth involves an increase in connective tissue, adipose tissue, and vascular channels and is stimulated by estrogen and progesterone released by the ovary.⁴³

During the menstrual cycle, there continues to be cyclic microscopic proliferation and regression of ductal breast tissue. The breast continues to enlarge slightly with further division of the ductal system until about the age of 28, unless pregnancy intervenes.

The Mature Breast

The mature breast is located in the superficial fascia between the second and sixth intercostal cartilages and is superficial to the pectoralis muscle. It measures 10 to 12 cm in diameter. It is located horizontally from the parasternal to the midaxillary line. The central thickness of the gland is 5 to 7 cm. In the nonpregnant state, the breast weighs about 200 g. During pregnancy, however, the size and weight increase

TABLE 9-1 BREAST ABNORMALITIES

Accessory breast: Any tissue outside the two major glands
Amastia: Congenital absence of breast or nipple
Amazia: Nipple without breast tissue
Hyperadenia: Mammary tissue without nipple
Hypoplasia: Underdevelopment of breast
Polythelia: Supernumerary nipple(s) (also hyperthelia)
Symmastia: Webbing between breasts

From Lawrence RA, Lawrence RM: *Breastfeeding: A Guide for the Medical Profession*, 6th ed. St. Louis, Mosby, 2005, p 45 (Box 2-1).

to about 400 to 600 g and to 600 to 800 g during lactation. A projection of mammary tissue into the axilla is known as the tail of Spence and is connected to the central duct system. The breast is usually dome shaped or conic, becoming more hemispheric in the adult and pendulous in the older parous woman.

Abnormalities

In some women, mammary tissue develops at other sites in the galactic band. This is referred to as hypermastia, which is the presence of accessory mammary glands that are phylogenetic remnants. These remnants may include accessory nipples or accessory gland tissue located anywhere along the milk line. From 2% to 6% of women have hypermastia. These remnants remain quiet until pregnancy, when they may respond to the hormonal milieu by enlarging and even secreting milk during lactation. If left unstimulated, they will regress after the birth. Major glandular tissue in the axilla may pose a cosmetic or management problem if the tissue enlarges significantly during pregnancy and lactation, secreting milk. It is distinct from the tail of Spence.

Other abnormalities include amastia (absence of the breast or nipple), amazia, hyperadenia, hypoplasia, polythelia, and symmastia (Table 9-1). Abnormalities of the kidneys have been associated with polythelia. Other variations include hyperplasia or hypoplasia in various combinations, as listed in Table 9-2. Gigantomastia is the excessive enlargement of the breasts in pregnancy and lactation, sometimes to life-threatening proportions. This enlargement may occur with the first or any pregnancy and may not recur. The enlargement recedes but rarely back to original size.¹ Breastfeeding has been suc-

TABLE 9-2 TYPES OF BREAST HYPOPLASIA, HYPERPLASIA, AND ACQUIRED ABNORMALITIES**Hypoplasia**

Unilateral hypoplasia, contralateral breast normal
 Unilateral hypoplasia, contralateral breast hyperplasia
 Unilateral hypoplasia of breast, thorax, and pectoral muscles (Poland syndrome)
 Bilateral hypoplasia with asymmetry

Hyperplasia

Unilateral hyperplasia, contralateral breast normal
 Bilateral hyperplasia with asymmetry

Acquired Abnormalities

Caused by trauma, burns, radiation treatment for hemangioma or intrathoracic disease, chest tube insertion in infancy, and preadolescent biopsy

cessful in some cases of gigantomastia with appropriate professional support. In extreme cases, gigantomastia may require heroic measures, including emergency mastectomy.

Mothers with congenital abnormalities of the breast may wish to breastfeed. Not all abnormalities or variations preclude breastfeeding, and the decision is made on a case-by-case basis.

Nipple and Areola

The skin of the breast includes the nipple and areola and the thin, flexible, elastic skin that covers the body of the breast. The nipple is a conic elevation in the center of the areola at the level of about the fourth intercostal space, just below the midline of the breast. The nipple contains smooth muscle fibers and is richly innervated with sensory and pain fibers. It has a verrucous surface and has sebaceous and apocrine sweat glands, but not hair.

The areola surrounds the nipple and is also slightly pigmented and becomes deeply pigmented during pregnancy and lactation. The average diameter is 15 to 16 mm, but the range may exceed 5 cm during pregnancy. The sensory innervation is less than that of the nipple. The nipple and areola are very elastic and elongate into a teat when drawn into the mouth by the suckling infant.

The surface of the areola contains Montgomery glands, which hypertrophy during pregnancy and lactation and resemble vesicles. During lactation, they secrete a sebaceous material to lubricate the nipple and areola and protect the tissue while the infant suckles. These glands atrophy after weaning and are not visible to the naked eye except during pregnancy or lactation.

Each nipple contains four to 18 lactiferous ducts, of which five to eight are main ducts surrounded by fibromuscular tissue.⁴⁴ These ducts end as small orifices at the tip of the nipple from which the milk flows. The corpus mammae is an orderly conglomeration of a number of independent glands known as lobes. The morphology of the gland includes parenchyma that contains the ductular-lobular-alveolar structures. It also includes the stroma, which is composed of connective tissue, fat tissue, blood vessels, nerves, and lymphatics.

The mass of breast tissue consists of tubuloalveolar glands embedded in adipose tissue, which gives the gland its smooth, rounded contour. The mammary fat pad is essential for the proliferation and

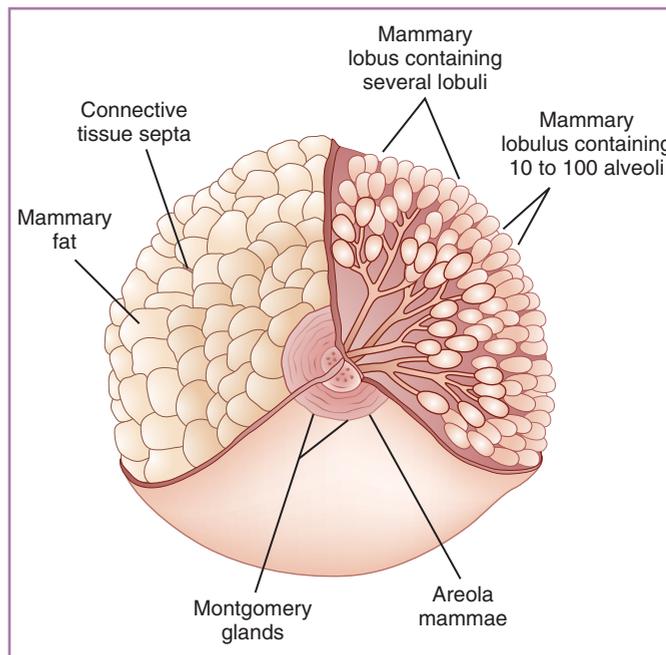

FIGURE 9-3 Morphology of mature breast. Diagrammatic dissection reveals mammary fat and duct system. (Modified from Lawrence RA, Lawrence RM: *Breastfeeding: A Guide for the Medical Profession*, 6th ed. St. Louis, Mosby, 2005, p 48 [Fig. 2-7].)

differentiation of the ductal arborization (Fig. 9-3). Each lobe is separated from the others by connective tissue, and opens into a duct that opens into the nipple. The extension of ducts is orderly and protected by an inhibitory zone into which other ducts cannot penetrate.⁴⁵

Blood is supplied to the breast from branches of the intercostal arteries and perforating branches of the internal thoracic artery. The main blood supply comes from the internal mammary artery and the lateral thoracic artery. The venous supply parallels the arterial supply.

Lymphatic drainage has been thoroughly studied by researchers of breast cancer. The main drainage is to axillary nodes and the parasternal nodes along the thoracic artery within the thorax. The lymphatics of the breast originate in lymph capillaries of the mammary connective tissue and drain through the deep substance of the breast.

The breast is innervated from the branches of the fourth, fifth, and sixth intercostal nerves. The sensory innervation of the nipple and areola is extensive and includes both autonomic and sensory nerves. The innervation of the corpus mammae is meager by comparison and is predominantly autonomic. Neither parasympathetic nor cholinergic fibers supply any part of the breast. The efferent nerves are sympathetic adrenergic. Most of the mammary nerves follow the arteries. A few fibers course along the walls of the ducts. They may be sensory fibers that sense milk pressure. No innervation has been identified to supply the myoepithelial cells. Thus, the conclusion is that secretory activities of the acinar epithelium of the ducts depend on hormonal stimulation, such as oxytocin.

When sensory fibers are stimulated, the release of adenohipophyseal prolactin and neurohipophyseal oxytocin occurs. The areola is most sensitive to the stimulus of suckling, the nipple the least, and the skin of the breast is intermediate. The large number of dermal nerve endings results in high responsiveness to suckling. Pain fibers are more numerous in the nipple, with few in the areola. All cutaneous nerves run radially toward the nipple. Breast nerves can influence the mammary blood supply and therefore also influence the transport of

oxytocin and prolactin to the myoepithelial cells and the lacteal cells, respectively.

Mammary Gland in Pregnancy

During the first trimester, rapid growth and branching from the terminal duct system into the adipose tissue is stimulated by the changing levels of circulating hormones. As epithelial structures proliferate, adipose tissue decreases. There is increased infiltration of the interstitial tissue with lymphatics, plasma cells, and eosinophils. By the third trimester, parenchymal cell growth slows and alveoli become distended with early colostrum. Alveolar proliferation is extensive.

The lactating mammary gland has a large number of alveoli that are made up of cuboidal, epithelial, and myoepithelial cells. Little connective tissue separates the alveoli. Lipid droplets are visible in the cells. By complex interplay of the nervous system and endocrine factors (progesterone, estrogen, thyroid, insulin, and growth factors), the mammary gland begins to function (lactogenesis stage I) and other hormones establish the milk secretion and maintain it (lactogenesis stage II).

Human prolactin has a significant role in both pregnancy and lactation. The levels are high during pregnancy, but the influence of prolactin on the breast itself is inhibited by a hormone produced by the placenta, originally referred to as prolactin-inhibiting hormone but believed to be progesterone.

Physiology of Lactation

Lactogenesis

Lactation is the physiologic completion of the reproductive cycle. The human infant is the most immature and dependent of all mammals except for marsupials, and thus the breast provides the most physio-

logically appropriate nutrients required by the human infant at birth. Throughout pregnancy, the breast develops and prepares to take over the role of fully nourishing the infant when the placenta is expelled. The breast is prepared for full lactation after 16 weeks' gestation. The physiologic adaptation of the mammary gland to its role in infant survival is a complex process, only the outline of which is discussed here. There are a number of complete reviews of the newer scientific studies on the physiology of lactation.^{37,42,44,46} Hormonal control of lactation can be described in relationship to the five major changes in the development of the mammary gland: embryogenesis, mammogenesis or mammary growth, lactogenesis or initiation of milk secretion, lactation or full milk secretion, and involution (Table 9-3). Detailed explanation of mammary growth is beyond the scope of this discussion. The two most important hormones involved in lactation itself are prolactin and oxytocin, and these are described with respect to their impact on lactogenesis.

Lactogenesis is the initiation of milk secretion, beginning with the changes in the mammary epithelium in early pregnancy and progressing to full lactation. Stage I lactogenesis occurs during pregnancy and is achieved when the gland is sufficiently differentiated to secrete milk. It is prevented from doing so by high circulating plasma concentrations of progesterone.⁴⁷ Stage II is the onset of copious milk secretion associated with delivery of infant and the placenta. The progesterone level decreases sharply, by 10-fold in the first 4 days.⁴⁵ This is accompanied by the programmed transformation of the mammary epithelium.⁴⁸ By day 5, the infant has 500 to 750 mL of milk available (Fig. 9-4). The changes in milk composition that occur in the first 10 postpartum days should be viewed as part of a continuum in which the rapid changes of the first 4 days are followed by slower changes in various components of milk throughout lactation.⁴⁵ A change in permeability of the paracellular pathways results in a shift from high concentrations of sodium, chloride, and the protective immunoglobulins and lactoferrin, little lactose, and no casein in colostrum to increasing amounts of all milk components.⁴⁹

TABLE 9-3 STAGES OF MAMMARY DEVELOPMENT

Developmental Stage	Hormonal Regulation	Local Factors	Description
Embryogenesis	?	Fat pad necessary for ductal extension	Epithelial bud develops in 18- to 19-week-old fetus, extending short distance into mammary fat pad with blind ducts that become canalized; some milk secretion may be present at birth
Mammogenesis			Anatomic development
Puberty			
Before onset of menses	Estrogen, GH	IGF-1, hGF, TGF- β ; others?	Ductal extension into mammary fat pad; branching morphogenesis
After onset of menses	Estrogen, progesterone; PRL?		Lobular development with formation of terminal duct lobular unit
Pregnancy	Progesterone, PRL, hPL	HER; others?	Alveolus formation; partial cellular differentiation
Lactogenesis	Progesterone withdrawal, PRL, glucocorticoid	Not known	Onset of milk secretion Stage I: midpregnancy Stage II: parturition
Lactation	PRL, oxytocin	FIL	Ongoing milk secretion
Involution	PRL withdrawal	Milk stasis; FIL?	Alveolar epithelium undergoes apoptosis and remodeling; gland reverts to pre-pregnant state

FIL, feedback inhibition of lactation; GH, growth hormone; HER, heregulin; hGF, human growth factor; hPL, human placental lactogen; IGF-1, insulin-like growth factor 1; PRL, prolactin; TGF- β , transforming growth factor-beta.

Modified from Neville MC: Mammary gland biology and lactation: A short course. Presented at the biannual meeting of the International Society for Research on Human Milk and Lactation, Plymouth, Mass, October 1997.

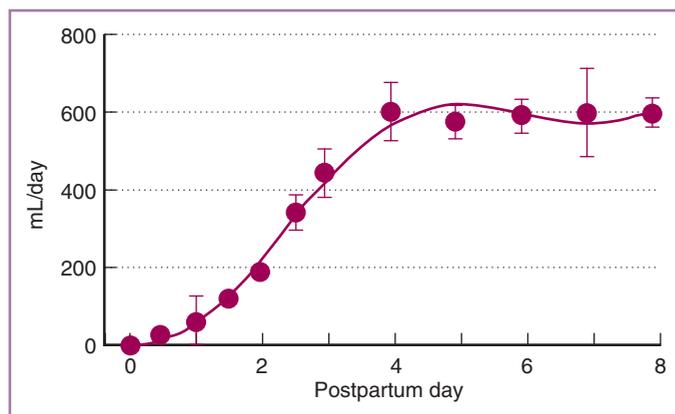

FIGURE 9-4 Milk volumes during 1st postpartum week. Mean values from 12 multiparous white women who test-weighed their infants before and after every feeding for the first 7 postpartum days. (Redrawn from Neville MC, Keller RP, Seacat J, et al: Studies in human lactation: Milk volumes in lactating women during the onset of lactation and full lactation. *Am J Clin Nutr* 48:1375-1386, 1988.)

Lactogenesis stage II results in an increase of milk from 100 mL in the first 24 hours to large volumes (500 to 750 mL/day) by day 4 or 5, gradually leveling off at 600 to 700 mL/day by day 8.⁵⁰ These volume changes are associated with a decrease in sodium and chloride concentration and an increase in lactose concentration. The production of lactose drives the production of milk. The early changes in sodium and chloride are a function of the closure of the tight junctions that block the paracellular pathway.^{51,52} Secretory IgA and lactoferrin represent 10% by weight of the milk produced in the first 48 hours, and although their amounts remain the same, the increased volume of milk produced decreases their concentration. At 8 days, secretory IgA and lactoferrin are 1% by weight and 2 to 3 g/day.⁵³

At 36 postpartum hours (in multiparas) and at up to 72 hours (in primiparas), milk production increases 10-fold (from 50 to 500 mL/day). Women refer to this as their milk “coming in”. It reflects a massive increase in synthesis and secretion of the components of mature milk, including lactose, protein, and lipid.⁵⁴

During pregnancy, hormones maintain the pregnancy and produce mammary tissue that is prepared to produce milk but does not do so. Progesterone, prolactin, and possibly placental lactogen are credited with the development of the alveoli. Progesterone has been identified as the major inhibitor of milk production during pregnancy.⁵⁵ Prolactin levels in pregnancy are greater than 200 ng/mL. Apparently, the continued high level of prolactin and a decrease in progesterone are necessary for stage II lactogenesis after parturition.⁵⁵ The placenta is the main source of progesterone in pregnancy. After the birth progesterone receptors are lost in the human breast and estrogen levels drop precipitously.

In addition to prolactin, insulin and corticoids are essential to milk synthesis.⁵⁶ Delayed lactogenesis is seen in women who had retained placenta, cesarean section, diabetes, and stress during delivery.^{50,56-58} In the 1940s, Jackson⁵⁹ first noted that stressful labors influenced the early breastfeeding experience in the rooming-in unit. Stress may be the trigger for delayed lactogenesis in the conditions other than retained placenta. The significance of having a high sodium concentration in breast milk requires further study.⁴⁹ It has been observed that high sodium levels in early milk samples are seen in pregnancy, mastitis, involution (weaning), premature birth, and inhibition of prolactin secretion by bromocriptine. These observations suggest that junctional

closure depends on adequate suckling or effective milk removal in the first 3 postpartum days.

If milk removal does not begin by 72 hours, the changes in milk composition associated with lactogenesis are reversed and the probability that lactation will be successful decreases. Thus, clinical efforts that facilitate early suckling by the newborn enhance the probability of lactation success. Early stimulation of the breast by pumping before 72 postpartum hours is essential when the infant is unable to nurse directly.

Let-Down (Ejection) Reflex

An effective let-down reflex is key to successful lactation. This reflex, also known as the ejection reflex, was first described in humans by Peterson and Ludwick in 1942,⁶⁰ and was later demonstrated clinically by Newton and Newton²³ to be caused by the release of oxytocin by the pituitary. Since that time, many refinements in the understanding of the process have been published, but the fundamental principles are unchanged (Fig. 9-5).

A mother may produce milk, but if it is not excreted, further production is eventually suppressed. The reflex is a complex function that depends on hormones, nerves, and glandular response and can be inhibited most easily by psychological influences.

Oxytocin is the hormone responsible for stimulating the myoepithelial cells to contract and eject the milk from the ductal system. The ducts begin at the alveoli, which are surrounded by a basket-like structure of myoepithelial cells that also surround the ducts all the way to the nipple. When the infant stimulates the breast by suckling, impulses sent to the central nervous system and to the posterior pituitary result in the release of oxytocin, which is then carried by the bloodstream to the myoepithelial cells. This is a neuroendocrine reflex. Oxytocin release can also be stimulated by other pathways of sight, sound, and smell that represent the infant. Oxytocin also stimulates the myoepithelial cells in the uterus, which are very sensitive to oxytocin during parturition and for a week or so after the birth. This causes the uterus to contract, decreases blood loss, and hastens postpartum involution. The uterus of a mother who breastfeeds returns to a pre-pregnant state more rapidly. The uterine cramping experienced while breastfeeding is a result of this stimulus (see Fig. 9-5).

Newton and Newton²³ demonstrated that pain and stress interfered with the let-down reflex because it interfered with oxytocin release. In their experimental model, they stimulated stress with pain, loud noises, or pressure to solve mathematical problems. In other species, oxytocin release has been shown to stimulate mothering behaviors.⁶¹ Levels of adrenocorticotropin and plasma cortisol are decreased in lactating women compared with nonlactating women in response to stress.

Prolactin is central to the production of milk and regulates the rate of synthesis. Its release depends on the suckling of the infant or the stimulation of the nipple by mechanical pumping or manual expression. Prolactin is also released through a neuroendocrine reflex. Its influence is modified, however, by the actual release of milk from the alveoli. Local factors in the ductal system or in the accumulated milk can inhibit milk release and thus inhibit further milk production. Prolactin is not released as a result of sound, sight, or smell of the infant, as is the case with oxytocin, but only by suckling (Fig. 9-6).

Initiation of Lactation

Although breastfeeding is a natural process in postpartum women, it is a learned skill, not a reflex. Because the incidence of breastfeeding in developed countries dropped to about 10% in the 1950s and 1960s,

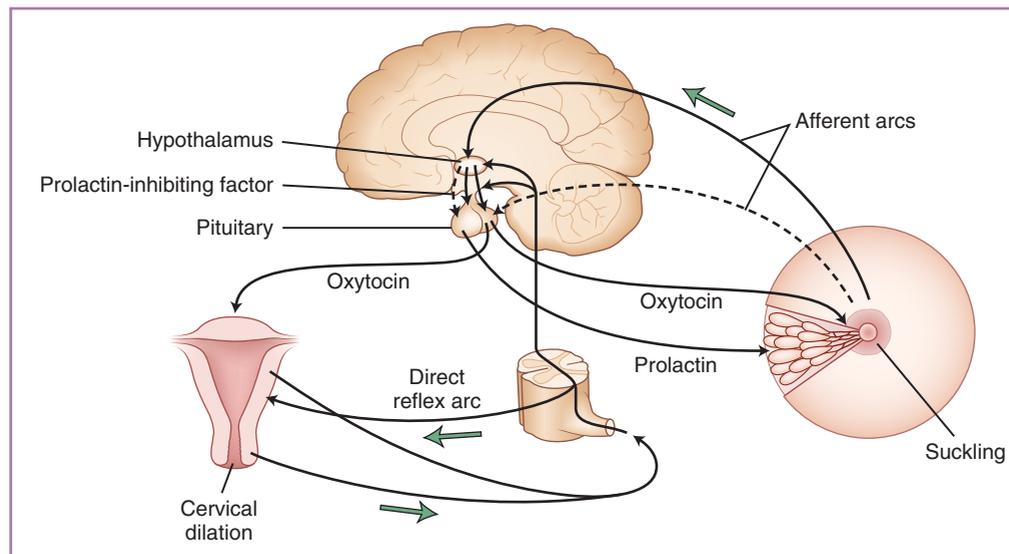

FIGURE 9-5 Neuroendocrine control of milk ejection. (Modified from Vorherr H: *The Breast: Morphology, Physiology and Lactation*. New York, Academic Press, 1974.)

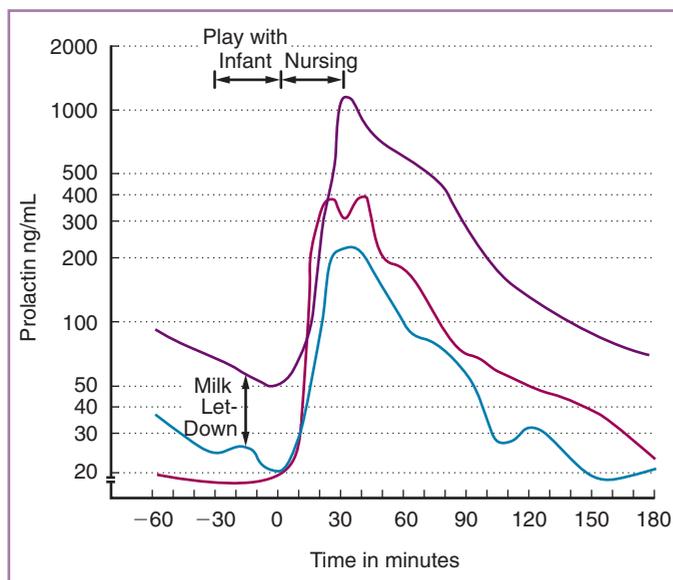

FIGURE 9-6 Plasma prolactin stimulation. Plasma prolactin levels were measured by radioimmunoassay before, during, and after a period of nursing in three mothers between 22 and 26 days after the birth. The levels rose with suckling but not with infant contact only. (Modified from Josimovich JB, Reynolds M, Cobo E: *Lactogenic hormones, fetal nutrition, and lactation*. In Josimovich JB, Reynolds M, Cobo E [eds]: *Problems of Human Reproduction*, vol 2. New York, John Wiley & Sons, 1974, p 1.)

there are few experienced role models available to support, encourage, and assist new mothers in feeding their infants at the breast. In the late 1940s, Edith Jackson at Yale, in cooperation with Herbert Thoms, established the first rooming-in unit in the United States, introduced “child birth without fear,” and reestablished breastfeeding as the norm for mothers and infants at the Yale–New Haven Hospital.⁶² Obstetric and pediatric residents were well schooled in the practical aspects of breastfeeding and human lactation. Jackson and her pediatric

colleagues published the classic article on the management of breastfeeding,⁶³ on which decades of publications, both lay and professional, were based.

The obstetrician and pediatrician have become more involved in the decision to breastfeed and in the practical management of the mother-infant dyad. Medical schools are gradually adding breastfeeding and lactation to their curriculum. Although it is not the physician’s role to put the infant to the breast, it is important to understand the process, to recognize problems, and to know how to solve them. Breastfeeding support is a team effort in which the physician works with many health care professionals, including nurses, midwives, doulas, and dietitians, to provide complete care to the perinatal patient. Lactation specialists may be nurses, dietitians, or nonmedical individuals with special training, or physicians with specialty designation. The physician should be sure that consultants are licensed and board certified by the International Board of Lactation Consultant Examiners, and that other physicians are recognized as fellows of the Academy of Breastfeeding Medicine.

Except in extreme cases, breast size does not influence milk production. Augmentation mammoplasty does not interfere with lactation unless a periareolar incision was made and nerves were interrupted. If augmentation was done for cosmetic enhancement, the tissue should function well, but if there was little or no palpable breast tissue before surgery, lactation may be improbable.

Reduction mammoplasty is more invasive surgery, and results depend on the technique used. If many ducts were severed and the nipple and areolar transplanted, lactation is interfered with. If, however, the nipple and areolar remained intact on a pedicle of ducts, lactation could be successful. Other incisions (e.g., for lump removal) should be discussed but usually do not interfere with lactation.

During pregnancy, the obstetrician should document the changes in the breasts in response to pregnancy, when the nipple and areola should become more pigmented and enlarged and the breast should enlarge several cup sizes. Lack of breast changes should also be communicated to the pediatrician, as it represents a risk for early failure to thrive because of insufficient milk supply. A breast examination should be conducted late in the pregnancy to check for any new find-

ings of masses, lumps, discharge, or pain. Berens⁶⁴ described the role of the obstetrician throughout pregnancy in detail.

Initiating Breastfeeding

The ideal time to initiate breastfeeding is immediately after birth (the Baby Friendly Initiative recommends within a half hour of birth). When left on the mother's abdomen to explore, the unmedicated newborn will move toward the breast, latch on, and begin suckling. This usually takes 20 to 30 minutes if unassisted.⁶⁵ The infant is ready to feed and has been sucking in utero since about 14 weeks' gestation, consuming amniotic fluid daily (about 1 g protein/kg of fetal weight is received daily from amniotic fluid). The infant at 28 weeks' gestation already has a rooting, sucking, and coordinated swallow while breastfeeding. The ability to coordinate suck and swallow while bottle feeding does not occur until 34 weeks.

Shortly after delivery, the mother should be offered the opportunity to breastfeed and should be assisted to assume a comfortable position, usually lying on her side. The infant can be placed beside her, tummy to tummy facing the breast. The mother should support her breast with her hand, keeping her fingers behind the areola so the infant can latch on. The mother should stroke the center of the lower lip with the breast. The infant should open the mouth wide, extend the tongue, and draw the nipple and areola into the mouth to form a teat. This teat is compressed against the palate by the tongue, and the gums and lips form a seal with the breast. It is the peristaltic motion of the tongue that stimulates the let-down reflex. The continued peristaltic motion travels to the posterior tongue, the pharynx, and down the esophagus as one coordinated motion so that swallowing is automatically coordinated with suckling during breastfeeding.

Ultrasound imaging of milk ejection in the breast of lactating women has provided a more detailed description of the process compared with the traditional serial sampling of plasma oxytocin levels and measurements of intraductal pressure. A significant increase in milk-duct diameter can be observed during milk ejection. Multiple milk ejections occur during the process and are correlated with milk flow and with the changes in milk-duct diameter, although they are not sensed by the mother.⁶⁶ The number of milk ejections influences the amount of milk available to the infant.

Sucking an artificial nipple is a very different tongue motion that is not coordinated with swallow. A newborn should not be given a bottle to test feeding ability before breastfeeding. It is wise to avoid all artificial nipples (bottles or pacifiers) in the early weeks of breastfeeding. If, for a medical necessity, the infant requires artificial formula, it can be given by medicine cup (cup feeding).^{67,68}

The initial contact may be limited to exploration of the breast by the infant, with licking and nuzzling of the nipple, or the infant may latch on and suck for minutes. Timing is not necessary because the infant will interrupt him- or herself. The first hour after birth, the term unmedicated infant will be quietly alert. It is an opportunity for the mother, father, and infant to get acquainted.

Ideally, mother and infant recover in the same room together. The infant is fed on awakening, and the mother learns the early signs of hunger. Crying is a very late sign. She also learns about caring for her infant. There should be no schedules and no intervention unless an infant does not feed for over 6 hours. The nursing staff and lactation consultants ensure that the infant latches on well and the mother's questions are answered. Breastfeeding should not hurt; when it does, the process should be observed and adjusted. The pediatrician should observe a feeding as part of the infant's discharge examination. The

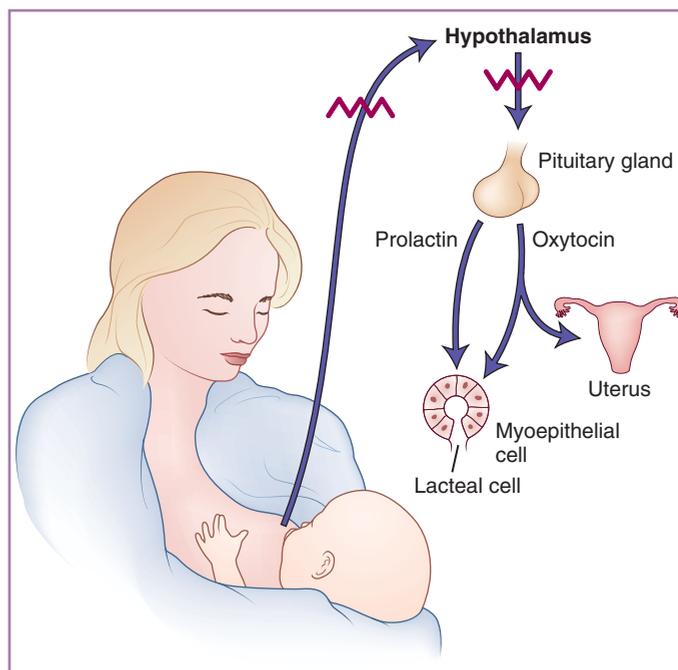

FIGURE 9-7 Diagram of ejection reflex arc. When the infant suckles the breast, mechanoreceptors in the nipple and areola are stimulated, which sends a stimulus along nerve pathways to the hypothalamus, which stimulates the posterior pituitary gland to release oxytocin. Oxytocin is carried via the bloodstream to the breast and uterus. Oxytocin stimulates myoepithelial cells in the breast to contract and eject milk from the alveolus. Prolactin is responsible for milk production in the lacteal cells lining the alveolus. Prolactin is secreted by the anterior pituitary gland in response to suckling. Stress (e.g., pain, anxiety) can inhibit the let-down reflex. Seeing or hearing the cry of the infant can stimulate the release of oxytocin but not prolactin. (From Lawrence RA, Lawrence RM: *Breastfeeding: A Guide for the Medical Profession*, 6th ed. St. Louis, Mosby, 2005, p 290 [Fig. 8-18].)

mother should be aware of the milk letting down by tingling in the breast or dripping from the opposite breast. The infant should be noted to swallow (Fig. 9-7).

The infant's weight is measured daily and again just before discharge. A weight loss of greater than 5% in the first 48 hours should be assessed by checking the feeding process and reviewing voidings and stoolings. Maximum weight loss should not exceed 7% in a breastfed infant by 72 hours. The weight should plateau after 72 hours. Birth weight should be regained by 7 days or, at the latest, 10 days. A healthy infant voids at least once and stools at least once in the first 24 hours, at least twice in the second 24 hours, and at least three times in the third 24 hours. From then on voidings should occur at least six times daily. An infant should stool at least once (and preferably three times) every day in the first month of life. After 3 to 4 months of age, a perfectly healthy breastfed infant may go a week without stooling and then pass a soft yellow stool, but this should not occur under 1 month of age.

Early discharge from the hospital has increased the need for newborn care visits within a few days after discharge and as required thereafter at 2- to 4-week intervals for assessment of weight and hydration. The AAP recommends a visit at 3 to 5 days of age for infants discharged at 48 hours or less.³⁸

Issues in the Postpartum Period

Breast Engorgement and Nipple Tenderness

A little engorgement of the breast in the first 24 hours is physiologically normal as the vascular supply shifts from the once-gravid uterus to the breasts. Absence of any engorgement, such as absence of breast growth during pregnancy, is cause for concern. Not only is excess engorgement painful but the increased vascular pressure compresses the alveoli and ducts and interferes with milk production and release.⁶⁹ Prevention of excessive engorgement is the best treatment and involves the following: (1) wearing a well-fitting nursing brassiere even before the breasts are engorged, and around the clock, (2) frequent feedings for the infant, being sure to balance the use of both breasts, (3) gentle massage and softening of the areola before offering the breast to the infant, so that proper latch-on can be accomplished, (4) if necessary, applying cold packs or cold compresses after a feeding, and (5) taking acetaminophen or ibuprofen, which may be safely used by the mother for discomfort.

Peak engorgement usually occurs between 72 and 96 postpartum hours when the mother has arrived home and is on her own. At the peak of discomfort, standing in a warm shower to let milk drip or applying warm compresses before pumping to relieve the pressure and stimulate flow provides relief before the phenomenon subsides.

Sore nipples are a common complaint when early lactation has gone unassisted. It should not hurt to breastfeed. When it does hurt, the infant should be taken off the breast by breaking the suction with a finger and reattaching the infant carefully, following the steps previously described. The major cause of sore nipples is inadequate latch-on. It is not caused by breastfeeding too long or too frequently. A newborn usually feeds about every 2 hours in the first few weeks of life. Persistent sore nipples, cracks, or oozing may require the assistance of a licensed certified lactation consultant who can take the time and has the experience to work with the mother to identify the cause, determine effective treatment, and assist the dyad in maintaining pain-free breastfeeding.

Faltering Milk Supply

Many misconceptions lead to the impression that a failing milk supply is a common occurrence. Many women discontinue breastfeeding before 3 postpartum months, believing their milk is diminishing because their breasts are no longer engorged. Once supply and demand have been equilibrated and the breast makes what the infant needs, the breasts are soft and do not constantly drip. The emptying time of the stomach of the infant fed human milk is 90 minutes, fed formula it is 3 to 4 hours, and fed cow's milk it is 6 hours. Continuing to feed every 3 hours is a testimony to its digestibility, not its inadequacy. Weight gain in the infant is the better barometer of success. The ACOG supports the AAP statement that exclusive breastfeeding should continue for 6 months, with continued breastfeeding while adding weaning foods for the next 6 months, and then as long thereafter as mutually desired by mother and child.^{38,70,71}

Genuine failure to produce enough milk may result from infant causes, such as increased need, increased fluid losses, or lack of adequate suckling, or to maternal causes, such as failure to let down or failure of production. Each case should be carefully reviewed because

most situations are remediable. Ideally, the pediatrician is experienced in lactation management or has a staff member who is. Working together with a licensed certified lactation specialist, the issues can be resolved and breastfeeding can continue successfully.

Breastfeeding after Premature or Multiple Births

Human milk is beneficial in the management of the premature infant according to the Policy Statement of the AAP.³⁸ The benefits include infection protection; improvement in gastrointestinal function, digestion, and absorption of nutrients; and neurodevelopmental outcomes. The psychological well-being of the mother is enhanced when she provides her milk for her compromised infant.⁷² Meeting the intrauterine rates of growth and nutrient accretion requires attention. Although human milk satisfies these needs for larger premature infants, it can be carefully supplemented for smaller infants and still preserve the benefits of human milk. Recently, a product created with 100% human milk has been developed to enhance mother's milk and replace supplementation made with cow's milk.⁷³

Twins and triplets present problems of time management for the mother.⁷⁴ The mother will make enough milk, as supply will meet demand. Twins learn quickly to nurse simultaneously and will continue to do so for months or years. Breastfeeding ensures a mother's interaction with her infants. Helpful friends and relatives can perform the other household duties. The mother can also provide enough milk for triplets. Some mothers prefer to nurse two at a feeding, giving the third a bottle but rotating the three, feeding by feeding. Any breast milk is valuable in this situation. Mothers of multiples need help. It may be necessary for the physician to prescribe help and careful attention to proper rest. Mothers have also breastfed quadruplets and higher. Usually, they nurse several at each feeding and rotate bottle feeding. Exclusive breastfeeding of quadruplets for the first year has been reported by Berlin.⁷⁵

Contraception

Lactation suppresses ovulation and thus helps prevent pregnancy for the first several months after delivery but should not be relied on as a sole method of contraception. Many couples resume coitus before the first postpartum visit and should be educated about the effects of breastfeeding on sexual function and fertility. Interest in sex may be reduced, not only by the endocrine environment of lactation but also by maternal fatigue, reduced vaginal lubrication during lactation, and the altered roles of wife and mother. Contraceptive choices are consequently affected by lactation.

Nonhormonal choices are preferred until ovulation resumes. ACOG recommends prelubricated condoms or other lubricated barrier methods such as a diaphragm. Intrauterine devices are appropriate once uterine involution has occurred. Supplemental lubrication may be required.

Use of hormonal contraceptives in breastfeeding women raises questions about maternal-fetal transfer of hormones, but the principal concerns relate to the effect on milk production and risk to the mother. Progestin-only contraceptives, such as the mini-pill tablet, injectable medroxyprogesterone acetate (Depo-Provera, Pharmacia), and levonorgestrel implants, are the hormonal methods of choice when nonhormonal methods are not acceptable. Unlike combined estrogen-progestin pills, the progestin-only methods have no effect on the quantity or quality of milk. The package inserts for progestin-only

methods recommend initiation of use at 6 postpartum weeks for women who are breastfeeding exclusively, and at 3 weeks for those who supplement breast milk with formula. The injectable medroxyprogesterone acetate is recommended only at 6 weeks after delivery. The reasons for the delayed use of the progestin-only methods are primarily theoretical, related to concerns about an immediate effect on the onset of milk production if used within 3 days of birth and on the uncertain ability of the newborn to metabolize progesterone. However, concern about the impact of early initiation of progestin-only pills has been ameliorated by a recent report that found no adverse effects on continuation rates in exclusive breastfeeding or when supplements are used.⁷⁶ Medroxyprogesterone injections before 6 weeks have been observed to affect milk supply, but there are no controlled studies.¹

Combined estrogen-progestin contraceptive tablets are not ideal during lactation because they reduce both the quantity and the quality of milk and may increase the risk of maternal thromboembolism in the already hypercoagulable postpartum period. If used at all, they should not be started until at least 6 postpartum weeks and after lactation is well established.

A thorough summary and suggested protocol, *Contraception during Lactation*, is available from the Academy of Breastfeeding Medicine.⁷⁷

Maternal Infections during Breastfeeding

Although often a mother is concerned about the risk to a breastfeeding infant when she has an infectious illness, maternal infection is not a contraindication to breastfeeding in most cases (Table 9-4). Proscribing breastfeeding out of fear of infection deprives infants of significant immunologic, nutritional, and emotional benefits of breastfeeding when they are most needed.¹

The decision-making process to breastfeed despite maternal infection should involve discussion of the usual route of infection transmission, reasonable infection control precautions, potential severity of infection in the infant or child, medications to treat the mother that are compatible with breastfeeding, the potential of prophylaxis for the infant, the protective effect of breast milk, and the acceptability of using expressed breast milk temporarily. The discussion should involve the mother (or both parents), weighing the known and potential risks of the infection against the known benefits of breastfeeding.¹

For example, diphtheria and active pulmonary tuberculosis in the mother are commonly transmitted via the respiratory route, so contact between infant and mother should be proscribed regardless of how the infant is being fed. In the case of cutaneous diphtheria or tuberculosis mastitis, as long as there are no lesions on the breast, expressed breast milk can be given to the infant during the initial treatment of the mother (probable infectious periods are 5 days for diphtheria, and 14 days or until the sputum is negative for acid-fast tuberculous bacilli). Diphtheria and tuberculosis are not transmitted in the milk. Prophylactic antibiotics for the infant are appropriate in each case—penicillin or erythromycin for diphtheria and isoniazid for tuberculosis.^{1,78,79}

In certain highly infectious and serious infections, such as the hemorrhagic fevers—specifically with Ebola or Marburg virus and Lassa fever—the risk of transmission from any contact with the infected mother is high, and the potential severity of the illness in mother or infant necessitates separation of the infant (breastfed or formula-fed) from the mother and proscription of breastfeeding as well as feeding expressed breast milk. For dengue virus or Hantavirus, standard pre-

cautions are appropriate, along with the temporary use of expressed breast milk and subsequent breastfeeding in the recovering mother.¹

Possible West Nile virus (WNV) transmission to an infant through breastfeeding has been reported,⁸⁰ but the data on this infection in pregnant or breastfeeding women and their infants are limited. Hinckley and coworkers reported 10 instances of maternal or infant WNV-related illness while breastfeeding. In five cases, the transmission of WNV through breast milk could not be confirmed or ruled out, and in the other five cases, there was no evidence of vertical transmission. They concluded that the information they presented does not support a change in breastfeeding practices after infection with WNV, and that more information is needed.⁸¹

The hepatitis C virus (HCV) is a blood-borne infection. The rate of mother-to-infant transmission is about 6%. Several cohort studies suggest that most infants acquire HCV infection in utero or the peripartum period. HCV has been detected in colostrum and breast milk at low levels. Bholra and McGuire, in their analysis of three large cohort studies involving a total of 1854 mother-infant pairs, concluded that although the studies showed slightly higher percentages of HCV infection among the breastfed children, the proportions were not statistically significant.⁸² Guidelines from the Centers for Disease Control and Prevention and from the AAP state that maternal HCV infection is not a contraindication to breastfeeding. HCV and HIV coinfection in the mother is a contraindication to breastfeeding in high-income countries. Because HCV is a blood-borne virus, some authorities recommend avoiding breastfeeding, at least temporarily, if a HCV-infected mother experiences nipples that are cracked or bleeding.

In the case of infections at specific sites, the management varies with the specific etiologic organism. For example, mastitis caused by *Staphylococcus* or group A *Streptococcus* requires contact precautions—delaying breastfeeding for 24 hours after beginning therapy in the mother and discarding the expressed breast milk for the first 24 hours. For endometritis caused by group B *Streptococcus*, standard precautions, breastfeeding after the initial 24 hours of therapy in the mother, and the use of expressed breast milk in the interim are appropriate. An example of the probable protective effect of breastfeeding is botulism.⁸³⁻⁸⁵ *Candida* mastitis is a situation in which breastfeeding should continue while the mother and infant are treated simultaneously for at least 2 weeks to prevent reinfection of the breast from contact with the infant's oral candidiasis.

In mothers with hepatitis, identification of the etiologic agent is required before the appropriate management can be determined. Before the etiologic agent is identified, care must include precautions for all potential organisms. Suspension of breastfeeding (pumping and discarding breast milk) until the etiology is determined may be required. Consultation with an infectious disease specialist is often appropriate. For hepatitis A virus, infection in the newborn or young infant is uncommon and not associated with severe illness. Breastfeeding can continue, and if the diagnosis is made within 2 to 3 weeks of the infant's initial exposure to the infected mother, then immune serum globulin and hepatitis A virus vaccine simultaneously can decrease infection in the infant. With hepatitis B virus, the risk of chronic hepatitis B virus infection and its serious complications is high (up to 90%) when infection occurs perinatally or in early infancy. The hepatitis B immune globulin and the hepatitis B virus vaccine given simultaneously prevents hepatitis B virus transmission in over 95% of cases, regardless of whether the infant is fed by breast or bottle. Therefore, it is very appropriate to continue breastfeeding as soon as effective immune therapy is given.⁷⁹

No clear data indicate hepatitis C virus transmission via breast milk in HIV-negative mothers (L. S. Barden, personal communication,

TABLE 9-4 BREASTFEEDING RECOMMENDATIONS FOR SELECTED MATERNAL INFECTIONS

Organism, Syndrome, or Condition*	Breastfeeding Acceptable [†]	Medications Compatible with Breastfeeding, Except as Noted [‡]
Candidiasis <i>Candida albicans</i> , <i>Candida krusei</i> : Mucocutaneous infection, vulvovaginitis <i>Candida tropicalis</i> invasive infections	Yes (simultaneous therapy for infant and mother) [§]	Topical agents, fluconazole, ketoconazole, itraconazole, amphotericin B, flucytosine
Chlamydia <i>Chlamydia trachomatis</i> : Urethritis, vaginitis, endometritis, salpingitis, lymphogranuloma venereum, conjunctivitis, pneumonia	Yes (consider treating the infant)	Erythromycin, azithromycin, clarithromycin, doxycycline, tetracycline, sulfisoxazole
Cytomegalovirus Asymptomatic infection Infectious mononucleosis	Yes (for term infants) No (for premature or immunodeficient infants); do not give expressed breast milk	
Endometritis, Pelvic Inflammatory Disease Anaerobic organisms	Yes	Clindamycin, metronidazole, ceftioxin, cefmetazole
<i>Chlamydia trachomatis</i>	Yes	Erythromycin, azithromycin, tetracycline
Enterobacteriaceae	Yes	Ampicillin, aminoglycosides, cephalosporins
Group B streptococci	Yes (after 24 hr of therapy, breast milk is okay; observation)	Penicillin, cephalosporins, macrolides
<i>Mycoplasma hominis</i>	Yes	Clindamycin, tetracycline
<i>Neisseria gonorrhoeae</i>	Yes [§]	Ceftriaxone, spectinomycin, doxycycline, azithromycin
<i>Ureaplasma urealyticum</i>	Yes	Erythromycin, azithromycin, clarithromycin, tetracycline
Gonorrhea Genital, pharyngeal, conjunctival, or disseminated infection; <i>Neisseria gonorrhoeae</i>	Yes [§]	Ceftriaxone, ciprofloxacin, spectinomycin, azithromycin, doxycycline
Hepatitis[§] A —Acute only B —Chronic hepatitis, cirrhosis, hepatocellular carcinoma C —Chronic hepatitis, cirrhosis, hepatocellular carcinoma D —Associated with hepatitis B E —Severe disease in pregnant women G	Yes (after immune serum globulin and vaccine) Yes (after HBIG and vaccine) Yes Yes (after HBIG and vaccine) Yes Inadequate data	
Herpes Simplex Types 1, 2 Mucocutaneous, neonatal, encephalitis	Yes (in the absence of breast lesions)	Acyclovir, valacyclovir, famciclovir
Human Immunodeficiency Viruses[§] Types 1 and 2	No/yes	Little or no information available on antiretrovirals in breast milk
Human T-Cell Leukemia Viruses[§] Type I (T-cell leukemia/lymphoma virus): myelopathy, dermatitis, adenitis, Sjögren syndrome Type II: Myelopathy, arthritis, glomerulonephritis	No No	
Lyme Disease <i>Borrelia burgdorferi</i> : Multistaged illness of skin, joints, and peripheral or central nervous system	Yes, with informed discussion	Ceftriaxone, ampicillin, doxycycline

TABLE 9-4 BREASTFEEDING RECOMMENDATIONS FOR SELECTED MATERNAL INFECTIONS—cont'd

Organism, Syndrome, or Condition*	Breastfeeding Acceptable [†]	Medications Compatible with Breastfeeding, Except as Noted [‡]
Mastitis		
<i>Candida albicans</i>	Yes, with simultaneous treatment of the infant	Nystatin, ketoconazole
Enterobacteriaceae	Yes	Fluconazole
<i>Staphylococcus aureus</i>	Yes (after 24 hr of therapy, during which milk must be discarded)	Dicloxacillin, oxacillin, erythromycin, clindamycin, cotrimoxazole, azithromycin, linezolid, vancomycin
Group A streptococci		First-generation cephalosporins, penicillin, ampicillin, amoxicillin, erythromycin, azithromycin
<i>Mycobacterium tuberculosis</i>	No breast milk or breastfeeding for 2 weeks of maternal therapy; consider prophylactic isoniazid for the infant	Isoniazid, rifampin, ethambutol, pyrazinamide, ethionamide
Pulmonary or extrapulmonary infection with <i>Mycobacterium tuberculosis</i>	Yes, expressed breast milk can be used during initial 2 weeks of maternal therapy, then breastfeeding can continue	Antituberculous medications are acceptable during breastfeeding
<i>Trichomonas vaginalis</i>		
Vaginitis, urethritis, or asymptomatic infections	Yes	Metronidazole
Adenoviruses		
Conjunctivitis, upper/lower respiratory infections, gastroenteritis	Yes [¶]	

*Patients with the syndromes or conditions listed may present with atypical signs and symptoms (e.g., neonates and adults with pertussis may not demonstrate paroxysmal or severe cough). The clinician's index of suspicion should be guided by the prevalence of specific conditions in the community and by clinical judgment. The organisms listed are not intended to represent the complete or even most likely diagnoses but rather possible etiologic agents.

[†]Yes means that if the proposed precautions are followed for a hospitalized mother and infant, breastfeeding is acceptable and may be beneficial to the infant. Any infant breastfeeding during a maternal infection should be observed closely for signs or symptoms of illness.

[‡]Refer to Suggested Readings for a more complete discussion of medications and compatibility with breastfeeding.

[§]See text for more complete discussion.

[¶]No, in the United States and many other countries where safe alternatives to breast milk are available. Yes, in countries where there is no safe alternative to breast milk available.

^{¶¶}Adenovirus types 4 and 7 have been known to cause severe respiratory disease in premature infants or individuals with immunodeficiency or underlying respiratory disease. In certain situations, feeding expressed breast milk to the infant may not be advisable.

HBIG, hepatitis B immunoglobulin.

Modified from Lawrence RA, Lawrence RM: *Breastfeeding: A Guide for the Medical Profession*, 6th ed. St. Louis, Mosby, 2005.

2000). However, given the multiple issues involved (e.g., low risk of hepatitis C virus transmission via breast milk, increased risk of transmission in association with HIV infection and high levels of hepatitis C virus RNA in maternal serum, lack of effective preventive treatments [vaccines or immune serum globulin] and the risk of chronic hepatitis C virus infection, and serious liver disease), it is essential to educate the parents about the possible risks of continued breastfeeding. If the mother is symptomatic, breastfeeding may not be indicated. If the mother is not symptomatic, breastfeeding is usually appropriate.

Maternal retroviral infection and breastfeeding is a highly controversial issue that continues to be evaluated and debated. HIV-1 is transmissible via breastfeeding and can significantly increase the risk of HIV infection in infants born to HIV-positive mothers. One meta-analysis of five studies of infants born to HIV-infected mothers reported the risk of HIV transmission to infants strictly from breastfeeding as 14% (95% confidence interval, 7% to 22%).⁸⁶ Among the many concerns about HIV and breastfeeding are the risk of transmission related to the duration of breastfeeding, the relative risks of exclusive versus nonexclusive breastfeeding, the risk of mortality and morbidity resulting from other infections and malnutrition associated with *not* breastfeeding, the significance of HIV viral loads and CD4 counts in the mother relative to transmission from breast milk, the

potential protective effects of breast milk against HIV infection, and the degree to which antiretroviral therapy for the mother or infant will be protective against HIV infection. Social issues involved in this debate include the right of the mother to make choices for herself and her infant, the social stigma of not breastfeeding in certain cultures and communities, and the possibility that breastfeeding rates in HIV-negative mothers will be adversely affected by the advice given to HIV-positive mothers. In many countries, neither choice is optimal: Breastfeeding risks HIV infection in the infant, but not breastfeeding increases the risks of other infections and malnutrition. The lack of adequate data from controlled trials about the various factors contributing to infection adds to the difficulty of making straightforward recommendations applicable to diverse situations around the world. In the United States, it is appropriate to advise no breastfeeding for infants of HIV-infected mothers to decrease the risk of HIV transmission to the infant.^{1,35}

There are limited reports that deal with the risk of HIV-2 transmission via breastfeeding. Studies suggest that HIV-2 transmission via breast milk is less common than HIV-1.⁸⁷ However, until adequate information is available, it is appropriate to use the same guidelines as for HIV-1. Until additional data are available from trials studying the administration of highly active antiretroviral therapy (HAART) to

mothers during lactation, the optimal time and method for weaning, and the potential benefit of a perinatal vaccine, those concerned about breastfeeding and HIV in resource-limited countries should follow the current WHO recommendations for the prevention of mother-to-child transmission of HIV.⁸⁸

Transmission of human T-cell leukemia virus type I (HTLV-I) infection is associated with breastfeeding, although short-term breastfeeding (<6 months) may pose no greater risk than the risk for formula-fed infants.⁸⁹⁻⁹¹ In Japan, where high rates of infection with this virus occur, proscription of breastfeeding is common. In the United States, when the mother has documented HTLV-I infection, it is appropriate to discuss the options, risks, and benefits of breastfeeding and to consider short-term breastfeeding. There are many uncertainties concerning HTLV-II, related to the diseases associated with infection and to whether transmission occurs via breast milk. Here again, it is appropriate to discuss the available data and to include an infectious disease consultant in the discussion.¹

Numerous reviews⁹²⁻⁹⁵ and studies^{96,97} attempt to address the many issues of breastfeeding by HIV-positive mothers. The two most helpful resources related to breastfeeding and infection are the AAP's Report of the Committee on Infectious Diseases,⁷⁹ and *Breastfeeding: A Guide for Medical Profession* by Lawrence and Lawrence¹; the latter contains a chapter and an appendix dedicated to the issue.

Complications of the Breast

Plugged Ducts

Tender lumps in the breast in a mother who is otherwise well are probably caused by plugging of a collecting duct. The best treatment is to continue nursing while manually massaging the area to initiate and ensure complete drainage. Holding the infant in a different position may encourage flow, as may application of hot packs before a feeding. If repeated plugging occurs, a check should be made for possible obstruction from a brassiere strap or other external forces. Some women can actually see small plugs ejected when they massage. For some, reducing polyunsaturated fats in the diet and adding lecithin¹ provides relief.

Galactocele

Milk-retention cysts are uncommon and are usually associated with lactation. The swelling is smooth and rounded and nontender. The cyst may be aspirated to confirm the diagnosis and to avoid surgery, but it will fill up again. The cyst can be removed with local anesthesia without interruption of the breastfeeding routine. The diagnosis can also be confirmed by ultrasound, by which the cyst and milk look similar but tumor is distinguishable.¹

Mastitis

Mastitis is an infectious process in the breast producing localized tenderness, redness, and heat, together with systemic symptoms of a flulike illness with fever and malaise. It can be distinguished from engorgement and plugged duct (Table 9-5). Usually a red, tender, hot, swollen, wedge-shaped area of the breast is visible, and it corresponds to a lobe (Fig. 9-8). The common organisms are *Staphylococcus aureus*, *Escherichia coli*, and, rarely, *Streptococcus*.

The major points of management are as follows:

- Breastfeeding should continue on both breasts.
- Antibiotics appropriate to the probable cause and relevant sensitivities should be prescribed.
- Antibiotics should be given for no less than 10 days, and preferably 14. The antibiotic should be safe for the infant.
- Bed rest is necessary, and the mother should bring the infant to bed to nurse. She will need assistance for the rest of the household responsibilities.

The most common cause of recurrent mastitis is delayed or inadequate treatment of the initial disease. On recurrence, cultures of a midstream flow of milk should be sent and antibiotics chosen accordingly.

Candidiasis of Nipple and Breast

Candidiasis of the breast is frequently overdiagnosed because there are several causes for the breast pain that is described by mothers

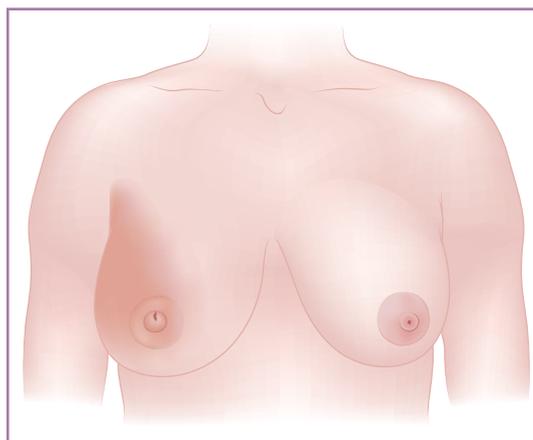

FIGURE 9-8 Mastitis of right breast, upper outer quadrant. (From Lawrence RA, Lawrence RM: *Breastfeeding: A Guide for the Medical Profession*, 6th ed. St. Louis, Mosby, 2005, p 563 [Fig. 16-1].)

TABLE 9-5 COMPARISON OF ENGORGEMENT, PLUGGED DUCT, AND MASTITIS

Symptom	Engorgement	Plugged Duct	Mastitis
Onset	Gradual, immediately after birth	Gradual, after feedings	Sudden, after 10 days
Site	Bilateral	Unilateral	Usually unilateral
Swelling and heat	Generalized	May shift; little or no heat	Localized, red, hot, swollen
Pain	Generalized	Mild but localized	Intense but localized
Body temperature	<38.4°C (101°F)	<38.4°C	>38.4°C
Systemic symptoms	Feels well	Feels well	Flulike symptoms

From Lawrence RA, Lawrence RM: *Breastfeeding: A Guide for the Medical Profession*, 6th ed. St. Louis, Mosby, 2005, p 279 (Table 8-5).

as feeling like “a stab with a hot poker.” On examination, there may be little to see except a pinkish hue to the nipple and central areola. Rarely are white plaques seen on the nipple. If the mother has a history of vaginal candidiasis, the infant’s mouth may have become colonized, and this could have resulted in inoculation of the nipples. The infant should also be examined for both thrush and diaper rash and treated simultaneously with the mother for a full 2 weeks. Nystatin ointment is applied after each feeding to nipples and areolae. The infant receives nystatin drops orally to the oral mucous membranes after each feeding. For a recurrent episode, the mother can be treated with 200 mg oral fluconazole systemically once daily for 3 days. The infant can be given 6 mg/kg on day 1 and then 3 mg/kg per dose every 24 hours orally. Pacifiers and bottle nipples that are put in the mouth should be discarded and new ones sterilized daily. Persistent thrush requires a complete evaluation of the mother and may require treatment for vaginal thrush, decreased sugar in diet, and colonization with lactobacillus by capsule or yogurt.

Medications while Breastfeeding

Questions about medication during breastfeeding are very commonly asked. The transfer of maternal drugs to the infant during lactation is different from transfer to the fetus during pregnancy. Although it is almost always better to breastfeed, the physician must weigh the benefit and risk of a medication against the substantial benefit of being breastfed for the infant. The risk-to-benefit ratio differs for each drug and clinical setting. Both scientific information and experienced clinical judgment are required to assess the risks and benefits and determine the therapeutic choice.

The AAP Committee on Drugs has published a list of commonly used drugs and chemicals that may transfer into human milk (Table 9-6).⁹⁸ The list is not all-inclusive and is revised intermittently.⁹⁷ Absence of a drug from the list merely indicates that the committee

TABLE 9-6 AAP DRUG GROUPS 1, 2, 3, AND 6

Rights were not granted to include this table in electronic media.
Please refer to the printed publication.

did not study it in reference to lactation. The categories are as follows:

1. Cytotoxic drugs that may interfere with cellular metabolism of the nursing infant (see Table 9-6, group 1)
2. Drugs of abuse for which adverse effects on the infant during breastfeeding have been reported (see Table 9-6, group 2)
3. Radioactive compounds that require temporary cessation of breastfeeding (see Table 9-6, group 3)
4. Drugs for which the effect on nursing infants is unknown but that may be of concern—for example, bromocriptine, ergotamine compounds, and lithium
5. Drugs that have been associated with significant effects on some nursing infants and should be given to nursing mothers with caution
6. Maternal medication usually compatible with breastfeeding (see Table 9-6, group 6)
7. Food and environmental agents that might have an effect on the breastfeeding infant

A readily available and frequently updated handbook, *Medications and Mother's Milk*, is published by Hale.⁹⁹ This reference provides a scale that is roughly the reverse of the long-established classification system developed by the AAP. The Hale definitions are as follows:

- L1 safest
- L2 safer
- L3 moderately safe
- L4 possible hazardous
- L5 contraindicated

A lack of information about a drug does not necessarily require cessation of breastfeeding. Understanding the pharmacology of a drug, the dosing schedule, and the stage of growth and development of the infant inform the decision about whether it would affect the infant. Characteristics of the drug that influence its passage into milk include the size of the molecule, its solubility in lipid or water, whether it binds to protein, the pH, and the diffusion rates (Table 9-7). The route of administration influences the blood levels and therefore the milk levels. Passive diffusion is the principal transport mechanism. How the drug is metabolized influences whether it is present in the milk in its active form or as an inactive metabolite (Fig. 9-9).

The infant's ability to absorb, digest, metabolize, store, and excrete a drug must be considered when choosing a medication for a nursing mother. A drug that is not orally bioavailable will not be absorbed from the milk by the infant. The ability to absorb and metabolize a drug depends on the infant's developmental age and the chronologic age. An 18-month-old who nurses briefly about four times a day for comfort will get little medication, has a substantial diet other than mother's milk, and can metabolize and excrete more efficiently than a newborn. In the first weeks of life, the maturation or gestational age should be considered when determining the safety of a medication, because the less mature the infant is, the less mature are the liver and kidneys.

With the exception of radioactive compounds such as iodine 131, there is no drug whose possible presence in the milk would require immediate withholding of breastfeeding because the physician does not know the data. Therefore, the arbitrary interference with breastfeeding until information can be obtained is not justified. Ample references and information lines are available to resolve the issue. For medications used once or for a short time, the time required for the

TABLE 9-7 THE PASSAGE OF DRUGS INTO BREAST MILK

1. Mammary alveolar epithelium represents a lipid barrier with water-filled pores and is most permeable for drugs during the colostrum phase of milk secretion (1st postpartum week).
2. Drug excretion into milk depends on the drug's degree of ionization, molecular weight, solubility in fat and water, and relationship of pH of plasma (7.4) to pH of milk (7.0).
3. Drugs enter mammary cells basally in the nonionized non-protein-bound form by diffusion or active transport.
4. Water-soluble drugs of molecular weight less than 200 pass through water-filled membranous pores.
5. Drugs leave mammary alveolar cells by diffusion or active transport.
6. Drugs may enter milk via spaces between mammary alveolar cells.
7. Most ingested drugs appear in milk; drug amounts in milk usually do not exceed 1% of ingested dosage, and levels in the milk are independent of milk volume.
8. Drugs are bound much less to milk proteins than to plasma proteins.
9. Drug-metabolizing capacity of mammary epithelium is not understood.

Modified from Lawrence RA, Lawrence RM: *Breastfeeding: A Guide for the Medical Profession*, 6th ed. St. Louis, Mosby, 2005.

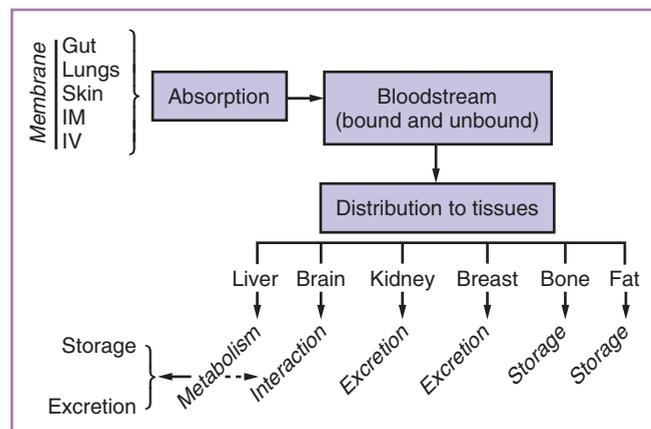

FIGURE 9-9 Distribution pathways for drugs. Distribution pathways vary with the drug and are relevant to advising the lactating mother about breastfeeding when drugs have been prescribed. IM, intramuscular; IV, intravenous. (Modified from Rivera-Calimlim L: Distribution pathways for drugs, once absorbed during lactation. *Clin Perinatol* 14:51, 1976.)

drug to clear the maternal system and her milk can be determined. The mother can pump and discard her milk for that period and return to breastfeeding (usually a few hours or days, not weeks).

Milk-to-Plasma Ratio

The *milk-to-plasma ratio*, a term applied to drugs being used by a lactating mother, indicates the level of the drug in the milk compared with the level in the plasma at a given time. The dosage of the drug, including time and route of dosing, must be known to interpret the ratio. If there is a very low level in the plasma and the same very low level in the milk, the ratio is 1. A ratio of 1 means that the level is of concern, even though the actual level in milk is low. Most drugs have

a milk-to-plasma ratio of less than 1. It is important to know peak plasma and peak milk levels, and peak plasma and peak milk times, to make appropriate recommendations to avoid feeding the infant when transfer of the drug would be greatest.

Chapter 10

Maternal Nutrition

Naomi E. Stotland, MD

Despite ample evidence about the importance of nutrition on health in general as well as during pregnancy, the typical American diet is falling short of the mark. Surveys of pregnant women reveal that much of their caloric intake comes from high-calorie, nutrient-poor foods such as soft drinks and white bread. Intakes of calcium, iron, and folate are often below the recommended levels, and fat intake is generally high and in the form of harmful saturated fats rather than beneficial vegetable or marine sources.¹

For much of the 20th century, the public health focus was on the prevention of undernutrition, as poor weight gain was considered a threat to optimal perinatal outcome. More recent studies reveal that excessive weight gain (above Institute of Medicine [IOM] guidelines) is increasingly common and is associated with multiple adverse outcomes. Overweight and obesity are now the norm, with 30.2% of reproductive-age women obese and 56.7% overweight.^{2,3} Not only do pre-pregnancy overweight and excessive pregnancy weight gain adversely affect perinatal outcomes but women's long-term health is compromised, with higher rates of metabolic and cardiovascular illness later in life. Recent research has also emphasized the role of maternal nutritional and metabolic status on the long-term health of offspring. Although it has been recognized for some time that growth-restricted fetuses have higher rates of cardiovascular and metabolic problems as children and adults, it is now clear that excessive fetal growth, related to maternal obesity and hyperglycemia, also leads to higher rates of these adverse outcomes.^{4,5} Despite this, approximately one third of prenatal patients report receiving no advice about weight gain during their pregnancy.^{6,7} All clinicians caring for reproductive-age women should educate themselves and their patients about the importance of good nutritional health before, during, and after pregnancy.

Pre-conception Issues

Perinatal outcome may be influenced by the maternal nutritional and metabolic status at the time of conception as much as during pregnancy, or even more. Organogenesis occurs early in the first trimester before many women are aware of the pregnancy. Hence, women who may become pregnant or who are attempting to conceive should optimize their nutritional and metabolic status before pregnancy. Women with pregestational diabetes mellitus should strive to achieve euglycemia before conception, as higher levels of hemoglobin A_{1c} (a marker for hyperglycemia) are associated with progressively higher rates of congenital deformities.⁸

Folic Acid

Folic acid and folate are forms of vitamin B₉, which is essential for nucleic acid synthesis, red blood cell synthesis and maintenance, and fetal and placental growth. Maternal folic acid deficiency is associated with neural tube defects in the fetus and other congenital anomalies. The U.S. Centers for Disease Control and Prevention (CDC) recommends 0.4 mg/day of folic acid from diet or supplements for all women capable of becoming pregnant, to reduce the risk for neural tube defects.⁹ Women with a previous pregnancy affected by a neural tube defect should take 4 mg of folic acid beginning 1 month before conception and throughout the first trimester. In 1998, the U.S. Food and Drug Administration (FDA) began requiring that most enriched breads, flours, corn meals, rice, noodles, macaroni, and other grain products be fortified with folic acid. After fortification, the incidence of pregnancies affected by neural tube defects decreased by 26%. The CDC had estimated a 50% reduction, and it is controversial whether intake of folic acid–fortified foods is adequate or whether additional supplementation is needed. Obese women have been found to have lower serum levels of folic acid, and they are also at increased risk for neural tube defects. However, a Canadian study found that the obesity-related risk for neural tube defects actually increased after the country instituted folic acid fortification of flour.¹⁰ The mechanism underlying the association between obesity and neural tube defects is unclear, and some have suggested it may be related to a higher serum glucose rather than a folic acid deficit. The popularity of low-carbohydrate diets has led to some concern that decreased intake of fortified flours and other grain products would lead to an increase in neural tube defects, and data from the CDC show that serum folic acid levels in women of childbearing age actually decreased by 16% between 1999 and 2004.¹¹ It is unknown whether this decline was associated with an increase in neural tube defects.

There is also evidence of a small decrease in the rate of orofacial cleft anomalies after folic acid fortification.¹²

Body Mass Index and Obesity

Increasing epidemiologic evidence suggests that a woman's pre-pregnancy body mass index (BMI) and adiposity have a greater impact on some perinatal outcomes than her gestational weight gain. Women who begin pregnancy underweight are at increased risk for both preterm delivery and delivering a small-for-gestational-age (SGA) infant when compared with women of normal pre-pregnancy BMI. However, otherwise healthy but underweight women appear to be at

decreased risk for multiple adverse outcomes, including macrosomia, cesarean delivery, and preeclampsia.^{13,14} Women who begin pregnancy obese have increased rates of spontaneous abortion, congenital anomalies (e.g., neural tube defects, cardiac and gastrointestinal anomalies), gestational diabetes mellitus (GDM), intrauterine fetal death, hypertensive disorders of pregnancy, cesarean birth, failed vaginal birth after cesarean, thromboembolic disease, and postoperative complications. Higher BMI is associated with lower rates of births involving SGA infants or intrauterine growth restriction (IUGR); however, obese women with chronic hypertension or diabetic vasculopathy may be at increased risk for IUGR. Obese women have lower rates of spontaneous preterm birth; however, there is some evidence that morbidly obese women have increased rates of medically indicated preterm birth, probably related to the increased rates of preeclampsia and gestational diabetes.

Postconception Obesity-Related Risks

The risk for spontaneous abortion in the first trimester is greater for obese women than for lean women.¹⁵ This increased risk is seen among both naturally conceived and in vitro fertilization pregnancies.¹⁶ Obesity is associated with an increased risk for congenital anomalies, including neural tube defects and cardiac malformations, even in the absence of overt diabetes.^{10,16} Although the mechanism linking obesity and congenital anomalies remains unclear, these same anomalies are associated with diabetes, and undiagnosed hyperglycemia early in gestation has been proposed as the mechanism. Such malformations are also more difficult to detect in obese women before the birth, because ultrasonography is less sensitive, and increased blood volume causes false-negative serum α -fetoprotein screening.¹⁷

Fetal Growth and Body Composition

Maternal pre-pregnancy weight and infant birth weight are highly correlated. Maternal obesity is a strong predictor of macrosomia or the birth of a large-for-gestational-age infant, even among women who are glucose tolerant.^{18,19} Additionally, infants born to obese mothers have a higher percentage of body fat compared with infants born to normal-weight mothers. In a study of 220 infants born to glucose-tolerant mothers, infants born to women with a BMI of 25 or greater were heavier than those born to women with a BMI less than 25. Of note, the increase in birth weights between the two groups was explained by an excess of fat mass rather than lean body mass in the infants.¹⁸ Although ultrasonographic detection of fetal anomalies may be impaired by maternal obesity,^{17,20} studies have shown that ultrasonographic estimation of fetal weight is not significantly impaired by elevated maternal BMI.^{21,22}

Intrauterine Growth Restriction

Underweight women are at increased risk of delivering an SGA infant, especially if gestational weight gain is inadequate,^{19,23,24} and a low pre-pregnancy BMI is a strong predictor of IUGR or an SGA infant. There is evidence that overweight and obesity are protective against the birth of a SGA infant, but the data (cited earlier) showing decreased lean body mass and increased fat mass among infants born to obese women suggest that this protection may not lead to better health outcomes in children.

Obesity increases the risks for hypertension and type 2 diabetes, and if vascular sequelae are present, it increases the risk for IUGR in

spite of significant obesity. In a Swedish cohort study, morbid obesity (BMI >40) was associated with an increased risk for the birth of a SGA infant, and this association lost statistical significance when subjects with preeclampsia were excluded, suggesting a possible mechanism.²⁵

Hypertensive Disorders of Pregnancy

Obesity and higher pre-pregnancy BMI have been shown to increase the risk for gestational hypertension and preeclampsia in many epidemiologic studies.^{26,27} A meta-analysis of BMI and preeclampsia showed a doubling of risk with each 5 to 7 kg/m² increase in maternal BMI.²⁸ This association persisted when accounting for confounders such as chronic hypertension, diabetes, and multiple gestations. The recent recognition of obesity as a chronic inflammatory state, characterized by elevated cytokine levels, has been hypothesized as playing a role in the association between obesity and preeclampsia. Subclinical hyperglycemia leading to decreased oxygen transfer to the uterus and abnormal placentation has also been proposed as a mechanism.⁴

Diabetes Mellitus

Obesity is a well-known risk factor for both pre-gestational and gestational diabetes mellitus. In a large U.S. cohort study, obese women (BMI, 30 to 34.9) had an adjusted odds ratio (OR) of 2.6 (range, 2.1 to 3.4), and morbidly obese women (BMI \geq 35) had an adjusted OR of 4.0 (range, 3.1 to 5.2) for gestational diabetes, compared with women with a BMI of less than 30.²⁹

Preterm Delivery

Most epidemiologic studies of pre-pregnancy BMI and preterm birth show an inverse relationship—that is, a lower BMI is associated with an increased risk for preterm birth.^{30,31} There also appears to be an interaction between pre-pregnancy BMI and gestational weight gain, with underweight, low-gaining women at especially increased risk for preterm birth. Approximately 75% of preterm births are spontaneous, and 25% are medically indicated. Because obese women have higher rates of hypertensive and diabetic disorders of pregnancy, they may be at higher risk for medically indicated preterm birth. A large, population-based cohort study of births in Scotland found that parity altered the relationship between BMI and preterm birth.³² For spontaneous preterm birth, lower BMI was associated with increased risk, and obesity was protective. BMI was a stronger predictor of spontaneous preterm birth among multiparous women. In contrast, risk for medically indicated preterm birth was increased with higher BMI, and this effect was stronger among nulliparous women.

Cesarean Birth

Higher BMI is associated with increased risk for cesarean birth.¹³ Higher BMI is also associated with lower rates of successful vaginal birth after cesarean section among women undergoing a trial of labor.³³

Intrauterine Fetal Demise

Overweight and obesity have been associated with increased rates of intrauterine fetal demise or stillbirth in large epidemiologic studies.^{34,35} This association persisted even when analysis was restricted to women with early ultrasound dating, ruling out undiagnosed postdatism as the cause. Increased stillbirths are also seen among obese women even when women with overt hypertension and diabetes are excluded from the analyses. The mechanism remains unclear, but some investigators have suggested that subclinical hypertension and hyperglycemia may be the etiology. Fetal monitoring may be more difficult among morbidly obese women, and obesity has been associated with decreased maternal perception of fetal movement.³⁶ Overweight and obese

women with hypertension or diabetes merit especially close antepartum monitoring, but the most beneficial and cost-effective regimen has not been established.

Postconception Nutritional Issues

Weight Gain During Pregnancy

The IOM established BMI-specific guidelines for gestational weight gain for women with singleton pregnancies in 1990 (Table 10-1).³⁷ Since that time, numerous epidemiologic studies have validated the IOM's recommended weight gain ranges, finding that gain within the guidelines is associated with the lowest rates of a number of adverse maternal and infant outcomes. However, controversy and uncertainty still exist over specific aspects of weight gain. In particular, the optimal weight gain range for obese women remains unclear, as is evidenced by the lack of an upper limit on the recommended range for this subgroup. In 2006, the IOM convened a workshop to review the current evidence on maternal weight and perinatal outcomes³⁸ (report available at www.iom.edu/CMS/12552/31379/41424.aspx [accessed February 2008]).

Conditions Associated with Inadequate Gestational Gain

Many studies have found an association between weight gain below the IOM guidelines and increased risk for spontaneous preterm birth.^{30,39} These studies are usually limited by the fact that the rate of gestational weight gain is not constant throughout pregnancy, with the gain being less rapid in the first trimester, speeding up in the second and early third trimesters, and then slowing once again near term. Low gain is also associated with an increased risk for an SGA infant, and this association is strongest among women with a low pre-pregnancy BMI.²⁴ Among obese women, there is only a weak association between gestational gain and birth weight.¹⁹ However, some studies have found an increased risk for an SGA infant even among obese women with

inadequate gestational gain, so it is still unclear how much weight gain is necessary for optimal fetal growth and development among obese women.

In a hospital-based cohort, weight gain below IOM guidelines was not associated with increased neonatal morbidity in term infants, but extremely low weight gain (less than 7 kg) was associated with increased risk for seizures and prolonged hospital stay.⁴⁰

Conditions Associated with Excessive Gestational Gain

Preeclampsia and Gestational Hypertension

Cedergren found an increased risk for preeclampsia among women who gained more than 35 lb during pregnancy compared with those gaining between 18 and 35 lb.⁴¹ This relationship held across all pre-pregnancy BMI categories.

Gestational Diabetes Mellitus

Although the relationship between high pre-pregnancy BMI and GDM is well established, it is difficult to study the role of gestational weight gain on GDM, as this diagnosis generally leads to dietary interventions and caloric restriction. Saldana and coworkers studied gestational weight gain up until the time the GDM diagnosis was made, and found that higher gain was associated with increased risk for GDM. Pre-pregnancy BMI was a much stronger predictor of GDM risk than weight gain, and there was an interaction between BMI and weight gain that indicated that excessive gain increased the risk for GDM only for those women who were overweight at the start of pregnancy.⁴²

Cesarean Delivery

Many epidemiologic studies have linked excessive gestational weight gain to an increased risk for cesarean birth, independent of pre-pregnancy BMI and birth weight. Using U.S. population-based data, Dietz and colleagues found that women gaining 41 lb or more had an increased risk for cesarean birth.¹³ Cedergren examined a cohort of Swedish women and found that regardless of pre-pregnancy BMI, a weight gain of greater than 35 lb was associated with cesarean birth.⁴¹ Among overweight and obese women in the cohort, cesarean risk was reduced if weight gain was less than 18 lb.

Macrosomia

Although pre-pregnancy BMI appears to be a stronger predictor of birth weight than pregnancy weight gain, excessive gain is a predictor of macrosomia and the birth of a large-for-gestational-age infant. In a cohort of 45,245 births to nondiabetic women in a California HMO, women gaining more weight than set by IOM guidelines had an OR of 3.05 for macrosomia compared with women gaining within the guidelines.⁴³

Neonatal Morbidity

In a hospital-based birth cohort, excessive gestational weight gain was associated with a low 5-minute Apgar score, neonatal seizures, hypoglycemia, polycythemia, meconium aspiration syndrome, and assisted ventilation.⁴⁰ In another study in a California HMO, weight gain greater than IOM guidelines was associated with neonatal hypoglycemia and hyperbilirubinemia.⁴³

Postpartum Weight Retention

Many studies have shown an association between excessive gestational weight gain, higher postpartum weight retention, and a greater risk for postpartum overweight and obesity. Women who are overweight or

TABLE 10-1 RECOMMENDED TOTAL WEIGHT GAIN RANGES FOR PREGNANT WOMEN BY PRE-PREGNANCY BMI*

	Recommended	Total	Gain
Weight for height	BMI	kg	lb
Underweight	<19.8	12.5-18	28-40
Normal weight	19.8-26.0	11.5-16	25-35
Overweight†	>26.0-29.0	7-11.5	15-25

*BMI (body mass index) is calculated using metric units.

†The recommended target weight gain for obese women (BMI >29.0) is at least 6.0 kg (15 lb).

obese at the start of pregnancy are at the highest risk of retaining pregnancy weight in the long term.^{44,45}

Interventions to Optimize Gestational Weight Gain

Although the amount of weight gained during pregnancy is related to many factors beyond simple energy balance (calories consumed versus calories expended), epidemiologic evidence indicates that a high caloric intake or low physical activity level (or both) are risk factors for excessive gestational weight gain.^{46,47} Olson and Strawderman examined the relative contributions of various biologic and psychosocial factors and gestational weight gain, and found that modifiable factors such as increased food intake and decreased physical activity explained 27% of the variance in gestational weight gain.⁴⁷

Few clinical trials have assessed the efficacy of specific prenatal interventions and programs to optimize weight gain during pregnancy. Polley and coworkers randomized pregnant women to a control arm or to an intervention that included diet and exercise counseling, weekly newsletters, and personalized goal-setting and weight gain graphs.⁴⁸ Among subjects with a normal pre-pregnancy BMI, there was a lower rate of excessive weight gain in the intervention group (33% versus 58%, $P < .05$). However, among overweight and obese women, the intervention group showed a trend toward a higher rate of excessive gain (59% versus 32%, $P < .09$). Interestingly, the overweight and obese women in the control arm had a much lower rate of excessive gain than is reported in observational studies. Olson and coworkers tested a weight gain intervention in pregnancy and compared outcomes to historical controls.⁴⁹ Gestational weight gains in the intervention group were monitored by health care providers, and this group received by-mail patient education. Among the low-income subgroup, the intervention reduced excessive weight gain more than in controls (OR = 0.41, 95% confidence interval [CI], 0.20 to 0.81), but no effect was seen among higher-income subjects.

Supplementation

Recommendations for vitamin and mineral intakes during pregnancy and lactation are shown in Table 10-2.

Multivitamin Supplementation

As noted earlier, surveys have shown that a large percentage of pregnant women in the United States consume diets inadequate in several vitamins and minerals. Prescription of “prenatal” multivitamin supplements during pregnancy is common practice in the United States. Although data exist supporting the benefits of folic acid and iron supplementation, the risks and benefits of routine prenatal multivitamin use in the U.S. population have not been clearly documented. One concern is that interactions between nutrients may inhibit or enhance the absorption or bioavailability of individual vitamins and minerals when consumed together in a multivitamin.⁵⁰ For example, magnesium and calcium inhibit iron absorption. An observational study of a cohort of low-income pregnant women in New Jersey found an association between first and second trimester multivitamin use and reduced risk for preterm delivery.⁵¹ In a multivariable analysis, risk for delivery before 33 weeks was reduced fourfold among first-trimester vitamin users. There are no randomized, controlled trials of prenatal multivitamin use in the U.S. population.

Iron Supplementation

Epidemiologic data show an association between lower hemoglobin levels and adverse perinatal outcomes, including low birth weight,

TABLE 10-2 RECOMMENDED VITAMIN AND MINERAL SUPPLEMENTATION

All Women Who May Become Pregnant and in the First Trimester of Pregnancy

Folic acid 0.4 mg

Multivitamin-Mineral Preparation for Women with Poor Diets or in High-Risk Categories

Iron	30 mg	Vitamin B ₆	2 mg
Zinc	15 mg	Folic acid	0.4 mg
Copper	2 mg	Vitamin C	50 mg
Calcium	250 mg	Vitamin D	5 μg

Supplementation for Women in Special Circumstances

Complete vegetarians, who consume no animal products whatsoever

10 μg (400 IU) vitamin D

2 μg vitamin B₁₂

Women under age 25 whose daily intake of calcium is less than 600 mg

600 mg calcium

Women with low intake of vitamin D–fortified milk, especially those who have minimal exposure to sunlight

10 μg (400 IU) vitamin D

prematurity, and maternal and infant mortality. The IOM recommends an iron intake of 27 mg/day during pregnancy.³⁷ Most pregnant women need a supplement to achieve this intake. A Cochrane Collaboration review of routine iron supplementation during pregnancy concluded that antenatal supplementation with iron or iron plus folic acid reduces the risk for anemia (hemoglobin levels below 10 to 10.5 g/L) at or near term.⁵² The review concluded that there was insufficient evidence that iron supplementation had any other benefits or any adverse effects on pregnancy outcome. However, a randomized trial in low-income pregnant women in North Carolina showed reductions in preterm birth and higher birth weights among women taking iron supplements.⁵³ Iron supplements are best absorbed when taken with citrus juices, as the vitamin C enhances absorption. Coffee, tea, milk, and calcium supplements inhibit iron absorption and thus should be consumed separately from iron supplements.

Calcium

Less than half of U.S. women meet the recommendation for dietary intake of calcium. The recommended daily intake of calcium for women 19 to 39 years old (whether pregnant or not) is 1000 mg/day. For women under age 18, 1300 mg/day is recommended.⁹ For optimal benefit, calcium should be taken with adequate doses of vitamin D and magnesium. Women with inadequate baseline calcium intake may also benefit from supplementation, which may reduce their risk for preeclampsia and the risk for bone loss.⁵⁴ Adequate calcium intake may also be protective against lead toxicity to the fetus, as lead is stored in bone, and increased bone turnover during pregnancy may release lead into the bloodstream.⁵⁵

Dietary Guidelines

Macronutrient Intake

The following is a general guide for otherwise healthy pregnant women with singleton gestations. Pregnant women with normal pre-pregnancy BMI should consume an additional 300 kcal/day above a normal nonpregnant intake.

Fruits and Vegetables. Pregnant women should eat seven or more servings of fruits and vegetables (in any combination) per day. This is necessary for adequate fiber intake, as well as for folic acid, vitamin C, vitamin A, and other nutrients. Consumption of higher-fiber diets is associated with lower risk for excessive gestational weight gain among obese women.⁴⁶ One serving of fruit means, for example, one medium apple or one medium banana. One serving of vegetables means 1 cup raw leafy vegetables or one-half cup of other vegetables (raw or cooked).

Carbohydrates. Carbohydrates should make up between 45% and 65% of calories. Pregnant women should consume six to nine servings of whole grains a day, such as whole wheat bread and whole grain cereals. Whole grains provide fiber as well as B vitamins and minerals. One serving of bread or cereal means one slice of bread, and one-half cup of cooked cereal, rice, or pasta.

Dairy Products. Pregnant women should eat at least four servings of low-fat or non-fat dairy products per day. Dairy products are good sources of calcium, vitamins A and D, protein, and B vitamins. Women who are lactose intolerant can get these nutrients from other food sources: cheese and yogurt are low in lactose, and reduced-lactose milk is commercially available. Women who avoid dairy products can choose other calcium-rich foods such as calcium-fortified citrus juice or soy milk, tofu made with calcium sulfate, canned salmon or sardines (with bones), ground sesame seeds, and leafy green vegetables.

Protein. Pregnant women need about 60 g of protein daily, 10 g above the requirement for nonpregnant women. However, most Americans consume more protein than necessary, and much of it is from animal sources high in saturated fat. Beneficial sources of protein include lean meats such as chicken without skin, fish, beans, tofu, nuts, and eggs. One serving of protein means 2 to 3 oz of cooked lean meat, poultry, or fish; one-half cup tofu or cooked dried beans; one egg; one-third cup of nuts; or two tablespoons of peanut butter

Fats. Total fat intake should be between 20% and 35% of calories. Beneficial fats include polyunsaturated fatty acids found in fish, nuts, and vegetable oils. Women should limit the intake of saturated fats and avoid *trans* fats.

Food-Borne Infections

Because pregnant women and fetuses are especially vulnerable to food-borne illnesses such as toxoplasmosis and listeriosis, pregnant women should avoid uncooked and undercooked meats and fish. More information on how to avoid infection with listeriosis can be found on the CDC website, www.cdc.gov/ncidod/dbmd/diseaseinfo/listeriosis_g.htm (accessed February 2008). General information on food safety in pregnancy can be found on the FDA website, www.cfsan.fda.gov/~pregnant/pregnant.html (accessed February 2008).

Fish Consumption: Mercury and Omega-3 Fatty Acids

In 2004, the U.S. government issued health advisories recommending that pregnant women limit their fish consumption to avoid exposure

TABLE 10-3 MERCURY IN COMMONLY EATEN FISH AND SEAFOOD

Fish high in mercury (avoid)	Shark Tilefish Swordfish King mackerel
Fish low in mercury	Salmon Shrimp Canned light tuna Pollock Catfish

to methyl mercury, a heavy metal and industrial pollutant or contaminant that accumulates in some seafood. Mercury is neurotoxic, and the developing fetus is especially vulnerable. These recommendations were based primarily on data from studies conducted in the Faroe Islands and New Zealand,^{56,57} which demonstrated worse performance on neurobehavioral tests among children exposed to higher levels of mercury-contaminated fish. However, a similar study from the Seychelles Islands showed no adverse effect of higher maternal fish consumption.⁵⁸ Subsequent to the governmental fish advisories, studies demonstrated that fish consumption dropped among women of reproductive age in the United States.⁵⁹

However, fish is a primary source of omega-3 fatty acids, which are important in fetal neurologic development. Higher consumption of dietary fish oils has also been associated in epidemiologic studies with lower rates of preterm birth, low birth weight, and preeclampsia.⁶⁰⁻⁶² In a large population-based study published in 2007 from the United Kingdom, lower maternal fish consumption was associated with lower verbal intelligence quotient scores and other neurobehavioral measures in children 6 months to 8 years of age.⁶³ Thus, controversy persists over the optimal fish intake during pregnancy. It remains unclear whether the benefits of higher seafood consumption outweigh the risks of mercury exposure. Avoidance of fish known to contain higher levels of mercury is prudent (Table 10-3), and more research is needed about the risks related to typical seafood consumption among U.S. women of reproductive age. The U.S. Environmental Protection Agency advisory related to mercury and fish can be found on their website, www.epa.gov/waterscience/fishadvice/advice.html (accessed February 2008).

Fish Oil Supplements in Pregnancy

Because of the observed epidemiologic associations between higher fish consumption and reduced rates of preterm birth, low birth weight, and preeclampsia, large multicenter trials were initiated to study whether fish oil supplements would prevent such adverse outcomes in pregnancy. Unlike dietary fish, supplements can be prepared to minimize mercury and other toxin contamination. A 2005 Cochrane review of existing trials of fish oil supplementation during pregnancy concluded that there was insufficient evidence to support routine use, although small beneficial effects were seen on birth weight and length of gestation.⁶⁴

Special Diets in Pregnancy

Vegetarian

Although the current prevalence of strict vegetarianism in the United States is not reported, data from the 1990s suggest that approximately

2.5% of U.S. adults consider themselves vegetarian.⁶⁵ Interestingly, only 0.9% of those surveyed reported eating no animal flesh, with over half of self-described vegetarians consuming some meat or fish. There is also a lack of data on the relationship of vegetarian and vegan diets during pregnancy to perinatal outcomes. The primary concern about vegetarian diets is vitamin B₁₂ deficiency, as this vitamin is found primarily in animal food sources. Women who are ovo-lacto-vegetarians (who consume eggs or dairy products, or both) may have adequate B₁₂ intake from dairy products. However, a German cohort study found that 39% of ovo-lacto-vegetarians had low serum levels of B₁₂ during at least one trimester of pregnancy (versus 3% of controls, $P < .001$), although clinical outcomes were not reported.⁶⁶ Vegans (those who consume no animal products) generally require a B₁₂ supplement for adequate intake. Vegans can also increase their B₁₂ intake with B₁₂-fortified vegetarian foods such as soy milk and meat substitutes. The vegan diet may also be so high in fiber and low in fat that caloric intake may be insufficient for pregnancy, and adherents to vegan diets are more likely to have a BMI in the underweight range. Intakes of calcium, vitamin D, riboflavin, and iron may also be inadequate. With dietary assessment and counseling, such women can maintain their diet and have an adequate nutritional intake during pregnancy.

Clinical Issues

Multiple Gestation

Women carrying more than one fetus should increase their caloric intake by 300 kcal/day per fetus. As is true for women carrying singleton gestations, optimal weight gain for twin pregnancies varies by pre-pregnancy BMI. In a large, multicenter cohort of liveborn twins, optimal gestational age and birth weight outcomes were associated with the following patterns of maternal gain⁶⁷:

- Underweight women: 1.25 to 1.75 lb/wk until 20 weeks, 1.50 to 1.75 lb/wk between 20 and 28 weeks, and 1.25 lb/wk from 28 weeks to delivery
- Normal-weight women: 1.0 to 1.5 lb/wk until 20 weeks, 1.25 to 1.75 lb/wk between 20 and 28 weeks, and 1.0 lb/wk from 28 weeks to delivery
- Overweight women: 1.0 to 1.25 lb/wk until 20 weeks, 1.0 to 1.5 lb/wk between 20 and 28 weeks, and 1.0 lb/wk from 28 weeks to delivery
- Obese women: 0.75 to 1.0 lb/wk until 20 weeks, 0.75 to 1.25 lb/wk between 20 and 28 weeks, and 0.75 lb/wk from 28 weeks to delivery

Women with triplets should aim for a total gain of at least 50 to 60 lb. Eating at least five times a day may help women achieve this large caloric intake. Vitamin supplementation is especially helpful in multiple gestations, and additional calcium, magnesium, and zinc may improve outcomes.⁶⁸

Nausea and Vomiting

A majority of pregnant women report some nausea and vomiting during pregnancy. Symptoms virtually always appear before 9 weeks of gestation, so a new onset of nausea or vomiting after 9 weeks should prompt a medical workup for other etiologies. Hyperemesis gravidarum is found in only 0.5% to 2% of pregnancies; this is usually defined as severe persistent vomiting with no other clear etiology

accompanied by large ketonuria or weight loss of at least 5% of pre-pregnancy body weight. Excluding cases of hyperemesis gravidarum, women who experience nausea and vomiting of pregnancy actually have better pregnancy outcomes than women who do not experience these symptoms. First-line therapy should be vitamin B₆, 10 to 25 mg, three or four times per day. Ginger has also been effective in clinical trials. Doxylamine, 12.5 mg three or four times per day, added to the vitamin B₆ regimen, may be of additional benefit.⁶⁹

Chapter 11

Developmental Origins of Health and Disease

Lucilla Poston, PhD, and Mark Hanson, DPhil

Environmental agents that are active at a sensitive or critical period of development are well recognized to cause teratogenic effects in the embryo or fetus. Obstetricians are also very familiar with the infant mortality and morbidity associated with compromised fetal growth (e.g., the growth restriction of preeclampsia or the macrosomia of maternal diabetes). The more subtle and persistent consequences of perturbations of in utero growth and nutrition are less widely appreciated, but even modest changes in growth and development may have unforeseen consequences that extend into adulthood. Although not immediately evident in the newborn period, these can alter an individual's response to the subsequent challenges of life, leading, ultimately, to a greater risk for adult disease.

The suggestion that compromised growth in utero may enhance risk for adult disease came from early studies implying that small size at birth conferred greater risk for chronic noncommunicable diseases such as cardiovascular disease (coronary heart disease, hypertension, stroke), type 2 diabetes, and osteoporosis.^{1,2} Indeed, the majority of work in this area has concentrated on perturbations in the nutritional environment during prenatal and early postnatal life. Other environmental influences have been implicated in animal models, including temperature, oxygen tension, fluid balance, and stress,^{3,4} but in this review we will concentrate largely on the human situation and early nutritional influences, discussing the evidence, the proposed underlying mechanisms, and possible interventions.

Associations between Low Birth Weight and Adult Disease

How the Concept Arose—The Early Studies

The concept of developmental programming was largely inspired by the reports from Barker and his colleagues in the 1980s, indicating an association between risk for cardiovascular disease and low birth weight in cohorts of middle-aged men and women in the United Kingdom for whom detailed birth records were available.¹ These followed Forsdahl's early study of Norwegian populations suggesting that chronic adult disease was linked to deficiencies in the early childhood environment. Forsdahl stressed that these effects persisted even if cir-

cumstances improved in later years.⁵ Similarly, Lucas had proposed that detrimental influences in early life may increase risk for later disease.⁶ The early papers from Barker and colleagues were followed by others showing that low birth weight was associated not only with increased risk for death from cardiovascular disease but also with insulin resistance and obesity—in fact, with each of the criteria that define the metabolic syndrome. It was proposed that in utero nutritional status could influence risk for both cardiovascular and metabolic disease in later life.

Contemporary Viewpoints

Now, almost 20 years since the “fetal programming” concept was first proposed, we have come to recognize that birth weight is a weak index of in utero nutrition and growth. Smallness at birth can arise either from poor growth beginning in early gestation or from early rapid growth followed by slow growth in late gestation—each likely to arise from different causes. However as growth trajectory data are usually not available for historical cohorts, most studies continue to investigate relationships between birth weight and incidence of later disease.

The validity of the concept has been questioned because of the wide variability reported among associations between birth weight and proxy markers of disease (e.g., adult blood pressure),⁷ but associations are much stronger, and criticism therefore less warranted, when the outcome measure is clinical disease.⁸ It must be kept in mind that pregnancies in the historical cohorts occurred when nutrition and health care were very different from those of contemporary developed societies. The lower-birth-weight individuals in these cohorts, for example, would be unlikely to include fetuses born long before term or with intrauterine growth restriction, and the higher-birth-weight group would be unlikely to include fetuses of diabetic mothers, as these would not have survived in those days.

Testing the Concept in Different Populations

The strength of the idea, however, lies in the reproducibility of the many geographically dispersed cohort studies that have now accumulated. Most, including those from countries other than the United Kingdom, have replicated the original association between lower birth weight and not only adult death from ischemic heart disease⁹ but also nonfatal coronary artery disease and stroke.¹⁰ Indeed, a recent study of

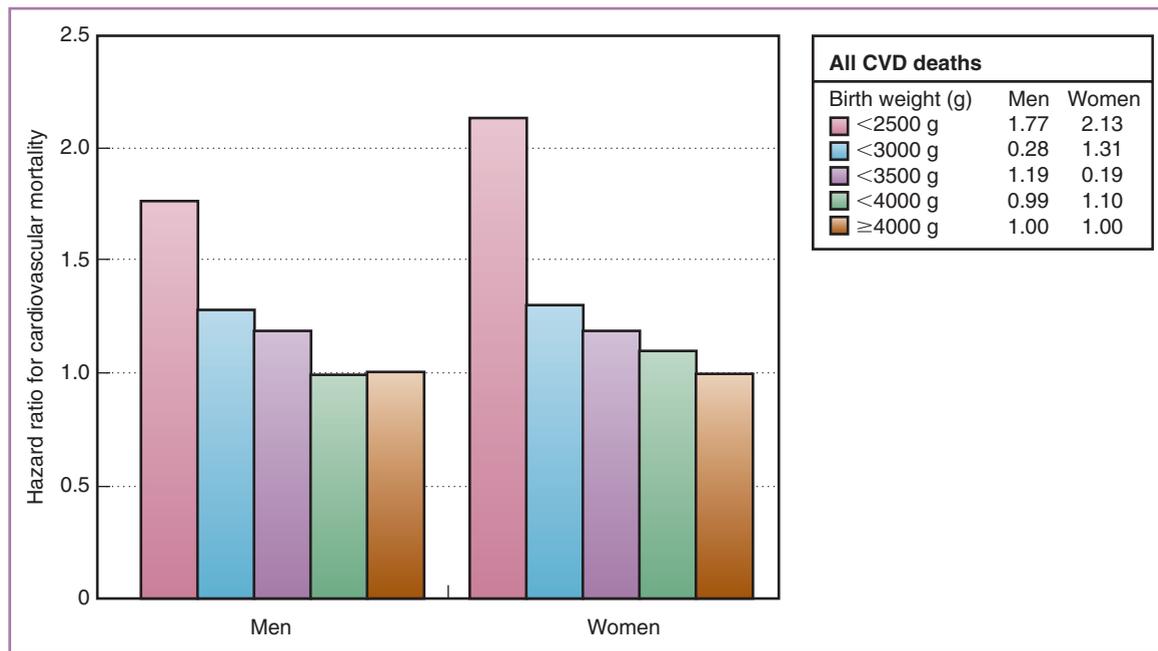

FIGURE 11-1 Risk for cardiovascular disease (CVD) mortality stratified by birth weight. The difference between the sexes is also shown. (Adapted from Kajantie E, Osmond C, Barker D, et al: Size at birth as a predictor of mortality in adulthood: A follow-up study of 350,000 person-years. *Int J Epidemiol* 34:655-663, 2005.)

13,830 men and women for whom records were available from the Finnish National Death Registry showed an association between low birth weight and *all cause* mortality among women.¹¹ The relationship between birth weight and cardiovascular mortality risk for men and women is shown in Figure 11-1.

A recent follow-up study of 10,803 children born in Aberdeen, Scotland, in the 1950s, at a time when environmental influences were more favorable for infants than in earlier studies, has confirmed an inverse association between birth weight and later coronary artery disease and stroke.¹² Other large cohort studies, such as that of almost 90,000 Swedish army recruits born between 1973 and 1981, have also continued to show that lower birth weight is linked to higher adulthood blood pressure and, although small in magnitude, the increment in blood pressure was independent of socioeconomic factors or familial effects.¹³

Even a small rise in blood pressure is important when viewed from the perspective of risk for later disease.¹⁴ A recent meta-analysis of data from 198,000 individuals in 20 Nordic studies (1910 to 1987 cohorts) shows unequivocally an inverse and linear association between birth weight in males, but a U-shaped relationship for females, those with birth weight higher than 4 kg having a higher systolic blood pressure in adult life.¹⁵ Similar confirmation of the association with low birth weight and raised systolic blood pressure has been derived from a British birth cohort study of 3157 men and women born in 1946.¹⁶ Some but not all studies correct adulthood outcomes for current body mass index (BMI), an adjustment that has led to a continuing controversy, as has the failure to account for the influence of growth trajectories at different stages of life and inclusion of subjects taking antihypertensive medication.^{17,18} These criticisms have themselves proved controversial.

A recent review of the literature investigating associations between low birth weight and insulin resistance shows that people with lower weight at birth generally have an adverse profile of later glucose and

insulin metabolism, which is related to insulin resistance rather than altered insulin secretion.¹⁹ Associations of low birth weight and adulthood obesity have also generally stood the test of time,²⁰ and criticisms that the use of BMI, an inaccurate assessment of central obesity, confounded interpretation have been countered by descriptions of inverse associations between birth weight and raised adulthood fat mass, and with reduced lean mass.^{21,22}

Associations between Maternal Weight, Birth Weight, and Adulthood Disease

Diabetes

The rising birth weight in developed countries (with the possible exception of Japan²³), associated with the prevalence of obesity in pregnancy and related gestational diabetes, may also have the potential for detrimental influences on the developing child.^{24,25} After the original suggestion by a few studies showing a U- or J-shaped relationship between birth weight and later insulin resistance and obesity, there is now good evidence that children of women who are diabetic in pregnancy are themselves more likely to develop insulin resistance in later life and to become overweight.²⁶ Although this may represent in part a genetically inherited disorder, studies of sib pairs discordant for maternal diabetes show that this relationship holds only in the offspring prenatally exposed to diabetes, strongly suggesting an acquired diabetic trait.^{27,28} Also, independent of birth weight, infants of mothers with gestational diabetes have a greater neonatal fat mass,²⁹ and a rather alarming report documents a higher rate of childhood meta-

bolic syndrome (central adiposity, insulin resistance, and hypertension) in large-for-gestational-age (LGA) infants born to mothers with gestational diabetes³⁰ than in appropriate-(weight)-for-gestational-age (AGA) infants. Importantly, the risk for metabolic syndrome was also present, but to a lesser extent, in LGA infants from normoglycemic mothers. Higher birth weight in normoglycemic pregnancies is generally associated with raised adulthood BMI, and larger infants tend to become heavier adults. However, detailed investigation of the relative contributions of lean and fat mass have sometimes suggested that this association reflects increased lean body mass rather than fat mass,³¹ although a recent study of infants from obese normoglycemic mothers shows clear evidence of increased adiposity.³²

There have been few attempts to define accurately the relationship between maternal, childhood, and adulthood body composition over any range of maternal BMIs. Ongoing prospective longitudinal studies in contemporary cohorts such as the Avon Longitudinal Study of Parents and Children (ALSPAC) cohort in Avon³³ and the Southampton Women's Survey³⁴ (both in the United Kingdom) will be very informative in this regard. In the latter, it is already clear that a woman's body composition and dietary balance before pregnancy can affect fetal cardiovascular development in late gestation.³⁵

Disorders Associated with Lower Birth Weight

The primary focus in this field has been on developmental origins of cardiovascular disease and disorders of glucose homeostasis, but associations have also been reported between low birth weight and adulthood reduced bone density,³⁶ schizophrenia,³⁷ breast cancer,³⁸ and asthma.³⁹ These have been reviewed recently.⁴⁰

Breastfeeding

Longitudinal studies that have tracked height and weight of the participants have suggested that children who demonstrate rapid growth, either in early infancy or in early childhood, are at risk for adulthood cardiovascular and metabolic disease—children who are small at birth being the most vulnerable.

Investigations among cohorts of very premature children have shown that rapid growth in the first weeks or even days of neonatal life associated with formula feeding may lead to increased risk for cardiovascular disease in adolescents.⁴¹ Rapid weight gain in infancy has, in many studies, been linked to childhood obesity,^{25,42,43} and formula feeding promotes rapid growth in early infancy⁴⁴ and thus may confer an increased risk for obesity in childhood and adolescence.⁴⁵ A study from a U.S. cohort has suggested that obesity in adults (20 to 32 years of age) may be linked to rapid growth in only the first 8 days of life in normal-birth-weight infants fed formula milk.⁴⁶ A meta-analysis of 61 studies has shown that breastfed infants have a reduced incidence of childhood or adulthood obesity compared with those whose mothers opted to feed their infants with formula milk.⁴⁷ These observations fit into the broader framework of greater risk associated with greater “mismatch” between the environment during development and that in later life.⁴⁸

Childhood Growth

One of the largest cohort studies published has linked coronary events to birth weight and early life growth trajectories.⁴⁹ Among 8760 Finnish men and women born between 1934 and 1944, those who suffered coronary events were more likely to have been small at birth and thin

at 2 years, and to have subsequently experienced a greater increase in BMI by 11 years of age. Lower BMI at 2 years of age and increased BMI from age 2 to 11 were also associated with a highly significant elevation of fasting insulin concentrations. Although this study noted a lower risk for coronary events with weight gain at 3 months, no analysis was presented of weight gain in the earliest weeks of life (see previous paragraph), although graphic representation did suggest a rapid growth trajectory in the first few weeks of life for those who had coronary events. Nonetheless, the overall growth trajectory closely resembled that found in India among men and women who developed insulin resistance or diabetes in adulthood.⁵⁰

Importantly, the influences of birth weight and growth during some critical period of childhood remain to be fully established in contemporary cohorts. The different conclusions drawn by Singhal and Lucas⁶ and Barker and colleagues⁴⁹ on the relative importance of postnatal growth may relate to the different historical periods studied, but it may also relate to differences in the subjects (e.g., preterm versus term). Preterm birth itself is also associated with increased risks of type 2 diabetes, independent of size for gestational age.⁵¹ Studies such as those from Finland and the United Kingdom investigated adults who were born in times when nutrition was not abundant and may have been unbalanced, particularly for those born in Finland around the Second World War. The rapid postnatal growth hypothesis has nonetheless been shown to hold in two contemporary studies. One is a study from the ALSPAC cohort of children born in the 1990s, which reported that increased insulin resistance and raised abdominal girth are evident in 8-year-olds born small and those who demonstrated greater weight gain between birth and 3 years.⁵² The other is a report on a young U.K. cohort (22 years of age) that showed that systolic blood pressure is highest in those who were born small but demonstrated rapid weight gain between the ages of 1 and 5.⁵³ Of course, growth from conception onward lies on a continuum, so it is difficult in all these studies to determine the time at which environmental influences induce effects, some of which are manifest later.

Developmental Effects of Antenatal Glucocorticoids

Antenatal steroids are widely used to hasten fetal lung maturation when premature delivery is threatened. However, antenatal administration of steroids in experimental animals evokes persistent and deleterious effects in the developing offspring, which become manifest only in adulthood. The administration of an exogenous glucocorticoid such as dexamethasone during a critical window of early development is detrimental to cardiovascular and renal function and to glucose homeostasis in several species.⁵⁴⁻⁵⁷ Whether this reflects exaggeration of naturally occurring prenatal processes inducing a change in the offspring phenotype or a disruption of *normal* development is not known, but understandable concern has arisen over the prolonged effects of antenatal glucocorticoids given to pregnant women at risk for preterm delivery, despite the uncontested improvement in neonatal respiratory outcome. A recent report has shown elevation of neonatal blood pressure 2 standard deviations above the normal range in 67% of children exposed to multiple courses and 24% exposed to a single course.⁵⁸ However, 31-year-olds who had been exposed to a single course of betamethasone in utero showed no difference in psychological functioning and health-related quality of life compared with those antenatally randomized to placebo.⁵⁹ A report from the same cohort at age 30 years showed a higher plasma insulin concentration at 30 minutes after a 75-g oral glucose tolerance test, possibly indicative of insulin resistance, although cardiovascular indices were unaffected.⁶⁰

The authors suggested that this modest influence on adulthood risk factors does not contraindicate the use of a single course of betamethasone. We must conclude that the gain from administration of antenatal corticosteroids significantly outweighs the potential disadvantage.

The pronounced consequences of maternal glucocorticoid administration described in the animal studies has logically led to concern over the potential effects of maternal stress on the fetus. Several studies in rodents have shown that stress in pregnancy can lead to altered behavior of the offspring and also to altered biochemical responses to stress.⁶¹ Cardiovascular function in adult offspring may also be compromised.⁶² Studies in humans are also strongly indicative of a deleterious and persistent effect of maternal stress on the offspring, with 14 independent prospective studies showing a link between antenatal maternal anxiety (or stress) and cognitive, behavioral, and emotional problems in the child.⁶³

Animal Models

The concept of developmental origins of health and disease has stimulated wide-ranging investigations in animal models.⁶⁴⁻⁶⁶ Studies in rats, mice, sheep, guinea pigs, and nonhuman primates lend strong support to the hypothesis. Most notably, several characteristics of the offspring phenotypes arising from a range of nutritional interventions are shared across species. Indeed, it has proved remarkably easy to demonstrate characteristics equivalent to human disease, particularly features of the metabolic syndrome, through experimental manipulation of the diet of the pregnant animal or her offspring. The effects include aspects of cardiovascular function and glucose homeostasis in the offspring. Adulthood adiposity has also been induced by maternal nutritional intervention, both by undernutrition and overnutrition. In addition, the behavioral effects on the offspring include reduced exploratory behavior and activity levels, and even impaired learning behavior.⁶⁷ These animal models offer the potential for investigation of mechanisms, and thereby suggestions for intervention. The most effective interventions reported have been supplementation of a low-protein diet during pregnancy in the rat with glycine^{68,69} or folate,⁷⁰ and neonatal treatment of the pups with leptin.⁷¹

Mechanistic Insights

Some clear leads regarding mechanisms of developmental programming are beginning to emerge. That sustained effects on the offspring can be produced in very early pregnancy, or even in the preimplantation environment, focuses attention on the early embryo⁷² and raises potential concern about the possible long-term effects of *in vitro* fertilization procedures. Even embryo transfer, with or without culture to blastocyst stage *in vitro*, produces elevated blood pressure in offspring.⁷³ Perhaps changes in the “test tube” milieu explain the increased rate of abnormalities associated with defects of genomic imprinting reported in *in vitro* fertilization infants.⁷⁴

Permanent epigenetic changes are proposed to occur in fetal or neonatal nuclear DNA, either by changes in methylation or in histone packaging, that alter gene expression permanently. Moreover, these changes can be reversed by dietary supplements that promote the provision of methyl groups.⁷⁵ More recently, epigenetic changes have been demonstrated for the first time in nonimprinted genes in the liver of rat offspring, effects that were inversely related to gene expression and that were reversed by maternal dietary folate supplementation.⁷⁶

The effects are associated with changes in DNA methyltransferase activity⁷⁷ and can be passed to grand-offspring.⁷⁸

Permanent alteration to mitochondrial DNA (mtDNA) offers another plausible hypothesis for developmental programming^{79,80} that may be additive to the effects on nuclear DNA. Persistent alteration to mtDNA has been proposed to explain the transgenerational transmission of disorders observed in several animal models^{81,82} and to development of metabolic disorders.

Induction of a phenotype with greater risk for later disease does not have to involve an overall reduction in somatic growth, as suggested by some of the epidemiologic studies and many of the animal models. It appears, therefore, that reduced body growth may not lie directly on the causal pathway to such disease. This does not of course preclude changes in the growth or structure of individual organs, especially if the environmental challenge occurs during sensitive developmental windows. A prime candidate is the kidney. Smaller-birth-weight children have a reduced nephron complement, and deficiency in nephron number has also been linked to the development of hypertension in humans.⁸³ Animal studies using unbalanced nutrition during pregnancy or glucocorticoid treatment have reported reduced nephron number in the offspring.⁸⁴ Moreover, reduction in fetal growth produced by uterine artery ligation in the rat produces epigenetic effects on expression of genes associated with apoptosis in the kidney.⁸⁵ Nearly all nutritional models and a model of reduced uterine blood flow have shown persistent alteration in the pancreatic structure, including a reduction in pancreatic beta cell density.⁸⁶ This may contribute to early pancreatic failure in the presence of peripheral insulin resistance and to the development of overt diabetes later in life. Intriguingly, many studies have suggested that persistent alteration in the appetite centers of the hypothalamus could play a role in inducing later hyperphagia and contribute to obesity.^{87,88}

Time for Intervention?

Nutrient Supplementation

In light of clinical and cohort studies, and indeed of all that is already accepted in relationship to infant morbidity and mortality in children who were small for their gestational age, low birth weight should clearly be prevented whenever possible. Balanced energy and protein supplementation may reduce the risk of delivering a small-for-gestational-age infant in an undernourished woman,⁸⁹ but prevention of low birth weight has proved to be an intractable problem in developed countries.^{90,91} Nutritional interventions with micronutrients may have small effects but have largely failed to show a significant impact,⁹² although it has been argued that the majority of studies have been of inadequate design, and that well-conducted randomized control trials of adequate sample size and appropriate outcome measures are still required.⁹³ Such a study is now under way in Mumbai, India. The Pune nutritional trial⁹⁴ has shown that birth weight is strongly related to maternal folate status and green vegetable intake at 28 weeks' gestation.

Maternal Body Composition

Optimization of maternal pre-pregnancy body composition and nutrition are likely to minimize the “developmental origins” problem, as may improved antenatal and maternal health care in developing countries. Animal models are likely to provide specific direction for effective intervention. For example, maternal administration of the amino acids

taurine and glycine has already been shown to have potential for reversal of disorders of cardiovascular function and glucose metabolism induced by unbalanced maternal nutrition. Importantly, prospective cohort studies are moving away from birth weight as a primary outcome, toward more accurate indices of body composition such as dual-energy x-ray absorptiometry (DEXA). Longitudinal studies of fetal growth trajectories, not just of the fetal body but also of organs such as the liver, kidneys, and placenta, are underway and will be linked to maternal pre-pregnancy characteristics as well as to measures of pregnancy outcome. These studies will have to be continued into childhood with measures of body composition, metabolism and physical activity, cardiovascular function, and glucose and lipid homeostasis. This will be expensive, but it will be an investment that will pay great dividends when translated into public health policy to identify in early life individuals who will be susceptible to later chronic disease, and to give them more individually based advice and interventions.

Maternal Obesity: An Important Public Health Problem

The numerous studies that implicate maternal obesity and associated gestational diabetes in impaired later health of the offspring provide a clear and immediate public health agenda, strongly supporting the benefits of pre-conceptual weight loss in obese women intending to conceive. A recent large cohort study from Scandinavia showing that weight gain between first and second pregnancies is a risk for adverse outcome in the second pregnancy reemphasizes the need to avoid excessive weight gain in pregnancy.⁹⁵ Although it is unwise to recommend calorie restriction in pregnant women, there is a need to identify ideal weight gain in pregnancy, and this will require careful consideration of pre-pregnancy weight, parity, and ethnicity. The Southampton Women's Survey has already made clear that maternal thinness, as judged from skinfold thicknesses, and imprudent diet produce adverse effects on the circulatory adaptations of the late-gestation fetus.³⁵ A range of maternal characteristics, including body composition, smoking, and strenuous exercise in pregnancy, are also associated with lower neonatal bone mineral density,⁹⁶ and most recently a marked correlation between maternal and neonatal adiposity has been observed.⁹⁷ Dietary and exercise interventions that aim to improve insulin sensitivity rather than reduce calorie intake may prove efficacious in improving pregnancy outcome.

Neonatal Feeding Regimens

Optimal neonatal feeding strategies need to be better defined in regard to subsequent risk for obesity and cardiovascular disease, and large randomized controlled trials are underway to define the optimal constituents of formula milk for infants of mothers unable or unwilling to breastfeed. These will also evaluate relationships between neonatal growth rates and risk for later disease.

Developmental Effects on the Human Phenotype: Pathology or Survival?

The acquisition of disease risk in utero as a result of imbalances in the nutritional environment is likely to confer advantage in terms of Darwinian fitness (i.e., survival to reproduce), or the underlying mechanisms would not have been selected during human evolution. The "thrifty phenotype hypothesis" of David Barker and the late Nicholas Hales⁹⁸ concerns a rather special case of this broader phenomenon, in

which fetal phenotypic adaptations are induced in response to nutritional imbalance in utero. These adaptations confer an immediate fetal and neonatal survival advantage, but the individual has to trade this advantage for later detrimental effects in terms of increased risk for adult disease. If disease were to occur only in the post-reproductive phase of life, then it would have no impact on fitness. Fetal blood flow for example, is directed to areas of the body where nutrient delivery is prioritized (e.g., brain, thus depriving the skeletal muscle, which grows less). In later life, the lack of skeletal muscle would confer the advantage of reducing glucose consumption when food was in poor supply—often thought to have been a valuable adaptive response in our hunter-gatherer ancestors. However, should nutritional status be surprisingly good or even excessive, as it is today in many developed nations, the poor capacity of the muscle to take up glucose could eventually contribute to the development of the insulin resistance of type 2 diabetes. In the case of placental insufficiency, the fetus would be tricked into the need to prepare for a life of nutritional inadequacy, when in reality the postpartum life today in developed nations is frequently one of nutritional plenty.

Thrifty Phenotype and Predictive Adaptive Models

The thrifty phenotype hypothesis seems valid in the case of the small-for-gestational-age infant, but it becomes problematic when we consider the graded relationship between, for example, size at birth and risk for later disease, which is manifest across the entire normal range of size at birth. The predictive adaptive response hypothesis proposed by Gluckman and Hanson⁹⁹ suggests that aspects of the prenatal environment are able to induce phenotypic changes in the embryo and fetus that confer advantage in terms of Darwinian fitness because they predict aspects of the postnatal environment. According to this view, the phenotype of the offspring has not been set to cope with a prenatal challenge, but to be best able to respond to predicted postnatal challenges. An accurate prediction would confer greater likelihood of health in the predicted environment, but an inaccurate or inappropriate prediction, such as might occur with a change in the environment caused by socioeconomic change or migration, would be associated with greater risk for disease. Thus it is the mismatch between the predicted and the actual environment that raises risk for disease.⁴⁸ Several lines of experimental evidence in animals now support this concept,^{82,100-102} and evidence is emerging in humans in terms of reproductive functions.¹⁰²

Conclusions

Epidemiologic studies from contemporary and historical cohorts implicate a role for prenatal influences on the risk for later development of adult disease. The influences considered to date have focused largely on maternal diet and body composition, but there is increasing evidence for important effects from maternal smoking, strenuous exercise, stress, drugs such as steroids, pathogens, and environmental pollutants that can act as endocrine disruptors. Many studies have linked lower birth weight with greater risk for adulthood cardiovascular morbidity, obesity, and insulin resistance. Also, considerable data support an association between maternal obesity, or gestational diabetes, and acquisition of risk for type 2 diabetes in the offspring.

Given this foundation of information, there is now a need to conduct more robust, prospective cohort studies to define the prenatal and postnatal phenotypic characteristics that are associated with later

risk for disease, and then to develop prognostic intermediate outcome markers and pilot potential interventions. A few are now underway. It is as yet too early to suggest any specific intervention in pregnancy or in the neonate, except to recommend that obese women lose weight before becoming pregnant and that regular exercise and a balanced diet be adapted. The concepts discussed support a focus for public health measures that aim to optimize nutrition for the mother and child as strategies to prevent obesity and insulin resistance in the population. A new focus on development as part of a life-course perspective is likely to have a very substantial effect in reducing the burden of chronic noncommunicable disease in both developed and developing societies.

Chapter 12

Fetal Cardiovascular Physiology

Jeffrey R. Fineman, MD, and Ronald Clyman, MD

Blood Flow Patterns and Oxygen Delivery

In the mammalian adult, oxygenation occurs in the lungs, and oxygenated blood returns via the pulmonary veins to the left side of the heart to be ejected by the left ventricle into the systemic circulation. In the fetus, gas exchange occurs in the placenta, and the fetal lungs are non-functional as far as the transfer of oxygen and carbon dioxide is concerned. For oxygenated blood derived from the placenta to reach the systemic circulation, the fetal circulation is so arranged that several sites of intercommunication (shunts) are present. In addition, preferential flow and streaming occur to limit the disadvantages of intermixing the oxygenated and deoxygenated blood that returns to the heart. The patterns of blood flow to and from the fetal heart are shown diagrammatically in Figure 12-1. With fetal stress, these preferential streaming patterns may be modified even more to mitigate the adverse effects of disorders such as reduced umbilical blood flow and fetal hypoxemia. Little quantitative information regarding primate fetal circulation is available; the data presented here were obtained mainly from fetal lambs.

Venous Return to the Heart

About 40% of total fetal cardiac output (thus about 200 mL/kg of fetal bodyweight per minute) is distributed to the placental circulation; a similar amount returns to the heart via the umbilical venous system. Because umbilical venous blood is the most highly oxygen-saturated blood in the fetal circulation, distribution of umbilical venous return is most important in determining oxygen delivery to fetal tissues. After entering the intra-abdominal portion of the umbilical vein, a portion of umbilical venous blood flow supplies the liver; the remainder passes through the ductus venosus, which directly connects the umbilical vein–portal sinus confluence to the inferior vena cava (see Fig. 12-1). Unlike the umbilical and portal veins, the ductus venosus has no direct branches to the liver. Umbilical venous blood can enter the ductus venosus directly. Portal venous return, however, can reach the ductus venosus only through the portal sinus.¹ Approximately 50% of umbilical blood flow passes through the ductus venosus; the remainder enters the hepatic-portal venous system and passes through the hepatic vasculature.²

The fetal liver receives its blood supply not only from the umbilical vein but also from the portal vein and hepatic artery. In normal fetal lambs in utero, umbilical venous blood flow contributes approximately

75% to 80% of total blood supply of the liver.²⁻⁴ Portal venous blood flow accounts for about 15%, and hepatic arterial blood flow from the aorta represents only 4% to 5%. The blood from these sources is distributed differently to the various parts of the liver. Hepatic arterial blood flow to the liver is equally distributed to the right and left lobes, but the left lobe is supplied almost exclusively (>95%) by umbilical venous blood. In contrast, the right lobe receives both umbilical venous blood (approximately 60%) and portal venous blood (approximately 30%). Because umbilical venous blood supplies a major portion of flow to the right liver lobe by traversing the portal sinus, little if any portal venous blood reaches the ductus venosus. The blood in the ductus venosus, therefore, has pH, blood gas values, and hemoglobin oxygen saturation values similar to those of umbilical venous blood. The portion of umbilical venous blood flow that passes via the ductus venosus directly into the inferior vena cava meets the systemic venous drainage from the lower body.

Blood flow through the thoracic inferior vena cava represents approximately 65% to 70% of venous return to the heart; flow from the ductus venosus accounts for about one third of this.^{2,5} The two streams (one from the abdominal inferior vena cava and one from the ductus venosus) do not mix, and they demonstrate definite streaming in the thoracic inferior vena cava; the well-oxygenated blood derived from the ductus venosus occupies the dorsal and leftward portion of the inferior vena cava.⁶ This separation of the more highly saturated umbilical venous stream and the desaturated inferior vena caval stream returning from the lower body produces preferential flow of umbilical venous return into the left atrium and then into the left ventricle and ascending aorta.⁶⁻⁸ Of particular importance is preferential streaming of umbilical venous blood to the brain and myocardium.

The preferential streaming of umbilical venous return to the left lobe of the liver and portal venous return to the right lobe also affects the distribution of oxygenated blood to the fetal body. The left hepatic lobe is perfused with umbilical venous blood, which has an oxygen saturation of 80% to 85%; the right lobe is perfused by a mixture of umbilical and portal venous blood, which has a much lower oxygen saturation (approximately 35%). The oxygen saturation of blood in the hepatic veins reflects this difference in perfusion saturation.^{1,4} The oxygen saturation in left hepatic venous blood is about 10% lower than that in umbilical venous blood but about 10% higher than that in right hepatic venous blood, in which the saturation more closely approximates that in the descending aorta.

In fetal lambs, the ductus venosus and left hepatic vein drain into the inferior vena cava, essentially at a common point; partial valves are seen over the entrance of the hepatic vein and ductus venosus into the

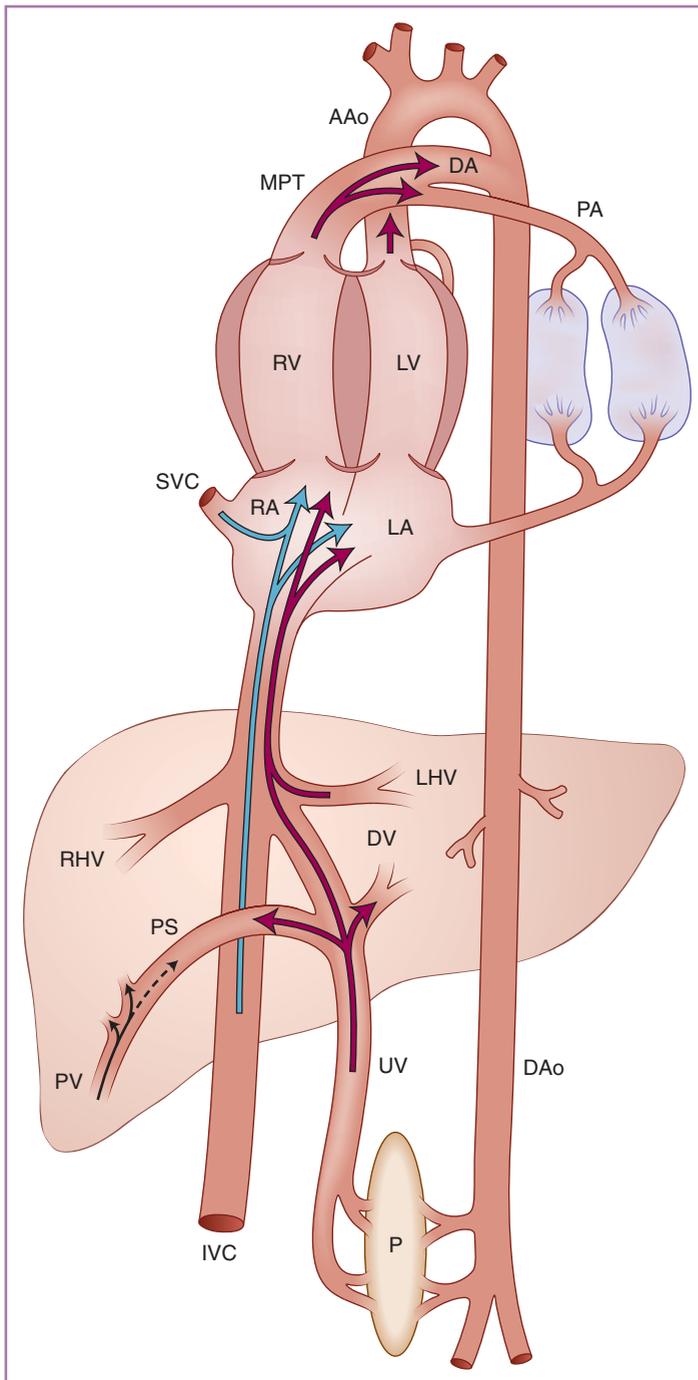

FIGURE 12-1 Diagrammatic representation of the normal fetal circulation and major fetal blood flow patterns. AAo, ascending aorta; DA, ductus arteriosus; DAo, descending aorta; DV, ductus venosus; IVC, inferior vena cava; LA, left atrium; LHV, left hepatic vein; LV, left ventricle; MPT, main pulmonary trunk; P, placenta; PA, main branch pulmonary arteries; PS, portal sinus; PV, portal vein; RA, right atrium; RHV, right hepatic vein; RV, right ventricle; SVC, superior vena cava; UV, umbilical vein.

inferior vena cava.¹ Similarly, the entrance of the right hepatic vein into the inferior vena cava has a valvelike membrane overlying the ostium. This arrangement probably allows left hepatic venous blood to be distributed in a manner similar to that of ductus venosus blood, whereas right hepatic venous blood is distributed similarly to the abdominal inferior vena caval stream. This is particularly important because about half of umbilical venous return passes through the liver, thereby accounting for about 20% of total venous return to the heart. In fetal lambs, left hepatic venous blood flow follows the same pattern as ductus venosus flow, with preferential streaming to the brain and heart.⁴ Similarly, right hepatic blood flow follows the distribution pattern of abdominal inferior vena caval blood flow.

The inferior vena caval blood then enters the right atrium, and because of the position of the foramen ovale, more preferential streaming occurs. The foramen ovale is situated low in the interatrial septum, close to the inferior vena cava. The cephalad margin of the foramen, formed by the lower margin of the septum secundum, lies on the right side of the atrial septum; it is called the crista dividens and is positioned so that it overrides the orifice of the inferior vena cava. The crista dividens therefore splits the inferior vena caval bloodstream into an anterior and rightward stream that enters the right atrium, and a posterior and leftward stream that passes through the foramen ovale into the left atrium. It is this latter stream that has the more highly saturated blood returning from the umbilical circulation through the ductus venosus and left hepatic lobe. Despite this anatomic arrangement and the preferential streaming in the inferior vena cava, some mixing of blood does occur; a portion of the more highly saturated umbilical venous blood passes directly into the right atrium, and some desaturated abdominal inferior vena caval blood passes into the left atrium. The net result, however, is still a significantly higher saturation in the left atrium than in the right (Fig. 12-2).

Blood returning to the heart via the superior vena cava also streams preferentially once it reaches the right atrium. The crista interveniens, situated in the posterolateral aspect of the right atrial wall, effectively directs superior vena caval blood toward the tricuspid valve. The coronary sinus, which drains blood from the left ventricular myocardium, enters the right atrium between the crista dividens and the tricuspid valve; the very desaturated coronary venous return (saturation approximately 20%) is therefore also preferentially directed toward the tricuspid valve. This preferential streaming of superior vena caval and coronary sinus venous return to the right ventricle is also advantageous in the fetal circulation, because this very desaturated blood is preferentially directed toward the placenta for reoxygenation. Pulmonary venous return to the heart enters the left atrium, where it mixes with the portion of inferior vena caval blood that has crossed the foramen ovale to enter the left atrium.

Approximately 65% of total cardiac output reaches the lower body and placenta and returns via the thoracic inferior vena cava to the heart. Of this inferior vena caval return, approximately 40% crosses the foramen ovale to the left atrium; the remaining 60% enters the right ventricle across the tricuspid valve. The amount of inferior vena caval return crossing the foramen ovale therefore represents about 27% of total fetal cardiac output. This blood then combines with pulmonary venous return (approximately 8% of total fetal cardiac output) and represents the output of the left ventricle, or approximately 35% of total fetal cardiac output. The venous return from the superior vena cava, the coronary sinus, and the remainder of the inferior vena caval return (approximately 40% of total fetal cardiac output) enters the right ventricle and represents the portion of total fetal cardiac output ejected by the right ventricle (approximately 65% of total fetal cardiac output).

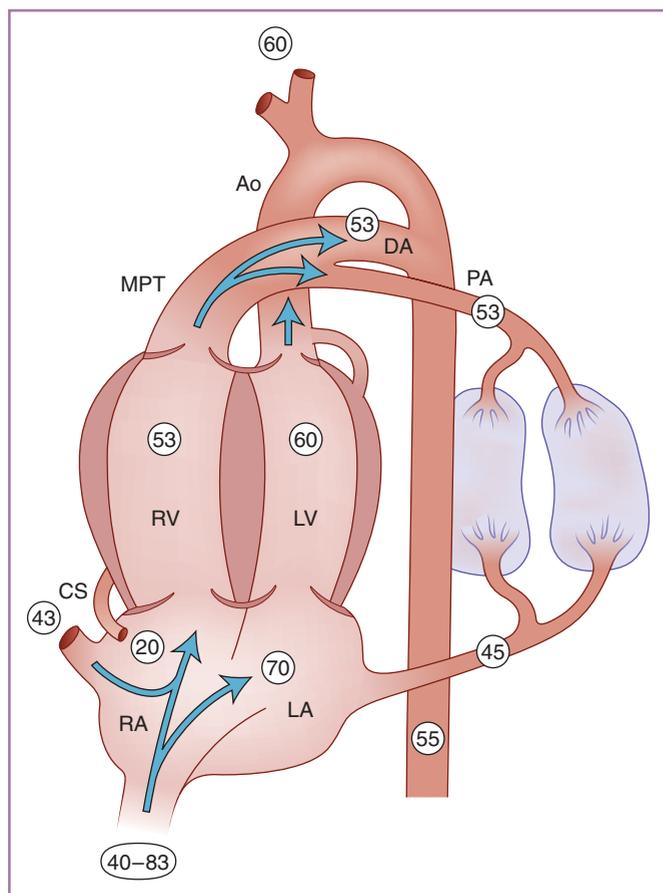

FIGURE 12-2 Hemoglobin oxygen saturation. Representative normal hemoglobin oxygen saturation data (circled numbers indicate percent saturation) in the heart and major vascular channels in fetal lambs. Ao, aorta; CS, coronary sinus; DA, ductus arteriosus; LA, left atrium; LV, left ventricle; MPT, main pulmonary trunk; PA, main branch pulmonary arteries; RA, right atrium; RV, right ventricle.

Cardiac Output and Its Distribution

In the fetus, because of the blood flow across the ductus arteriosus into the descending aorta, lower body organs are perfused by both the right and left ventricles (across the aortic isthmus). For this reason and because of intracardiac shunting, it is customary to consider fetal cardiac output as being the total output of the heart, or the combined ventricular output. In fetal lambs, this is about 450 mL/kg/min. Unlike in the adult, and because of the various sites of intracardiac and extra-cardiac shunting, the left and right ventricles in the fetus do not eject in series and therefore do not need to have the same stroke volume. In fact, as shown in Figure 12-3, the right ventricle ejects approximately two thirds of total fetal cardiac output (approximately 300 mL/kg/min), whereas the left ventricle ejects only a little more than one third (approximately 150 mL/kg/min).⁹

Echocardiographic studies in human pregnancy have suggested that in humans also, the right ventricle dominates the left.¹⁰⁻¹⁴ Of the 65% of cardiac output ejected by the right ventricle, only a small amount (8%) flows through the pulmonary arteries to the lungs. The remainder (57%) crosses the ductus arteriosus and enters the descending aorta. Because right ventricular output contains all superior vena caval and coronary sinus return, it allows this unoxygenated venous blood to be preferentially returned to the placenta. Left ventricular

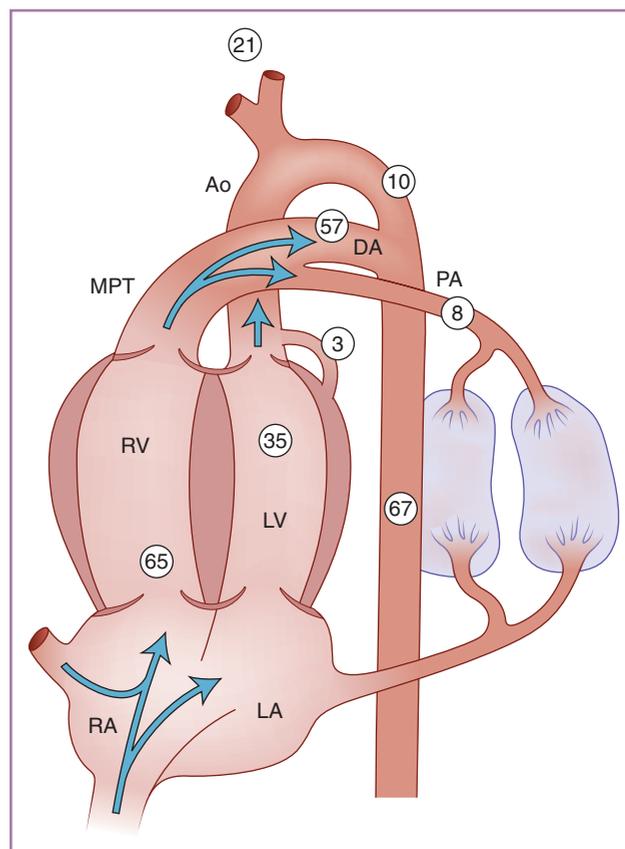

FIGURE 12-3 Cardiac output leaving the heart. Representative normal values for percentages (circled numbers) of total cardiac output (combined ventricular output) ejected by the heart and passing through the major arteries leaving the heart in fetal lambs. Ao, aorta; DA, ductus arteriosus; LA, left atrium; LV, left ventricle; MPT, main pulmonary trunk; PA, main branch pulmonary arteries; RA, right atrium; RV, right ventricle.

output (approximately 35% of cardiac output) enters the ascending aorta; in the fetal lamb, approximately 21% reaches the brain, head, upper limbs, and upper thorax. About 10% of cardiac output traverses the aortic isthmus and joins the blood flowing across the ductus arteriosus to perfuse the descending aorta.

The level of hemoglobin oxygen saturation in the ventricles and great arteries is determined by the streaming patterns into, through, and out of the fetal heart. The highly saturated umbilical venous return streams preferentially across the foramen ovale into the left atrium, where it mixes with the relatively small amount of desaturated blood returning from the pulmonary veins. The net result is that blood ejected by the left ventricle to the ascending aorta is relatively well oxygenated (saturation about 60%). On the other hand, the extremely desaturated coronary sinus venous return and the desaturated blood returning from the brain and upper body flow almost exclusively across the tricuspid valve into the right ventricle. This blood mixes with the inferior vena caval stream, which is primarily composed of desaturated blood returning from the lower body but also contains some umbilical venous return. The net result is that the oxygen saturation of blood in the right ventricle is lower than that in the left. This blood perfuses the fetal lungs and traverses the ductus arteriosus to the descending aorta, from which it perfuses lower body organs and reaches the placenta for reoxygenation.

TABLE 12-1 NORMAL FETAL pH AND BLOOD GAS DATA

	Umbilical Vein	Descending Aorta	Ascending Aorta
pH	7.40-7.43	7.36-7.39	7.37-7.40
PO ₂ (mm Hg)	28-32	20-23	21-25
PCO ₂ (mm Hg)	38-42	43-48	41-45

PCO₂, partial pressure of carbon dioxide; PO₂, partial pressure of oxygen.

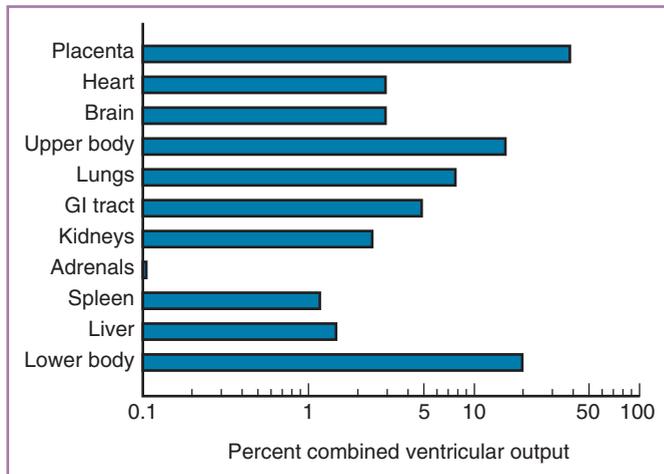

FIGURE 12-4 Cardiac output to organs. Representative normal values for the percentages of total cardiac output (combined ventricular output) distributed to different organs or parts in fetal lambs. GI, gastrointestinal.

Blood gas and pH values in the fetus also reflect the preferential streaming patterns. The data shown in Table 12-1 represent values usually found in healthy catheterized fetal animals. Both daily variability and variability between animals are seen. During a normal uterine contraction, arterial blood has a lower partial pressure of oxygen than under truly resting conditions. In addition, during the last 7 to 10 days of gestation, partial pressure of oxygen declines slightly and partial pressure of carbon dioxide increases commensurately.

The distribution of blood flow to individual organs is shown in Figure 12-4. Because arterial blood supply to lower body organs is derived from both the left and right ventricles, it is customary to express organ flow as a percentage of the combined output of both ventricles (i.e., the combined ventricular output), and the values shown in Figure 12-4 are typical.^{5,15} These values remain fairly constant throughout the last third of gestation, the period in which such measurements have been made. There is, however, a slight increase in the percentage of combined ventricular output distributed to the heart, brain, and gastrointestinal tract in the 10 days before parturition. The flow distributed to the lungs increases from approximately 4% to 8% of combined ventricular output between 125 and 130 days (0.85) of gestation. Organ blood flows are shown in Table 12-2. Umbilical placental blood flow, like combined ventricular output, is usually not considered in relationship to placental weight, which is quite variable, but rather is expressed in relationship to fetal weight. Placental blood flow is approximately 200 mL/kg/min.

TABLE 12-2 BLOOD FLOW TO ORGANS IN NORMAL, NEAR-TERM FETAL LAMBS

Organ	Blood Flow (mL/100 g organ weight/min)
Heart	180
Brain	125
Upper body	25
Lungs	100
Gastrointestinal tract	70
Kidneys	150
Adrenals	200
Spleen	200
Liver (hepatic arterial)	20
Lower body	25

Intracardiac and Vascular Pressures

Vascular pressure in the fetus reflects the preferential streaming patterns described previously. Although the ductus venosus is a fairly large and widely dilated structure, there is a high flow returning from the placenta through the umbilical veins, and therefore this structure offers some resistance to flow. Umbilical venous pressure is generally 3 to 5 mm Hg higher than that in the inferior vena cava (Fig. 12-5). Right atrial pressure is also higher than left atrial pressure because of the greater volume of flow through the right atrium. Although the ductus arteriosus is widely patent, it too offers a small resistance to flow. Therefore, systolic pressures in the main pulmonary trunk and the right ventricle are slightly higher (1 to 2 mm Hg) than those in the aorta and left ventricle.

The representative pressure data shown in Figure 12-5 would be expected in a fetus close to term. Arterial pressures increase slowly and progressively over the last third of gestation, reaching these values shortly before parturition. Measurement of intravascular pressures in the fetus reflects the additional amniotic pressure not found after birth. Because intra-amniotic pressure is used as the zero reference point, the values presented exclude this additional pressure and are therefore true vascular pressures.

Myocardial Function

Cardiac output is determined by the interrelationships of preload, afterload, myocardial contractility, and heart rate. Preload (ventricular filling pressure) reflects the initial muscle length, which by the Frank-Starling principle influences the development of myocardial force. Afterload (the impedance to ejection from the ventricles) is reflected basically by arterial pressure. Contractility reflects the intrinsic inotropic capability of the myocardium.

Studies of fetal myocardium show immaturity of structure, function, and sympathetic innervation relative to the adult.¹⁶⁻²⁰ At all muscle lengths along the curve of length versus tension, the active tension generated by fetal myocardium is lower than that generated by adult myocardium.¹⁶ In addition, resting, or passive, tension is higher in fetuses than in adults, suggesting lower compliance of fetal myocardium.

Studies in chronically instrumented intact fetal lambs showed that after volume loading by the infusion of blood or saline, the right

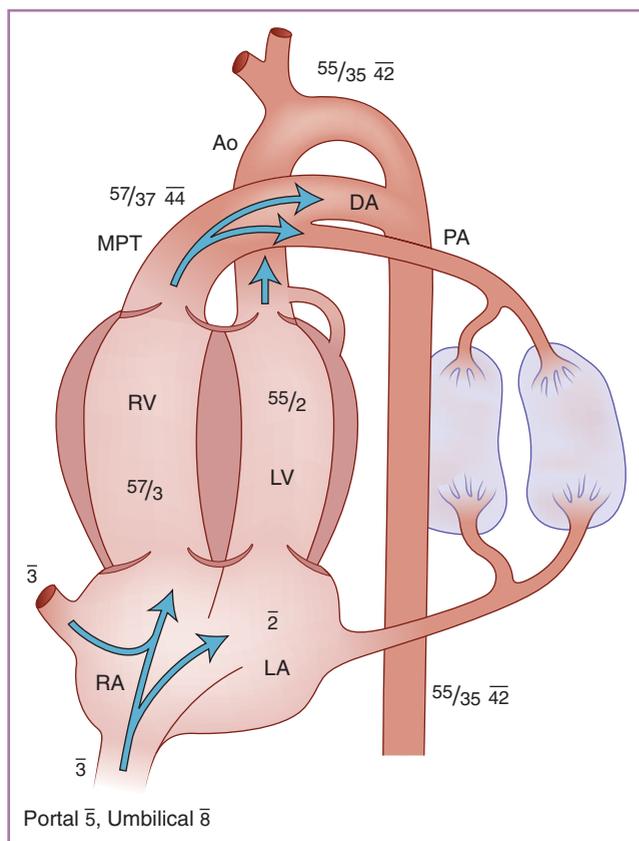

FIGURE 12-5 Normal vessel and chamber pressures. Representative normal pressures in millimeters of mercury (mm Hg) in various vessels and cardiac chambers in fetal lambs. (Measurements given as systolic pressure/diastolic pressure; $\bar{}$ indicates mean pressure.) Ao, aorta; DA, ductus arteriosus; LA, left atrium; LV, left ventricle; MPT, main pulmonary trunk; PA, main branch pulmonary arteries; RA, right atrium; RV, right ventricle.

ventricle is unable to increase stroke work or output to the same extent as in the adult.¹⁷ This is particularly true in less-mature fetuses, in whom right ventricular end-diastolic pressure is markedly elevated without any obvious change in right ventricular stroke work. Similar results are found for both the left and right ventricles but with some ability to increase output or work at lower pressures, between 2 and 5 mm Hg.¹⁸⁻²⁰ Limitations in stroke work increase with increasing filling pressure have been shown to be afterload dependent and, for the left ventricle, are probably affected by right ventricular mechanical constraint.^{21,22}

Fetal and adult sarcomeres have equivalent lengths,²³ but there are major ultrastructural differences between fetal myocardium and adult myocardium. The diameter of the fetal cells is smaller and, perhaps more importantly, the proportion of noncontractile mass (i.e., of nuclei, mitochondria, and surface membranes) to the number of myofibrils is significantly greater than in the adult. In the fetal myocardium, only about 30% of the muscle mass consists of contractile elements; in the adult, the proportion is about 60%. These ultrastructural differences are probably responsible for the age-dependent differences in performance.¹⁶

In newborn lambs, stroke volume is decreased at afterload levels considered low for adult animals.²⁴ Gilbert²⁰ showed that in fetal animals, an increase in arterial pressure of about 15 mm Hg, produced

by methoxamine infusion, depresses the cardiac function curve so that cardiac output averages 25% to 30% less than normal. The extent of shortening is less in the fetus at any level of tension than in the adult—a potential explanation for the effects of afterload on stroke volume.¹⁶

In chronically instrumented fetal lambs, there is a close relationship between cardiac output and heart rate. Spontaneous and induced changes in heart rate are associated with corresponding changes in left or right ventricular output. Increasing heart rate from the resting level of about 180 up to 250 to 300 beats/min increases cardiac output 15% to 20%. Likewise, decreasing heart rate below the resting level significantly decreases ventricular output.

The fetal heart normally appears to operate near the top of its cardiac function curve. An increase in heart rate results in only a modest increase in output; however, bradycardia can reduce output significantly. At an atrial filling pressure of greater than approximately 8 mm Hg, there is little or no increase in output because the length-to-tension relationship has reached a plateau. In addition, the fetal heart is sensitive to changes in afterload.

Sympathetic and Parasympathetic Innervation

Isolated fetal cardiac tissue has a lower threshold of response to the inotropic effects of norepinephrine than does adult cardiac tissue and is more sensitive to norepinephrine throughout dose-response curves.¹⁶ Because isoproterenol, a direct β -adrenergic agonist that is not taken up and stored in sympathetic nerves, has similar effects on fetal and adult myocardium, the supersensitivity of fetal myocardium to norepinephrine is probably the result of incomplete development of sympathetic innervation in fetal myocardium. Myocardial concentrations of norepinephrine in the fetus within several weeks of term are significantly lower than in newborn animals, and activity of tyrosine hydroxylase, the intraneuronal enzyme responsible for the first transformation in catecholamine biosynthesis, is also reduced.¹⁶ In contrast, adrenal gland tyrosine hydroxylase activity at the same gestational age is not suppressed, possibly because the decrease in myocardial activity is related to delayed sympathetic innervation rather than to a generalized immaturity.

Monoamine oxidase, the enzyme responsible for oxidative deamination of norepinephrine, is also present in lower concentrations in the fetal heart than in the adult. Histochemical evaluation of the development of sympathetic innervation using the monoamine fluorescence technique has further substantiated the delayed development of sympathetic innervation of the fetal myocardium. At term, sympathetic innervation is incomplete. Patterns of staining indicate a progression of innervation, starting at the area of the sinoatrial node and progressing toward the left ventricular apex.^{25,26}

Although sympathetic nervous innervation appears to begin developing in the fetal heart by about 0.55 of gestation, β -adrenergic receptors seem to be present much earlier and can be stimulated by appropriate agonists before 0.4 of gestation.²⁷ Before about 0.55 of gestation (80 days of gestation in the lamb), fetal myocardium may be affected by circulating catecholamines, but local reflex activity through the sympathetic nervous system is not likely to play a major role in circulatory regulation.

Vagal stimulation at about 0.85 of gestation produces bradycardia. Administering atropine at 0.55 of gestation produces a modest increase in fetal heart rate,²⁸ indicating that vagal innervation is present by this stage of development. Histochemical staining for acetylcholinesterase in close-to-term fetuses has shown that the concentrations of this

enzyme, which is responsible for metabolism of acetylcholine, are similar to those found in adults.

Energy Metabolism

In the normal unstressed fetus, myocardial blood flow is about 180 mL/min/100 g tissue, approximately 80% more than in the adult. Fetal myocardial oxygen consumption, as measured in the left ventricular free wall, is about 400 mM/100 g/min, similar to that in the adult. In adult sheep, free fatty acids provide the major source of energy for the myocardium, and carbohydrate accounts for only about 40% of myocardial oxygen consumption.²⁹ In fetal sheep under normal conditions, however, free fatty acid concentrations are extremely low, and almost all the oxygen consumed can be accounted for by carbohydrate metabolism—glucose for 33%, pyruvate for 6%, and lactate for 58% of the oxygen consumed by the left ventricular free wall.

ATPase activity in fetal myocardium is equal to that in adult myocardium, suggesting that energy utilization by the contractile apparatus is similar in fetal and adult myocardium.¹⁶ Mitochondria from fetal myocardium demonstrate higher oxidative phosphorylation than those from adult myocardium. The higher oxygen consumption in fetal mitochondria uncoupled by deoxyribonucleoprotein suggests that the augmented respiratory rate in mitochondria is a reflection of increased electron transport.¹⁶ This is consistent with the greater cytochrome oxidase activity in fetal mitochondria.

Control of the Cardiovascular System

Maintenance of normal cardiovascular function, blood pressure, heart rate, and distribution of blood flow represents a complex interrelationship between local vascular and reflex effects. These effects are initiated by the stimulation of various receptors, and they are mediated through the autonomic nervous system as well as through hormonal influences. Although some information is available about how these mechanisms affect the circulation after stress, little is known about their role in normal fetal cardiovascular homeostasis. To complicate the situation, other factors, such as sleep state, electrocortical activity, and uterine activity, transiently affect the circulation. As a result, this area of fetal physiology is difficult to study and the data are difficult to interpret.

Local Regulation

As the oxygen content of blood perfusing the fetus falls, blood flow to the brain, myocardium, and adrenal gland increases; on the other hand, pulmonary blood flow falls as oxygen content decreases. Local effects of changes in oxygen environment are less clearly established for other organs.

Many adult organs exhibit autoregulation, the ability to maintain constant blood flow over a fairly wide range of perfusion pressures. In the fetus, the umbilical-placental circulation does not exhibit autoregulation, and blood flow changes in relation to changes in arterial perfusion pressure.³⁰ On the other hand, the cerebral circulation in fetal lambs does show autoregulatory capability.³¹

Baroreflex Regulation

In chronically instrumented fetal lambs, the fetal heart rate slows after an acute increase in systemic arterial pressure.^{32,33} This baroreflex

response, although present by 0.55 (80 days) of gestation, is poorly developed early on, but the sensitivity of the reflex to induced changes in pressure increases with advancing gestation. Carotid denervation partially inhibits the response, and combined carotid and aortic denervation abolishes it. Parasympathetic blockade with atropine also abolishes the reflex. Although the existence of the arterial baroreflex is established, Dawes and associates³⁴ suggested that the threshold for fetal baroreflex activity is above the range of the normal fetal arterial blood pressure and that this reflex is not important in controlling cardiovascular function in utero.

Carotid sinus and vagus nerve activity are synchronous with the arterial pulse, suggesting continuous baroreceptor activity.^{35,36} Marked fluctuations in the arterial blood pressure and heart rate are observed after sinoaortic denervation, although the average arterial blood pressure and heart rate are not different from those in controls.³⁷

The baroreflex in fetal animals requires fairly marked changes in pressures to produce relatively minor responses. Sinoaortic denervation increases heart rate and blood pressure variability, however. Under normal circumstances, therefore, baroreceptor function acts to stabilize the heart rate and blood pressure. In the fetus, as in the adult, baroreflex control is also influenced by hormonal systems.³⁸

Chemoreflex Regulation

In general, chemoreceptor stimulation by sodium cyanide injection induces hypertension and bradycardia.^{39,40} Central or carotid chemoreceptor stimulation causes hypertension and mild tachycardia with increased respiratory activity, whereas aortic chemoreceptor stimulation produces bradycardia with modest increases in arterial blood pressure. Because the carotid chemoreceptors are less sensitive than the aortic chemoreceptors, hypertension and bradycardia usually result. In chronically instrumented fetal lambs, sodium cyanide produces bradycardia with variable blood pressure changes, responses abolished by sinoaortic denervation.⁴¹ Fetal hypoxia produces bradycardia and hypertension, which are abolished by carotid sinus denervation.⁴²

Autonomic Nervous System and Adrenal Medulla

As described earlier, sympathetic innervation of the heart is not complete until term or, in some species, until after delivery. In contrast, cholinergic innervation, as measured by the presence of acetylcholinesterase, appears to be fully developed during fetal life. The innervation of other vascular beds also appears to proceed at different rates during gestation.⁴³

Adrenergic receptors are present in the fetus and have been demonstrated in myocardium.⁴⁴⁻⁴⁶ Receptor populations that have been studied in the fetus exhibit characteristics similar to those in adults.^{47,48} The fetus possesses mature adrenergic receptors fairly early in gestation, but the concentration of receptors is different from that in adult organs.⁴⁴ The fetal concentration of receptors can be altered by administering thyroid hormone or isoxsuprine to the mother.

Injecting cholinergic or adrenergic agonists into fetal sheep produces responses at as early as 0.4 (60 days) of gestation.^{27,49} α -Adrenergic stimulation with methoxamine produces an increase in arterial blood pressure, a small decrease in cardiac output, an increase in blood flow to the lungs, and a marked decrease in kidney and peripheral blood flow at as early as 0.5 of gestation. β -Adrenergic stimulation by isoproterenol causes a response earlier in gestation and an increase in heart rate with little or no change in arterial blood pres-

sure and cardiac output. Blood flow to both the myocardium and the lungs is increased. Administration of acetylcholine decreases blood pressure and heart rate and increases pulmonary blood flow markedly, particularly in fetuses close to term.

Although receptor affinity is well developed during fetal life, the response to a specific agonist is blunted relative to the adult. The maximal constrictor response to norepinephrine or nerve stimulation increases throughout the latter part of gestation, and even more after birth.⁵⁰ The increase might result from gestational differences in neurotransmitter release in the fetus. During the last trimester of gestation, there is a progressive increase in maximal pressor response to ephedrine, which exerts its effect indirectly through neurotransmitter release; phenylephrine has a direct pressor effect.⁵¹ In addition, neurotransmitter reuptake in sympathetic nerve terminals is not fully mature in the fetus.⁴⁸ Similarly, the differences between fetal and adult myocardium with respect to threshold and sensitivity to norepinephrine indicate an immature reuptake mechanism for norepinephrine in the fetus.¹⁶

As gestation progresses, these variable rates of maturation of different components of the autonomic nervous system modify control mechanisms relating to the autonomic nervous system. The role of β -adrenergic stimulation in resting circulatory regulation has been evaluated by pharmacologic blockade of β -adrenergic receptors with propranolol. This component of the sympathetic nervous system exerts a positive influence over fetal heart rate that first appears at about 0.6 (80 to 90 days) of gestation,²⁸ but this influence is relatively small.⁵² During stress such as hypoxia or hemorrhage, however, β -adrenergic activity appears to be increased because propranolol produces much greater changes in heart rate.

α -Adrenergic control of the circulation has a somewhat clearer developmental pattern. α -Adrenergic blockade with phentolamine or phenoxybenzamine reduces arterial blood pressure very little, if at all, before 0.75 (100 to 110 days) of gestation; thereafter, there is a progressive increase in response, indicating a progressive increase in resting vascular tone attributed to α -adrenergic nervous activity. The parasympathetic nervous system exerts an inhibitory influence over fetal heart rate that is present by 0.55 (80 days) of gestation.^{28,52} Parasympathetic blockade with atropine produces small changes at this age, with a progressive increase in parasympathetic control as gestation advances. After approximately 0.85 (120 to 130 days) of gestation, no further increase is evident.

Hypoxemia or asphyxia increases circulating plasma catecholamine concentrations in fetal sheep.⁵³⁻⁵⁵ In fetuses younger than about 120 days' gestation, when the adrenal gland becomes innervated, extremely low fetal blood oxygen concentrations are required to stimulate the adrenal gland; thereafter, catecholamine secretion can be induced by more moderate hypoxemia.⁵³ Infusing catecholamines to reach plasma concentrations that mimic those observed during hypoxemia produces circulatory changes similar to those seen during hypoxemia.⁵⁶ Adrenal medullary responses to stress appear to play a role in circulatory adjustments; whether catecholamine secretion exerts a continuous regulatory function is not clear.

Hormonal Regulation of the Circulation Renin-Angiotensin System

The renin-angiotensin system is important in regulating the normal fetal circulation and its response to hemorrhage. The juxtaglomerular apparatus in the kidneys is well developed in fetuses and is present by 0.6 (90 days) of gestation.⁵⁷ Plasma renin activity, as well as circulating angiotensin II, is present in fetal plasma as early as about 0.6 (90 days)

of gestation.⁵⁸⁻⁶⁰ The effects of fetal stress such as hemorrhage and hypoxia on the renin-angiotensin system are not absolutely clear. In some studies, small amounts of hemorrhage increase plasma renin activity^{57,58}; other studies, however, have shown little effect.⁶¹ Similarly, the effects of hypoxemia on the renin-angiotensin system in the fetus are controversial, but most likely hypoxemia is of little consequence.

When angiotensin II is infused to achieve plasma concentrations similar to those that occur after a moderate (15% to 20%) hemorrhage, there are broad cardiovascular effects.⁶² Arterial blood pressure increases markedly, and after an initial abrupt bradycardia, heart rate increases. Combined ventricular output increases, as does blood flow to the lungs and myocardium. Renal blood flow decreases, but umbilical placental flow is unchanged; this latter phenomenon indicates vascular constriction in the umbilical-placental circulation because arterial blood pressure increases but flow does not. The increase in myocardial blood flow is probably caused by an increase in stroke work, and the large increase in pulmonary blood flow probably reflects the release of some other local pulmonary vasodilating substance, such as one of the prostaglandins.⁶³

Inhibiting the action of angiotensin II by specific inhibitors, such as saralasin, has somewhat variable effects. In unstressed fetal animals, however, generally a fall in mean arterial pressure and a slight decrease in heart rate occur.⁵⁹ Combined ventricular output is unaltered, but umbilical-placental blood flow falls, probably in association with the fall in systemic arterial pressure. Blood flow to the peripheral tissues, adrenal glands, and myocardium increases. During hemorrhage, the effects of saralasin are markedly accentuated and result in profound hypotension and bradycardia.

Under normal resting conditions, endogenous angiotensin II appears to exert a tonic vasoconstriction on the peripheral vascular bed, thereby maintaining systemic arterial blood pressure and umbilical-placental blood flow. In response to hemorrhage, angiotensin II is released and produces more vasoconstriction in the periphery, as well as other cardiovascular effects, thereby maintaining systemic arterial blood pressure and umbilical blood flow.

Vasopressin

Arginine vasopressin (antidiuretic hormone) has been detected as early as 0.4 (60 days) of gestation in fetal lambs.⁶⁴ Although hypoxia and hemorrhage, as well as many other stimuli such as hypotension and hypernatremia, induced a marked increase in plasma vasopressin concentrations,^{64,65} it is unlikely that vasopressin plays a major role in normal circulatory regulation. Maximal antidiuresis in adults occurs with vasopressin concentrations that have no discernible effects on systemic blood pressure. Fetal vasopressin concentrations are below this level.

Infusing vasopressin into fetal sheep to produce concentrations similar to those observed during fetal hypoxemia produces hypertension and bradycardia.⁶⁰ Combined ventricular output decreases slightly, but the proportion distributed to the gastrointestinal tract and peripheral circulations falls, whereas that to the umbilical-placental, myocardial, and cerebral circulations increases. These findings indicate that vasopressin probably participates in fetal circulatory responses to stress not only directly but also by enhancing pressor responses to other vasoactive substances. Under resting conditions, however, vasopressin apparently has little regulatory function.

Natriuretic Peptides

Atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP), belong to a potent volume-regulating family of cardiac hormones

released from the atria and ventricles in response to myocyte stretch, and other stimuli such as α -agonist stimulation, endothelin 1 (ET-1), and cytokines.⁶⁶ These peptides have potent vasodilatory, diuretic, natriuretic, and growth inhibitory actions via the secondary messenger cGMP. The natriuretic system appears to be functional by mid gestation, and it is able to regulate systemic and pulmonary blood pressures as well as salt and water balance in the fetus. In addition, these peptides are regulated during heart development, suggesting an important role for the natriuretic peptides in the developing cardiovascular system. Finally, both ANP and BNP have potent vasodilating properties in the placenta and thus may be important regulators of placental blood flow.^{67,68}

Arachidonic Acid Metabolites

Although prostaglandins generally are locally active substances that do not normally circulate in adult blood, relatively high concentrations do normally circulate in the fetus.^{69,70} It is likely that these prostaglandins are derived from the placenta. The fetal vasculature is also capable of producing prostaglandins, and the umbilical vessels, ductus arteriosus, and aorta produce significant amounts of prostaglandin E and prostacyclin (also known as prostaglandin I₂ [PGI₂]).

Prostaglandins administered to the fetus have diverse and extensive cardiovascular effects. Prostaglandin E₁ (PGE₁) and prostaglandin E₂ (PGE₂) constrict the umbilical-placental circulation.^{71,72} Prostaglandin F_{2 α} and thromboxane also cause constriction, whereas PGI₂ dilates the umbilical-placental circulation. PGE₁, PGE₂, PGI₂, and prostaglandin D₂ produce pulmonary vasodilatation in the fetus, whereas prostaglandin F_{2 α} produces constriction.⁷³ Infusing PGE₁ into fetal sheep has no effect on cardiac output or systemic pressure, but in addition to a reduction in umbilical-placental blood flow, there are increases in flow to the myocardium, adrenals, gastrointestinal tract, and peripheral tissues.⁷⁴

Of great interest is the role of prostaglandins in maintaining patency of the ductus arteriosus in the fetus. Circulating prostaglandins, as well as PGE₂ and PGI₂ produced locally in the ductus arteriosus, play a major role in maintaining the ductus arteriosus in a dilated state in utero.⁷⁵⁻⁷⁷ For details of the overall physiologic regulation of the ductus arteriosus (see Ductus Arteriosus, later).

The role of endogenous prostaglandin production in regulating other fetal vascular beds has been elucidated by administering inhibitors of prostaglandin synthesis to the fetus. Although PGE₂ produces umbilical-placental vasoconstriction, inhibition of prostaglandin synthesis has little effect on umbilical-placental vascular resistance, suggesting that prostaglandins do not normally regulate the umbilical-placental circulation. When prostaglandin synthesis is inhibited, the proportion of blood flow to the gastrointestinal tract, kidneys, and peripheral circulation decreases, indicating an increase in vascular resistance in these tissues. Vascular resistances to other tissues are essentially unchanged.

Although prostaglandins do not appear to be central to regulation of the resting fetal pulmonary circulation, PGI₂ may act to modulate tone and thereby maintain pulmonary vascular resistance relatively constant. However, leukotrienes, also metabolites of arachidonic acid and potent smooth muscle constrictors, may play an active role in maintenance of the normally high fetal pulmonary vascular resistance. In newborns,⁷⁸ leukotriene inhibition attenuates hypoxic pulmonary vasoconstriction. In fetal lambs, leukotriene receptor blockade⁷⁹ or synthesis inhibition⁸⁰ increases pulmonary blood flow about eightfold, suggesting a role for leukotrienes in the maintenance of the normally high fetal pulmonary vascular resistance; the presence of leukotrienes in fetal tracheal fluid further supports this.⁸¹

Endothelial-Derived Factors and Endothelin

In addition to PGI₂, vascular endothelial cells can be stimulated to produce other important vasoactive factors, including potent vasoconstrictors, such as endothelin, and potent vasodilators, such as endothelium-derived nitric oxide (EDNO).⁸² EDNO is produced by most endothelial cells in response to various stimuli, generally involving specific receptors or changes in shear stress; smooth muscle relaxation is produced through several messenger systems, such as guanylyl cyclase/cyclic guanosine monophosphate, K channels, or PGI₂/cyclic adenosine monophosphate. In the fetus, EDNO is produced by umbilical vascular endothelium^{83,84}; nitroso compounds reduce umbilical vascular resistance in vitro,⁸⁵ and EDNO modulates resting umbilical vascular tone in fetal sheep in utero.⁸⁶ Disturbances in normal EDNO production may also be involved in the genesis of preeclampsia.⁸⁷

EDNO clearly is involved in regulation of vascular tone in the fetal pulmonary circulation, although it plays a far more important role in postnatal transition to air breathing.⁸⁸ Superfused fetal sheep pulmonary arteries release endothelium-derived relaxing factor when stimulated with bradykinin.⁸⁹ In fetal lambs, the vasodilating effects of bradykinin are attenuated by methylene blue and resting tone increases with N ω -nitro-L-arginine, an inhibitor of NO synthesis by NO synthase from precursor L-arginine,⁹⁰ suggesting that a cyclic guanosine monophosphate-dependent mechanism, such as EDNO production, continuously modulates or offsets the increased tone of the resting fetal pulmonary circulation. Inhibition of EDNO synthesis also blocks the pulmonary vasodilatation with oxygenation of fetal lungs in utero and markedly attenuates the increase in pulmonary blood flow with ventilation at birth.^{90,91}

Endothelin 1, a 21-amino acid polypeptide, also produced by vascular endothelial cells, has potent vasoactive properties.⁹² The hemodynamic effects of ET-1 are mediated by at least two distinct receptor populations, ET_A and ET_B, the densities of which are different depending on the vascular bed studied. The ET_A receptors are located on vascular smooth muscle cells and mediate vasoconstriction, whereas the predominant subpopulation of ET_B receptors is located on endothelial cells and mediates vasodilation.⁹³⁻⁹⁵ However, a second subpopulation of ET_B receptors is located on smooth muscle cells and mediates vasoconstriction.⁹⁶ The vasodilating effects of ET-1 are associated with the release of NO and potassium channel activation.⁹⁷⁻¹⁰¹ The vasoconstricting effects of ET-1 are associated with phospholipase activation, the hydrolysis of phosphoinositol to inositol-1,4,5-triphosphate and diacylglycerol, and the subsequent release of Ca²⁺.¹⁰² In addition to its vasoactive properties, ET-1 has mitogenic activity on vascular smooth muscle cells and may participate in vascular remodeling.¹⁰³

The predominant effect of exogenous ET-1 in the fetal and newborn sheep pulmonary circulation is vasodilation, mediated via ET_B receptor activation and NO release. However, the predominant effect in the juvenile and adult pulmonary circulations is vasoconstriction, mediated via ET_A receptor activation. In fetal lambs, selective ET_A receptor blockade produces small decreases in resting fetal pulmonary vascular resistance. This suggests a potential minor role for basal ET-1-induced vasoconstriction in maintaining the high fetal pulmonary vascular resistance.^{98,100} Although plasma and urinary concentrations of ET-1 are increased at birth,^{104,105} in vivo studies suggest that basal ET-1 activity does not play an important role in mediating the transitional pulmonary circulation.¹⁰⁶ ET-1 causes fetal renal vasodilation¹⁰⁷ and thus may be involved in the regulation of fetal renal blood flow.

Other factors, such as calcitonin gene-related peptide and a related substance, adrenomedullin, have vasodilatory effects on the fetal pulmonary circulation and too may play a role in the regulation of pul-

monary vascular tone in the fetus.^{108,109} The effects of these substances probably also are mediated by NO release.¹¹⁰

Ductus Arteriosus

Patency of the fetal ductus arteriosus is regulated by both dilating and contracting factors. The factors that promote ductus arteriosus constriction in the fetus have yet to be fully identified. The ductus arteriosus maintains a tonic degree of constriction in utero that appears to be both dependent and independent of extracellular calcium.¹¹¹ ET-1 also appears to play a role in producing the basal tone of the ductus arteriosus.¹¹²

The factors that oppose ductus arteriosus constriction in utero are better understood. The vascular pressure within the ductus arteriosus lumen opposes ductus arteriosus constriction.¹¹³ Vasodilator prostaglandins appear to be the most important factors opposing ductus arteriosus constriction in the latter part of gestation.^{111,114} Inhibitors of prostaglandin synthesis (e.g., indomethacin) constrict the fetal ductus arteriosus both in vitro and in vivo.^{76,115,116} Their vasoconstrictive effects appear to be most pronounced beyond 30 weeks' gestation in humans. Both the cyclooxygenase-1 and cyclooxygenase-2 isoforms of cyclooxygenase are present within the fetal ductus arteriosus and are responsible for synthesizing the prostaglandins that maintain ductus arteriosus patency.¹¹⁷ Inhibitors of both cyclooxygenase-1 and cyclooxygenase-2 will individually produce fetal ductus arteriosus constriction in vivo.¹¹⁷ On the other hand, PGE₂ will dilate the constricted ductus arteriosus both in vitro and in vivo. PGE₂ produces ductus arteriosus relaxation by interacting with several of the PGE receptors (EP₂, EP₃, and EP₄).¹¹⁸ The EP₄ receptor appears to play a prominent role in ductus arteriosus vasodilation.^{119,120} NO also is made by the fetal ductus arteriosus and appears to play an important role in maintaining ductus arteriosus patency in rodent fetuses.¹¹⁴ Although NO is also made in the ductus arteriosus of larger species, its importance in maintaining ductus arteriosus patency under normal conditions has not been conclusively demonstrated¹²¹ (see next paragraph for the role in fetuses exposed to indomethacin tocolysis).

Although pharmacologic inhibition of prostaglandin synthesis produces ductus arteriosus constriction in utero, genetic interruptions of either prostaglandin synthesis (i.e., homozygous combined cyclooxygenase-1 and cyclooxygenase-2 knockout mice)¹²² or signaling (i.e., homozygous EP₄ receptor knockout mice)¹²⁰ do not lead to ductus arteriosus constriction in utero. Contrary to expectations, both genetic interruptions produce newborn mice in which the ductus arteriosus fails to close after birth. The mechanisms through which the absence of prostaglandins early in gestation alter the normal balance of other vasoactive factors in the ductus arteriosus have yet to be elucidated. It is interesting to note that pharmacologic inhibition of prostaglandin synthesis in human pregnancy also is associated with an increased incidence of patent ductus arteriosus after birth.¹²³ When the fetus is exposed to indomethacin in utero, the ductus arteriosus constricts. Ductus arteriosus constriction in utero produces ischemic hypoxia, increased NO production, and smooth muscle cell death in the ductus arteriosus wall. These factors prevent the ductus arteriosus from constricting normally after birth and make it resistant to the constrictive effects of indomethacin administered postnatally.^{124,125}

Chapter 13

Behavioral State Activity and Fetal Health and Development

Bryan S. Richardson, MD, and Robert Gagnon, MD

Studies in human adults more than 50 years ago first demonstrated that sleep occurs in two distinct phases—rapid eye movements (REM) sleep and slow-wave sleep (SWS), or non-REM sleep—which are recognized by temporal patterns in various electrophysiologic and behavioral parameters. Since that time, much study has been directed at the nature of these so-called sleep states, including their physiologic correlates, control mechanisms, and possible function, and their use as an expression of neurodysfunction with apparent maldevelopment. Sleep states have been shown to exist in apparently healthy newborn infants, although they are not evident in preterm infants born much before 36 weeks of gestation.

Over the past 3 decades, the use of chronic catheterization techniques in fetal animals, primarily sheep, and the use of high-resolution ultrasound equipment for the study of the human fetus have firmly established the existence of activity or behavioral states in utero that have similarities to postnatal sleep states. From such study, it has become evident that fetal behavioral activities are important and necessary for normal growth and development of the lungs and musculoskeletal system. These activities also serve to characterize the healthy fetus, and they become altered when oxygenation is compromised, providing a basis for the use of activity parameters in the biophysical assessment of fetal health. Moreover, a developmental process is evident whereby the REM behavioral state predominates in early life, which may have functional importance for the growth and development of the brain.

Fetal Behavioral State Activity

Animal Studies

Studies involving chronic placement of electrodes and pressor sensors in unanesthetized fetal animals near term have identified the equivalents of behavioral or sleep states with similarities to those described after birth in neonates and adults. Most of these studies have involved the use of the chronic fetal sheep preparation, which has been the primary animal model for the study of fetal behavioral activity. Behavioral state classification is based for the most part on electrophysiologic recordings (electrocortical activity with an electrocorticogram [ECoG], electro-ocular activity with an electro-oculogram [EOG], and nuchal

muscle activity with an electromyogram [EMG]) (Fig. 13-1), with the following states recognized¹⁻³:

- High-voltage (HV) ECoG/NREM—high-voltage, low-frequency ECoG activity, eye movements absent, nuchal muscle tone mainly present
- Low-voltage (LV) ECoG/REM—low-voltage, high-frequency ECoG activity, rapid eye movements, nuchal muscle atonia
- Awake—low-voltage, high-frequency ECoG activity, eye movements present or absent, nuchal muscle tone present

The HV/NREM and LV/REM behavioral states described for the ovine fetus are directly comparable to these same states seen after birth and thus are seen to represent in utero sleep state activity.¹⁻³ The third behavioral state (wakefulness) can also be characterized using criteria used to identify postnatal wakefulness. Direct observations of exteriorized sheep fetuses, behavioral responses to external stimuli, and the different effects of evoked potentials in skeletal muscles provide further support for the existence of a fetal awake-like state.¹⁻⁴

As seen with sleep state activity after birth, additional physiologic parameters are recorded as consistent concomitants to fetal behavioral state activity, although species differences may be evident. In the ovine fetus, rapid irregular breathing movements, as identified in recordings of tracheal pressure, occur only during the LV/REM state.⁴ They are not continuous, however, as approximately one third of LV/REM time is not associated with breathing movements, and thus this parameter cannot be used as a criterion for defining the presence or absence of this state. Similarly, in the ovine fetus, wakefulness or arousal is generally associated with higher blood pressure and heart rate, whereas heart rate is lower during HV/NREM and further decreased during LV/REM, which is thought to be mediated by a decrease in sympathetic activity.⁴⁻⁶ On the other hand, fetal heart rate variability is generally increased during LV/REM in association with the presence of breathing movements, and this can be attributed in part to a respiratory sinus arrhythmia.⁴ In fetal sheep, episodes of repeated swallowing (resembling postnatal feeding episodes) and bladder contractions (indicative of bladder emptying) are also influenced by behavioral state. Near term, both of these activities mainly occur during LV ECoG activity in association with eye movements and increased nuchal muscle activity, suggesting a state of heightened arousal resembling wakefulness (Fig. 13-2).^{7,8}

Detection of temporal patterns in individual state criteria as well as concomitant physiologic parameters, as noted, that are relatively

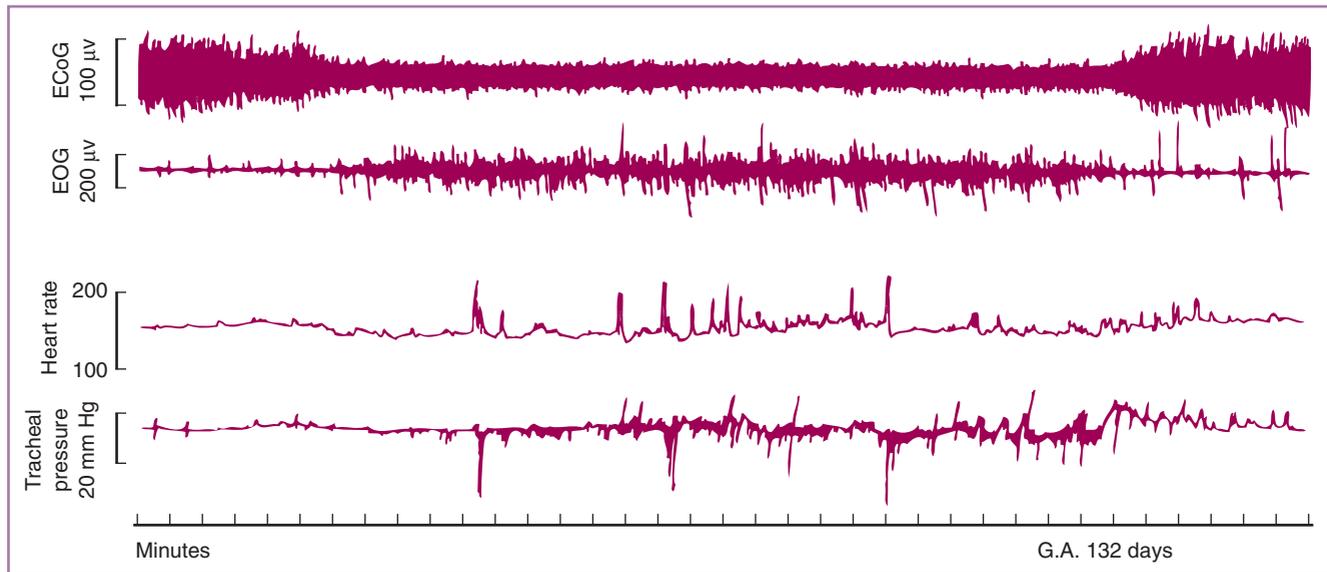

FIGURE 13-1 Electro-ocular activity and fetal breathing movements. Chart recording demonstrating that electro-ocular activity (EOG) and fetal breathing movements normally occur during times of low-voltage electrocortical activity (ECoG). G.A., gestational age.

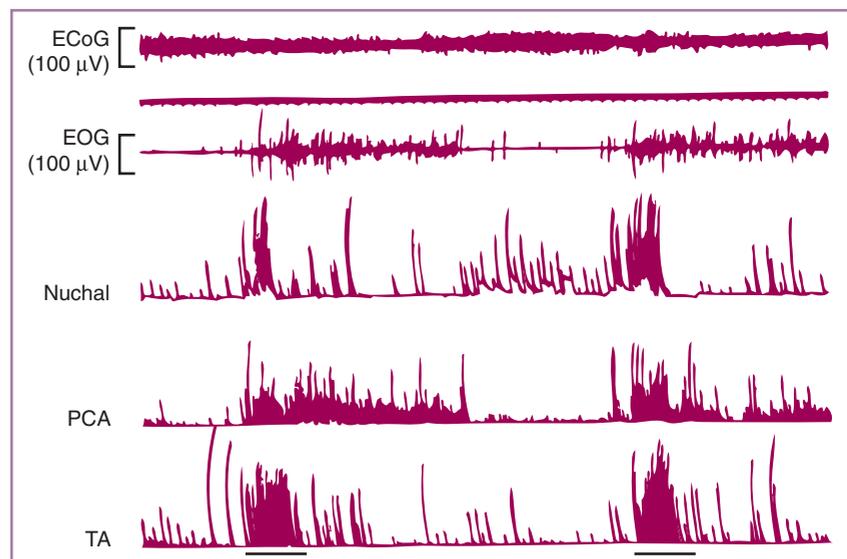

FIGURE 13-2 Phasic activity in the thyroarytenoid muscle. Chart recording demonstrating two bouts of swallowing (*underlined*) noted by the phasic activity in the thyroarytenoid (TA) muscle. Each bout occurs during low-voltage rapid eye movements (LV/REM) with phasic activity in the nuchal and posterior cricoarytenoid (PCA) muscles (the latter as a measure of breathing activity). Electromyographs of PCA, TA, and nuchal muscles are shown in an integrated form. ECoG, electrocorticogram; EOG, electro-oculogram. (From Harding R, Sigger JH, Poore ER, Johnson P: Ingestion in fetal sheep and its relation to sleep states and breathing movements. *Q J Exp Physiol* 69:477-486, 1984.)

stable and repeat over time provide evidence for the existence of fetal behavioral states in other animal species, including the rhesus monkey,⁹ baboon,¹⁰ and guinea pig.¹¹

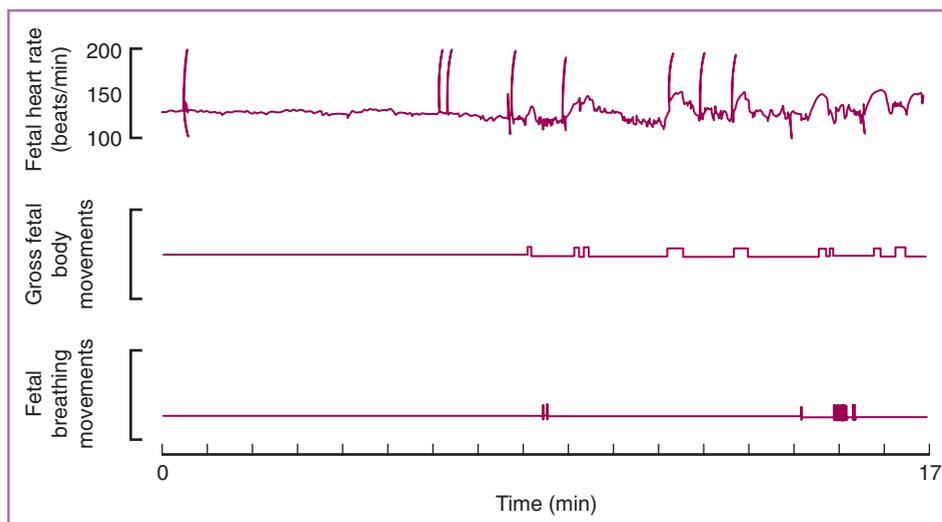

Human Studies

Body movement and heart rate patterns in the human fetus near term reveal a cyclicity which, by reference to postnatal patterns, appear to also have a state-related basis (Fig. 13-3). Initial studies used fetal body movements and heart rate patterns as scoring criteria for behavioral state assessment.^{12,13} With improvement in real-time ultrasound imaging the scoring of fetal eye movements also became possible. One set of state definitions widely used is that introduced by Nijhuis et al.¹⁴ based on parameters observed with ultrasound and the simultaneous recording of fetal heart rate patterns. Following the strategy used for the newborn infant by Precht et al.,¹⁵ four distinct behavioral states

were recognized from the stability of the temporal association of parameters over prolonged periods, and by the simultaneous changes in these parameters at state transition.

- State 1F (fetal)—quiescence (occasional brief gross body movements), eye movements absent, fetal heart rate stable with a narrow oscillation bandwidth;
- State 2F—frequent gross body movements, eye movements continually present, fetal heart rate with a wider oscillation bandwidth and frequent accelerations during body movements;
- State 3F—no gross body movements, eye movements continually present, fetal heart rate stable but with a wider oscillation bandwidth than for state 1F;
- State 4F—frequent and vigorous gross body movements, eye movements continually present, fetal heart rate unstable with large and long-lasting accelerations.

FIGURE 13-3 A chart recording of behavioral parameters from a healthy human fetus near term. For the first 8 minutes, there are no gross body movements and the heart rate pattern demonstrates no accelerations. From 8 to 17 minutes, a normal episode of gross body movements accompanied by accelerations in the heart rate occurs. (From Richardson BS, Campbell K, Carmichael L, Patrick J: Effects of external physical stimulation on fetuses near term. *Am J Obstet Gynecol* 139:344-352, 1981.)

When eye movements, body movements, and heart rate patterns are compared, states 1F and 2F are directly comparable to NREM or quiet sleep, and REM or active sleep, respectively, in the newborn. However, comparisons between fetal states 3 and 4 and postnatal states are less clear, as state 3F is seldom seen and the frequency of body movements for state 4F is somewhat less than that seen in active wakefulness after birth. Nonetheless, the behavioral response of the human fetus to external stimuli including vibroacoustic stimulation supports the existence of a fetal awake state near term^{16,17} in keeping with comparable findings in the ovine fetus.

Additional behavioral parameters are evident as state-related concomitants, but are not continuously present and thus again are unsuitable for use as state-defining criteria. Fetal breathing movements are more regular during state 1F than 2F, while their incidence is increased during 2F.^{18,19} Fetal micturition detected by ultrasound recognition of bladder emptying, while inhibited during episodes of low heart rate variation suggestive of state 1F, appears facilitated by a change to an episode of high heart rate variation with rapid eye movements and fetal breathing movements suggesting state 2F or possibly 4F.²⁰ Conversely, regular mouthing movements, as in the neonate, only occur during periods of quiescence and can be considered a concomitant for state 1F.²¹

Developmental Changes

The study of the temporal relationship between behavioral and physiologic parameters has firmly established not only the existence of behavioral states in the fetus, which are analogous to postnatal sleep states, but also developmental changes whose timing is species dependent and intricately linked to brain maturation.

For the ovine fetus (term, approximately 145 days), well-differentiated ECoG patterns are evident from approximately 120 days of gestation onward, with a temporal relationship to episodic muscle and breathing activity that is indicative of behavioral states.³ Initially, there is a high proportion (>50%) of time in the LV/REM state, with approximately 40% of the time in the HV/NREM state and only brief periods of apparent wakefulness. Thereafter, there is a progressive decrease in the incidence of LV/REM, to approximately 40% by term, mainly because of an increase in periods of wakefulness, although HV/NREM is also increased.³ Postnatally, there is a marked falloff in the incidence

[‡]Data (median values) from Nijhuis JG, Prechtl HFR, Martin CB Jr, Bots RS: Are there behavioural states in the human fetus? *Early Hum Dev* 6:177-195, 1982.

of LV/REM sleep, to less than 10%, again primarily because of an increase in time spent awake.¹³ The durations of both HV/NREM and LV/REM also show a developmental increase with advancing gestation until a stable level is attained at 130 days.³ At this time, the average duration of a sleep cycle is 20 minutes, with approximately 11 minutes in LV/REM and 8 minutes in HV/NREM, interspersed with brief periods of wakefulness lasting no more than 2 to 4 minutes.³ The ovine fetus also has a cycling of behavioral parameters before the appearance of a differentiated ECoG, but these are not well synchronized, and episodic breathing and ocular movements are initially associated with increased, rather than decreased, activity in the neck muscles.²²

The human fetus first demonstrates clearly defined behavioral states at approximately 36 weeks of gestation with stable alignment of behavioral parameters and synchrony of change at state transitions.¹⁴ At this time, state 2F (or REM sleep) predominates, occurring approximately 40% of the time (Table 13-1). State 1F (or NREM sleep) occurs approximately 25% of the time, and state 4F (or wakefulness) occurs but briefly. Behavioral states cannot be identified approximately 20% of the time. With advancing gestation, the incidence of NREM sleep and wakefulness increases, that of the REM state remains little changed, whereas the percentage of time with no identifiable states decreases. This time course of behavioral state development in utero is qualita-

tively similar to that observed in healthy premature neonates.¹⁵ Moreover, although the NREM and REM states are observed more frequently in the fetus at term (approximately 80%) than in the neonate during early infancy (approximately 70%), the ratio of these two states remains similar.^{14,15} Before 36 weeks of gestation, periods of activity and quiescence are again evident, but although the coinciding behavioral parameters may mimic states, they lack stability in temporal relationship and synchrony of change at transition of states (see Table 13-1).^{14,23} Of note, the duration of this activity-quiescence cycle also shows a maturational change, with a progressive increase from about 20 minutes at 28 weeks' gestation to about 60 minutes by term, and this length is similar to that of the REM-NREM cycle of the newborn infant.^{14,15}

Observations on the maturation of ECoG patterns in utero or of behavioral state activity after birth provide insights into the development of sleep-wake states in other species. The organization of ECoG activity in the guinea pig fetus is similar to that in the ovine fetus, with the onset of cyclic differentiation occurring prenatally and with progressive maturation in ECoG waveforms thereafter.¹¹ Likewise, fetal baboons show well-differentiated ECoG patterns near term with maturational changes thereafter.¹⁰ Newborn guinea pigs, monkeys, baboons, and sheep clearly demonstrate the behavioral state aspects of NREM sleep, REM sleep, and wakefulness at the time of birth.^{1,10,11,24} On the other hand, the adult-like ECoG aspects of sleep and wakefulness are not fully developed until several postnatal days in the rat, rabbit, and cat, with an associated delay in the appearance of delineated sleep states.^{25,26} Although comparison between the immature of several species of animals thus indicates considerable difference in the rate of development of sleep-wake patterns, all demonstrate a similarly high proportion of the REM state with the establishment of well-defined behavioral states.

Hypoxia and Intrauterine Growth Restriction

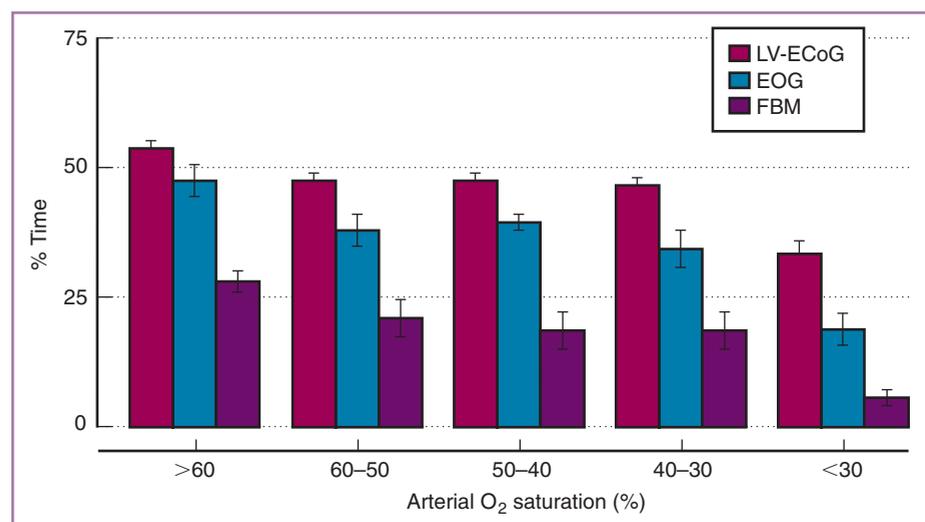

In the near-term ovine fetus, moderate hypoxemia of short-term duration²⁷ and prolonged and graded reductions in fetal oxygenation over several days²⁸ result in little change in ECoG activity until hypoxemia is severe enough to result in associated metabolic acidosis with a decrease in the incidence of the LV ECoG state, whereas forelimb, eye, and breathing movements are variably decreased with lesser degrees of hypoxemia (Fig. 13-4). This hierarchical response of fetal activities to

hypoxia can be seen as protective, as ECoG activity that may have an impact on brain development (see later) is initially minimally changed, whereas movement activities that result in increased energy expenditure^{29,30} are variably decreased. However, it should be noted that a marked decrease in fetal movement activity with chronic hypoxemia is also seen only at the level at which acidemia becomes apparent.²⁸ Thus, clinical assessment of fetal movement should be used as a marker for moderate to severe hypoxemic change.

Growth is known to account for a consequential fraction of the substrate consumption of fetal sheep near term.³¹ With both prolonged reduction in fetal O₂ delivery over several days³² and induced intrauterine growth restriction (IUGR),³³ total O₂ consumption by the fetus is reduced approximately 20%. This decrease in oxidative metabolism represents the energy savings from decreased tissue growth, but it also reflects, in part, changes in behavioral activity and associated energy requirements. Worthington and colleagues³⁴ studied the effects of reducing placental size in sheep with resultant asymmetrical IUGR and chronic hypoxemia without acidemia. The incidence of fetal breathing movements was marginally decreased to approximately 20% of the time, thereby providing a decrease in oxidative needs. However, there has been no similar study of the effects on ECoG activity, although these are likely to be minimal given the findings with induced hypoxemia of shorter duration.^{27,28}

In human pregnancies with IUGR and presumed chronic fetal hypoxemia, the incidence of fetal breathing movements and gross body movements is generally decreased but appears to depend on the severity of the IUGR and the conditions of study.³⁵⁻⁴⁰ Although the related decrease in energy expenditure is probably biologically important, there is considerable overlap with population norms, which limits the clinical usefulness of these movement parameters as markers for IUGR. When behavioral state organization was assessed in growth-restricted fetuses during the latter part of human pregnancy, little difference was noted in the incidence of the coincidence of states 1F and 2F when compared with that of appropriately grown fetuses.⁴¹ This finding is similar to the ECoG findings in the ovine fetus with prolonged hypoxemia in the absence of any acidemia.²⁸ However, subtle differences are noted: IUGR fetuses show a delay in the appearance of well-delineated behavioral states with a lack of synchrony in parameter change at state transition and the interruption of stable associations by periods of no coincidence. This indicates that some aspects of central nervous system function are disturbed.^{41,42}

FIGURE 13-4 Percentage of time with graded reductions in fetal arterial oxygen saturation over 5 days of study as measured by low-voltage electrocortical (LV-ECoG), electroocular (EOG), and fetal breathing movement (FBM) activities. (From Richardson B: Metabolism of the fetal brain: Biological and pathological development. In Hanson M: The Fetal and Neonatal Brain Stem. Cambridge, Cambridge University Press 1991, p 87.)

Assessment of Fetal Health

Breathing Activity and Body Movements

The recognition of the presence of episodic fetal breathing movements (FBM) and gross fetal body movements (GFBM) in animal studies⁴ and their subsequent inhibition by acute hypoxia⁴³ has formed the basis for using these biophysical parameters as part of an ultrasound-based assessment of fetal health (see Chapter 21). The resultant composite biophysical profile score includes markers of both acute and chronic fetal compromise. The markers for acute fetal compromise and fetal oxygenation include FBM, GFBM, fetal tone, and fetal heart rate (FHR) reactivity. Amniotic fluid volume is usually considered a marker of chronic fetal or placental compromise, although acute deterioration in amniotic fluid volume preceding fetal death has been reported.⁴⁴ According to Manning and colleagues,⁴⁵ both fetal breathing and body movements are assessed using a semiquantitative scoring method and are given a score of 2 if present or a score of 0 if absent by predefined criteria. Assessment of fetal tone, FHR reactivity, and amniotic fluid volume are combined with that score for a maximum score of 10 out of 10 if all five criteria are met (see Table 21-1 in Chapter 21). The negative predictive value for a normal perinatal outcome is high (>95%) among the four dynamic biophysical variables (FBM, GFBM, fetal tone, and reactive nonstress test).^{46,47} However, it is only when test results are combined into a composite score that the positive predictive value for abnormal outcome is improved.^{46,47} A score of either 10 of 10 or 8 of 10 with normal amniotic fluid volume, or 8 of 8 without nonstress testing, is interpreted as indicative of fetal health, and interventions for fetal indications are not recommended.⁴⁵ Repeat testing is recommended at specific intervals depending on the risk situation^{48,49} (see Chapter 21). However, antepartum fetal health assessment reflects the metabolic fetal status *at the time of the test*, and furthermore, the frequency at which it should be repeated in high-risk pregnancies is still uncertain.

Acute biophysical markers of fetal assessment are also affected by rest-activity cycles reflecting fetal behavioral activity,¹⁴ gestational age,^{50,51} and IUGR,¹⁷ which may lead to false-positive results and unnecessary early premature deliveries. Fetal breathing and body movements are more likely to be falsely abnormal at 26 to 33 weeks' gestation when compared with results at 34 to 41 weeks,⁵⁰ reflecting the maturational changes in these biophysical dynamic variables. Similarly, nonstress testing is more likely to be falsely nonreactive before 30 weeks' gestation,⁵¹ because of both the maturational changes in fetal biophysical parameters and the autonomic control of the fetal heart with advancing gestation.¹⁷ Growth-restricted fetuses experience lower incidences of FBM and GFBM in addition to lower FHR reactivity than fetuses growing normally in the absence of metabolic acidosis.^{39,40} Therefore, different strategies have been used to decrease the false-positive rate of an abnormal biophysical profile, such as an immediate extension of the biophysical profile if a score of 4 or less is found after 30 minutes.⁴⁵ Assessment of FHR reactivity has included the use of objective computerized FHR analysis to take into account gestational age and to identify the lower-amplitude FHR accelerations expected in healthy, normally growing premature (<30 weeks) fetuses and in growth-restricted fetuses,^{51,52} in addition to providing a more accurate assessment of FHR variability.⁵³ Although Devoe and coworkers⁵⁴ have tried to adjust FBM and GFBM scoring criteria for gestational age to reduce the false-positive rate and improve positive predictive value, this approach has not been tested in large population-based studies.

Also, because of the inherent periodicity in FBM and GFBM, it is unlikely that such an approach would be sufficient to improve the positive predictive value of the current biophysical profile scoring system for growth-restricted fetuses.

Each of the four acute markers of fetal metabolic status has a different time course during which it becomes abnormal in relationship to the metabolic status of the fetus. A nonreactive nonstress test and absent FBM are early and therefore sensitive markers of fetal hypoxemia or metabolic acidosis, but they can be expected to have higher false-positive rate.^{55,56} Furthermore, GFBM and fetal tone are late markers and therefore can be expected to have a better positive predictive value.^{55,56} Current protocols for responding to abnormal scores (i.e., less than 8) are detailed in Chapter 21. The risk for fetal metabolic acidosis and perinatal mortality rises exponentially with progressive decrease in biophysical profile score.⁵⁷

In the presence of preterm premature rupture of membranes, there may be a reduction in amniotic fluid volume. In addition, there is a significant risk of intrauterine infection, which may compromise neonatal outcome. An early retrospective report from Vintzileos and colleagues⁵⁸ suggested that with the onset of intrauterine infection, an abnormal biophysical profile may occur, and it could correlate with the subsequent development of neonatal sepsis. However, subsequent reports^{59,60} in prospective cohorts could not confirm these observations, indicating that changes in biophysical profile scoring cannot be used as a reliable marker for intrauterine infection but still can be used to assess fetal metabolic status.

Fetal Movements versus Other Means of Fetal Surveillance

Currently, the biophysical profile is the primary method to indirectly estimate fetal oxygenation and the onset of metabolic acidosis. Umbilical artery Doppler ultrasound is a placental function test that provides important diagnostic and prognostic information in growth-restricted fetuses and is a useful addition to the assessment of fetal health by the dynamic biophysical profile score⁶¹ (see Chapter 21). Umbilical artery Doppler velocimetry has shown a significant correlation with the umbilical artery pH and is also a sensitive indicator of fetal acidosis, comparable to the biophysical profile score.⁶¹ In the presence of abnormal umbilical artery Doppler, fetal growth rate is reduced likely associated with a reduction in fetal oxygen consumption as a survival mechanism. Under clinical conditions where prematurity is a concern within the context of IUGR, the addition of assessment of the fetal circulation, and particularly the ductus venosus Doppler, appears to be a useful adjunct to identify IUGR fetuses at high risk for adverse outcome (particularly stillbirth), and thus requiring delivery, independent of the umbilical artery Doppler waveform and biophysical profile testing.^{62,63} It is against these complex interactions between causative factors of fetal hypoxemia and reactive or adaptive responses that the different means of fetal health surveillance can be compared and the clinical decision made to deliver the compromised fetus.

Fetal Growth and Development

Brain

Brain growth and development are characterized by a series of events that include the proliferation and migration of nerve cells, gliogenesis,

the growth of axons and dendrites, the formation of functional synapses, cell death, myelination of axons, and the fine tuning of neuronal specificity. These events proceed in a temporally and regionally dependent manner that is well coordinated, and for the most part the events are similar across mammalian species, albeit with considerable variance in their degree of advancement at the time of birth. For the ovine species, the increase in brain weight occurs in two phases: one up to 90 days after conception and the second a more rapid and longer increase after 90 days that continues to birth,⁶⁴ leading to the classification of sheep as prenatal brain developers. These two phases appear to reflect an increase in neuroblast multiplication followed by neuroglial multiplication and myelination.^{64,65} For monkeys, neurogenesis is also largely complete well before birth, although the most rapid phase of synaptogenesis occurs thereafter within a time-window of approximately 40 days, centered on birth.⁶⁶ Although early neuronal connectivity with synaptogenesis and dendritic arborization is largely mediated by an intrinsic growth program, specific refinement occurs later on to generate class-specific dendritic morphologies regulated in part by patterns of synaptic activity.⁶⁷ Sensory-driven activity contributes to this during postnatal brain development, and recent study has pointed to a similar requirement for endogenous neural activity generated by the nervous system itself before sensory input is widely available, and presumably more so for those species whose development is extensively prenatal.⁶⁸ From a comparative standpoint using the timing for peaks in growth velocity of brain development, guinea pigs as well as monkeys can also be classified as prenatal brain developers, humans as perinatal brain developers, and cats and rats as postnatal brain developers.⁶⁴

The anatomic development of the brain as studied across species thus appears to correlate with its electrophysiologic development as indicated by behavioral state maturation. Thus, whereas sheep and guinea pigs as prenatal brain developers from a neuroanatomic standpoint have relatively mature electrocortical patterns at birth, rats as postnatal brain developers have a poorly differentiated ECoG. This neurodevelopmental correlation, along with the high proportion of REM sleep or behavioral like activity during early life, indicate that the immature being has a high requirement for such activity and that the REM state itself might play a role in the brain's growth and development. The concept of a functional role for the REM state mechanism in brain development is further supported by the finding in the ovine fetus of an increase in cerebral metabolic rate at this time, which is most pronounced in mid brain and pontine structures⁶⁹⁻⁷¹ (Table 13-2), presumably reflecting increased neuronal activity associated with the generation of the REM state. Doppler flow velocity studies in the human fetus suggest a similar REM state effect, given the tight flow-metabolism coupling reported for the brain.⁷² There is also a maturational increase in the cerebral metabolic rate of the ovine fetal LV/REM state⁷⁰ (see Table 13-2) which, along with the reported maturational change in the power spectrum of the ECoG waveform,⁷³ may thus reflect increasing endogenous stimulation of and by the brain as proposed by Offswarg and coworkers⁷⁴ for the REM state over 40 years ago. For the ovine fetus, the cerebral metabolic rate of the prenatal LV/REM state at term is also similar to that of the awake state at 24 hours after birth, a time of increasing exogenous stimulation for the brain's functional activity (see Table 13-2).⁷⁰ Thus, it is not surprising that drug-induced REM sleep deprivation in rat pups during the period of rapid brain maturation and when there is normally a high amount of REM sleep, results in disturbed sleep-wake patterns during later life and a significant reduction in the size of the cerebral cortex.⁷⁵ Although these findings are not conclusive, collectively they support a role for REM state activity during early brain development, most likely

with the provision of endogenous stimulation that might then promote synapse refinement and the formation of orderly connections during the critical period of synaptic plasticity.^{68,76}

Although most study and speculation has been directed at the REM state, there is reason to believe that the NREM state may also be important for the brain's development. The developmental change in NREM sleep coincides with the formation of thalamocortical and intracortical patterns of innervation and thereby with periods of heightened synaptogenesis, and it may also be associated with important processes in synaptic remodeling.^{77,78} Furthermore, study in the near-term ovine fetus with infusion of an amino acid tracer has shown that leucine uptake by the brain is increased during the HV/NREM state rather than during the LV/REM state, indicating that protein synthesis and degradation must also be increased at this time.⁷⁹ This finding is consistent with that in adult animals, where higher rates of cerebral protein synthesis have been shown to be positively correlated with the occurrence of NREM sleep.^{80,81} These studies also indicate that the decrease in the brain's metabolic demand during NREM sleep as seen in the ovine fetus^{69,70} and in other species postnatally, including humans,⁸² does not result from a decrease in biosynthetic activity and may, in fact, favor the synthesis of new proteins. This would support the restorative theory of sleep⁸³ whereby energy conservation during NREM sleep favors the anabolic restoration of tissues. Thus, REM and NREM sleep state activity may both have an impact on the brain's development, with the former providing a degree of endogenous stimulation through neuronal activity and leading to synaptic remodeling with increased protein synthesis or degradation,⁸⁴ which subsequently occurs during the following NREM period when energy needs for neuronal activity are lower. An interaction between sleep state and the brain's development is also supported by the finding in the near-term ovine fetus that HV/NREM episode duration is positively correlated with the duration of the previous LV/REM episode,⁸⁵ in keeping with a homeostatic model of REM/NREM sleep control as proposed for the adult rat.⁸⁶

Lungs

Evidence from animal experimentation and from observations of human fetuses has indicated that fetal breathing movements are important for the normal development of the fetal lungs. Studies in fetal rabbits⁸⁷ and sheep⁸⁸ have shown that, after section of the upper

cervical spinal cord and elimination of phasic respiratory movements of the diaphragm, the DNA content of the lungs was reduced. Circumstantial evidence from anomalous development of human fetuses also supports the conclusion that loss of fetal breathing movements plays a role in abnormal lung growth with pulmonary hypoplasia, although loss of thoracic volume may be just as important if not more so.⁸⁹ Although the mechanisms whereby fetal breathing movements affect lung growth are not well understood, phasic distortion of the lungs leading to pulmonary cell division and the maintenance of lung liquid volume or distention appear to be important.⁹⁰ Of interest, the experimental induction of growth restriction in fetal sheep does lead to a reduction in lung growth that affects the airways and alveoli.^{91,92} However, the extent to which these growth effects are the result of an associated decrease in fetal breathing activity, or the related chronic hypoxemia, and the longer-term consequences for pulmonary function remain to be determined.

Because fetal breathing movements are important for lung growth, they have been studied in patients with oligohydramnios in relation to the subsequent development of pulmonary hypoplasia.⁹³⁻⁹⁶ Although fetal breathing movements appear to be variably decreased or absent in fetuses who are subsequently shown to have pulmonary hypoplasia,^{95,96} this may depend on the gestational age studied. Fetuses with preterm rupture of the membranes and oligohydramnios, as studied during the latter half of pregnancy, are certainly capable of making breathing movements.^{58,97} Moreover, fetuses with renal agenesis and oligohydramnios and subsequently shown to have pulmonary hypoplasia, but studied after 29 weeks of gestation, are also seen to make breathing movements.⁹³ Thus, fetal breathing movements may be seen as decreased or absent in the younger fetus with oligohydramnios as a result of developing pulmonary hypoplasia and increased "lung stiffness." With advancing gestation and an increase in the stimuli for respiratory movements and chest wall excursion, breathing movement activity may now be evident despite underlying pulmonary hypoplasia. However, it is also possible that oligohydramnios of a marked degree mechanically restricts chest wall movement in the younger fetus, in turn contributing to the development of pulmonary hypoplasia.

Musculoskeletal

The loss of muscle mass and strength in later life is called sarcopenia, and it influences the proportion of lean mass. In vivo studies show that lean body mass represents 98% of total weight of term growth-restricted infants. In contrast, lean body mass is 87% in normally grown newborn infants, which suggests a reduction in fat deposition with fetal growth restriction.⁹⁸ Padoan and colleagues⁹⁹ recently used ultrasound estimation of fetal body fat and lean mass to demonstrate that growth-restricted fetuses have reduced subcutaneous fat and lean mass compared with control fetuses, particularly in the presence of adverse perinatal outcome. However, it is unknown if this relative sarcopenia persists into adulthood. A number of studies have demonstrated a significant, positive association between birthweight and muscle mass at different stages of life. Furthermore, there is evidence that small size at birth is associated not only with reduced muscle mass and strength but also with changes in metabolic function, with a small study showing that impaired fetal growth was associated with reduced muscle glycolysis in adult life as revealed by phosphorus 31 magnetic resonance spectroscopy.¹⁰⁰ However, the link between the mechanical and metabolic functions of muscle remains unclear, and there was no evidence in this study for differences in skeletal morphology according to size at birth. Although evidence from animal models suggests that early influences on the growth and development of muscle fibers may

underlie the relationship between size at birth and adult muscle mass and function, the concept that there is a fixed number of muscle fibers determined at birth appears outdated. Recent evidence suggests that postmitotic myonuclei lying within mature myofibers might be able to reform myoblasts or stem cells, and there is increasing recognition of the role that satellite cells play in postnatal muscle growth and regeneration.¹⁰¹

De Vries and Fong¹⁰² recently described the changes in the pattern of fetal body movements and motility associated with several genetic fetal anomalies. Hypokinetic fetal movement patterns were associated with several autosomal recessive disorders, whereas other chromosomal anomalies were associated with hyperkinetic gross fetal body movements but restriction in distal joint mobility resulting in clenched wrists. Therefore, abnormal fetal body movement patterns or the quality of movement activity may be associated with major fetal anomalies and contribute to abnormal neuromuscular development. However, although the neural activity of fetal motility and its motor effects may contribute to the development of muscles, joints, and even the fine structure of the central nervous system itself,¹⁰³ there has been little study, either experimental or clinical, in this area to date.

Chapter 14

Placental Respiratory Gas Exchange and Fetal Oxygenation

Giacomo Meschia, MD

Knowledge of respiratory gas exchange across the human placenta depends on the integrating of observations in pregnant patients with experimental findings in laboratory animals. This integration is necessary because data on the physiology of the human fetus are scant and cannot be interpreted correctly in the absence of experimental evidence. The evidence in laboratory animals consists of a fairly comprehensive set of data in sheep with chronically implanted vascular catheters in the maternal and fetal circulation, and a more limited but important set of data in nonhuman primates and other mammals.

Transport of Atmospheric Oxygen to the Gravid Uterus

The transport of oxygen (O_2) from the atmosphere to fetal tissues can be visualized as a sequence of six steps that alternate bulk transport with transport by diffusion (Fig. 14-1).¹ The first three steps of this process are part of general physiologic knowledge and therefore are presented here briefly.

In step 1, transport from the atmosphere to the alveoli is by action of the respiratory muscles, which move air in and out of the maternal lungs. This action maintains the partial pressure of oxygen (PO_2) in the alveoli at a level that is regulated by several physiologic mechanisms, some of which are driven by sensors of the PO_2 , of partial pressure of carbon dioxide (PCO_2), and of maternal blood pH. During pregnancy, the maternal organism is set to regulate arterial PCO_2 at a lower level than in the nonpregnant state.

In step 2, oxygen diffuses from the alveoli into the maternal red blood cells that circulate through the lungs. In the normal organism at sea level, the diffusion rate is so rapid that the PO_2 at the venous end of the pulmonary capillaries becomes virtually equal to the PO_2 in the adjacent alveoli. Nevertheless, the PO_2 of maternal arterial blood is somewhat less than the PO_2 in a sample of alveolar air, in part because some deoxygenated blood bypasses the lungs and in part because ventilation and perfusion of the alveoli are not matched evenly throughout the lungs. Under pathologic conditions that prevent the equilibration of PO_2 between alveoli and blood, increase the degree of uneven ventilation-perfusion, or shunt more deoxygenated blood directly into the arterial system, the PO_2 difference between alveolar air and arterial blood becomes larger.

In step 3, maternal blood, propelled by action of the maternal heart, transports oxygen from the lungs to the gravid uterus via the pulmo-

nary veins, left atrium, left ventricle, aorta, uterine arteries, and branches of the ovarian and vaginal arteries. Oxygen is transported by blood in two forms, free and bound to hemoglobin. In any blood samples, these two forms are in reversible equilibrium. The special nomenclature for the components of this equilibrium is summarized in Table 14-1.

Oxygen Uptake by the Uterus and Fetus

The oxygen uptake by the uterus and the fetus can be calculated by measuring simultaneously uterine and umbilical blood flows and the oxygen content of blood samples drawn from four blood vessels: maternal artery, uterine vein, umbilical vein, and umbilical artery. A numerical example of these calculations is presented in Figure 14-2.

The rationale, commonly known as the Fick principle, is as follows. Each milliliter of maternal blood in passing through the pregnant uterus gives up a certain amount of oxygen, which can be calculated by measuring the difference in oxygen content between maternal arterial blood and uterine venous blood. The quantity of oxygen lost by each milliliter of blood is then multiplied by the milliliters of blood flowing through the pregnant uterus to obtain the uterine oxygen uptake.

To calculate the rate at which the fetus takes up oxygen from the placenta, exactly the same reasoning can be applied to the umbilical blood data. Note that the oxygen uptake by the gravid uterus is greater than the oxygen uptake by the fetus. This is so because the placenta is metabolically active and consumes a relatively large fraction of the oxygen that the uterine circulation delivers to the gravid uterus.

Fetal growth is accompanied by an increase in fetal oxygen uptake. However, oxygen uptake and fetal weight do not increase proportionally. A 200-g mid-gestation fetal lamb has an average oxygen uptake of $0.460 \mu\text{mol}/\text{min}/\text{g}$, whereas a 3000-g near-term fetus has an average uptake of $0.340 \mu\text{mol}/\text{min}/\text{g}$.² The differences in uptake are much larger if the uptake is related to fetal dry weight because fetal growth is accompanied by a decrease in fetal water content. Oxygen uptake expressed per unit fetal dry weight is about 2.5 times higher at mid-gestation.

Given this complexity and the lack of comparable information for the human fetus, it is important to ask whether fetal oxygen uptake measurements in experimental animals can be used to estimate human fetal oxygen uptake. If the aim is an accurate estimate, the answer must

Rights were not granted to include this figure in electronic media.

FIGURE 14-1 Transport of oxygen to fetal tissues. Transport of oxygen from the atmosphere to the fetal tissues in a sequence of steps that alternate bulk and diffusional transport. (From Meschia G: Supply of oxygen to the fetus. J Reprod Med 23:160, 1979.)

TABLE 14-1 BLOOD OXYGEN TRANSPORT: TERMINOLOGY, MEASUREMENT, AND RELATIONSHIPS

Nomenclature	Symbol	Units	Methods of Measurement
Free O ₂	[O ₂]	mM*	—
O ₂ bound to hemoglobin	[HbO ₂]	mM*	—
O ₂ content	[O ₂ Tot]	mM*	e.g., Van Slyke apparatus
O ₂ pressure	Po ₂	mm Hg	Po ₂ electrode
Hemoglobin	[Hb]	mM*	Spectrophotometer
O ₂ capacity	[O ₂ CAP]	mM*	—
O ₂ saturation	S	—	Spectrophotometer
O ₂ saturation × 100	% S	—	—
[O ₂ Tot] = [HbO ₂] + [O ₂]			
[O ₂ CAP] = 4 [Hb] [†]			
S = [HbO ₂] ÷ [O ₂ CAP]			
[O ₂] = αO ₂ Po ₂ (where αO ₂ = O ₂ solubility coefficient).			

*Another unit used often in reporting quantities of O₂ is mL_{STP} (1 millimole = 22.4 mL_{STP}).

†Each hemoglobin molecule can combine with four molecules of oxygen.

be No, because several interspecies differences are likely to affect oxygen demand. For example, in comparing near-term ovine and human fetuses of equal bodyweight, one must note that the human fetus has a much larger brain mass, has more adipose tissue, lives at a lower body temperature, and grows more slowly. It would be surprising if all these differences did not add up to a significant difference in oxygen uptake. However, attempts to measure near-term fetal oxygen consumption rates in different species (horse, cattle, rhesus monkey, guinea pig) have yielded values of oxygen uptake per gram wet weight that are within ±20% of the fetal lamb value despite very large differences in body size, rate of growth, and body composition.³ Therefore, it may be assumed that data in experimental animals provide an approximate estimate of human fetal oxygen demand.

Oxygen Pressures in Uterine and Umbilical Circulations

The PO₂ of umbilical venous blood (i.e., the blood that transports O₂ from placenta to fetus) is quite low in comparison with maternal arterial and uterine venous PO₂, even under normal physiologic conditions. Table 14-2 presents representative data for sheep.⁴ A large PO₂ difference is also present across the human and rhesus monkey placentas, suggesting that what has been learned about the transplacental PO₂ difference in sheep is relevant to human fetal physiology.

Measured Quantities

Maternal arterial O₂ content (A): 0.143 mL_{STP}/mL of blood
 Uterine venous O₂ content (V): 0.109 mL_{STP}/mL of blood
 Umbilical arterial O₂ content (a): 0.078 mL_{STP}/mL of blood
 Umbilical venous O₂ content (v): 0.115 mL_{STP}/mL of blood
 Uterine blood flow (F): 1412 mL/min
 Umbilical blood flow (f): 716 mL/min
 Fetal body weight (BW): 4.0 kg
 Uteroplacental unit weight (UPW): 1.0 kg

Calculations

O₂ uptake by the gravid uterus: $(A - V) \times F = 48.0$ mL_{STP}/min
 O₂ uptake by the fetus: $(v - a) \times f = 26.5$ mL_{STP}/min
 O₂ uptake per kg by fetus: $(v - a) \times f \div BW = 6.6$ mL_{STP}/min/kg
 O₂ uptake per kg by fetus and uteroplacental unit: $(A - V) \times F \div (BW + UPW) = 9.6$ mL_{STP}/min/kg

FIGURE 14-2 The Fick principle. Application of the Fick principle to a calculation of oxygen uptake by the pregnant uterus and the fetus using representative data from experiments in chronic sheep preparations during the last 2 weeks of pregnancy. STP, standard temperature and pressure.

TABLE 14-2 REPRESENTATIVE PO₂ VALUES IN UTERINE AND UMBILICAL CIRCULATIONS OF SHEEP HOMOZYGOUS FOR OVINE B HEMOGLOBIN

Location	PO ₂ (mm Hg)
Uterine artery	72
Uterine vein	48
Umbilical vein	27
Umbilical artery	19

In any given near-term, normal ovine pregnancy, umbilical venous PO₂ varies as a function of uterine venous PO₂, and the uterine-umbilical venous PO₂ difference remains virtually constant in response to wide PO₂ changes. Figure 14-3 shows the umbilical venous PO₂ response to variations of uterine venous PO₂ that were induced by changing the percentage of O₂ in maternal inspired air, or by shifting to the right the oxyhemoglobin dissociation curve of maternal blood via a decrease in the pH of maternal blood.⁵ Figure 14-4 shows the results of experiments in five animals in which the uterine venous PO₂

Rights were not granted to include this figure in electronic media. Please refer to the printed publication.

FIGURE 14-3 Relationship of umbilical venous PO₂ to uterine venous PO₂ in a near-term pregnant sheep. Uterine venous PO₂ was varied by administration of different gas mixtures to the mother and by displacing the maternal hemoglobin dissociation curve to the right via a decrease of maternal blood pH. The *dashed line* is the identity line. (From Rankin JHG, Meschia G, Makowski EL, et al: Relationship between uterine and umbilical venous PO₂ in sheep. Am J Physiol 220:1688, 1971.)

FIGURE 14-4 Relationship of umbilical to uterine venous PO₂ in five near-term sheep. The uterine venous PO₂ was decreased by decreasing uterine blood flow. Each animal is represented by a different symbol. (From Wilkening RB, Meschia G: Fetal oxygen uptake, oxygenation, and acid-base balance as a function of uterine blood flow. Am J Physiol 244:H749, 1983.)

was decreased by decreasing uterine blood flow.⁶ It is apparent that the two figures demonstrate a similar umbilical-versus-uterine venous PO₂ relationship, despite the different means that were used to vary uterine venous PO₂. Changes in the percentage of O₂ in maternal inspired air cause changes of PO₂ and O₂ content in maternal arterial blood, but they have virtually no effect on uterine blood flow.⁷ In contrast, a

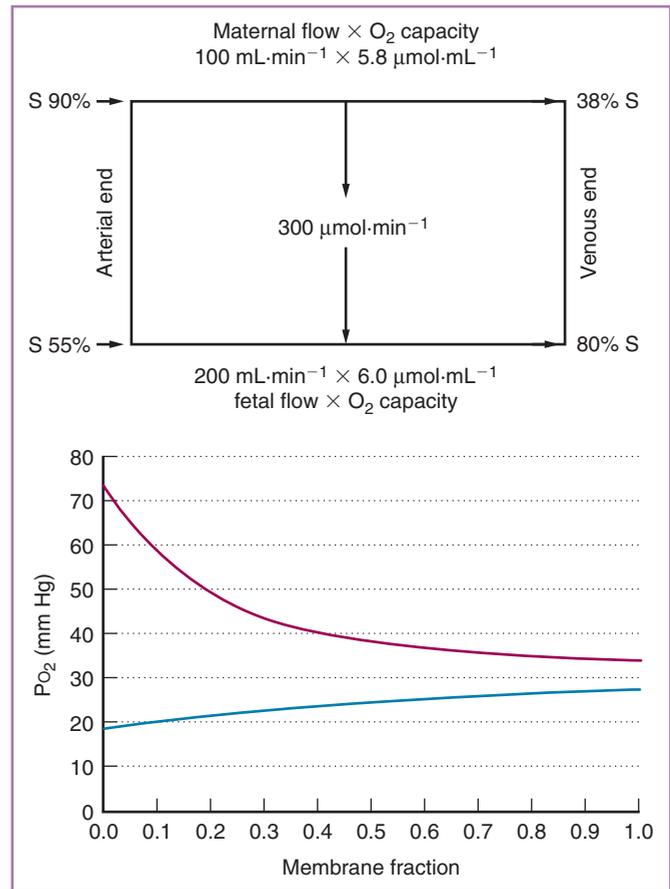

FIGURE 14-5 Concurrent blood flow model of O₂ transport across a structurally homogeneous membrane that does not consume any oxygen. In this model, the fetal O₂ saturations (S), blood flow, and O₂ capacity are representative of normal values at two-thirds gestation. The membrane is assumed to have an O₂-diffusing capacity that provides almost complete PO₂ equilibration at the venous end of the exchanger. The graph of PO₂ versus membrane fraction shows the PO₂ changes from the arterial to the venous end within the maternal (*red line*) and the fetal (*blue line*) vascular channels.

decrease of uterine blood flow does not change the oxygenation of maternal arterial blood.

In an attempt to explain this basic information, it is useful to address two questions: (1) why does umbilical venous PO₂ vary as a function of uterine venous PO₂? and (2) why is umbilical venous PO₂ so much less than uterine venous PO₂?

The Venous Equilibration Model of Transplacental Exchange

Studies on the transplacental diffusion of molecules that rapidly cross the placental barrier (e.g., tritiated water, ethanol) have established that, in sheep, the maternal and fetal placental circulations form an exchange system that tends to equilibrate the venous concentrations of any molecule that diffuses across the barrier.⁸

The physiologic concept of venous equilibration is easy to grasp by considering the hypothetical model shown in Figure 14-5. This model assumes that the basic unit of transplacental exchange consists of a membrane that separates two bloodstreams flowing in the same

direction. At the arterial end of the exchanger, the maternal blood-stream enters with a higher PO_2 than fetal blood (72 versus 19 mm Hg), thus establishing a PO_2 gradient that drives O_2 across the membrane into fetal blood. As the two streams flow concurrently past the membrane, transfer of O_2 into the fetal circulation causes a progressive decrease of PO_2 in the maternal stream and a progressive increase of PO_2 in the fetal stream, so that the transmembrane PO_2 difference at the venous end tends toward zero. This model explains why, in a venous equilibration system, umbilical venous PO_2 depends directly on uterine venous PO_2 , whereas it has no direct relationship to maternal arterial PO_2 .

The Uterine-Umbilical Venous PO_2 Difference

Several theories have been proposed to explain why the placenta maintains umbilical venous PO_2 to a much lower level than uterine venous PO_2 even under normal conditions. The following explanation is what I consider the one that best fits our current knowledge.

The placental epithelial barrier that separates maternal and fetal blood consumes O_2 . Because O_2 transport into and across the barrier is by diffusion, the placenta has no intrinsic mechanisms that would make it utilize O_2 drawn from the maternal rather than the fetal circulation. The mother-to-fetus polarity of placental O_2 transport depends on extrinsic mechanisms that maintain a positive PO_2 difference between the maternal and the fetal circulation. This transplacental PO_2 difference is the sum of two terms—the PO_2 difference that is generated by the O_2 consumption of the placental barrier and the PO_2 difference that draws O_2 all across the barrier from the maternal to the fetal circulation. If we try to imagine how the transplacental PO_2 difference changes from the arterial to the venous end of the barrier, it becomes apparent that its two components do not behave the same. The PO_2 difference that draws O_2 into fetal blood decreases toward zero as O_2 is transferred from one circulation to the other. In contrast, the PO_2 difference that is generated by the O_2 -consuming barrier does not change systematically from the arterial to the venous end. Placental mitochondria, like those in other organs, do not appreciably change their O_2 utilization rate in response to changes in PO_2 , as long as the PO_2 is kept above a critical level, which is generally quite low. As a consequence, the PO_2 difference generated by placental O_2 consumption can be a larger fraction of the transplacental PO_2 difference at the venous, than at the arterial, end of the placental barrier. Furthermore, it contributes to the remarkable stability of the uterine-umbilical venous PO_2 difference in response to changes in uterine venous PO_2 .

For any given value of umbilical O_2 uptake and placental O_2 consumption, the magnitude of the transplacental PO_2 difference depends on the surface and thickness of the placental barrier. It can be understood intuitively, for example, that a large difference would be necessary to maintain a high rate of O_2 transport into and across a thick barrier with a small surface. Respiratory physiologists would say that such a barrier has a low “ O_2 -diffusing capacity.” Placental O_2 -diffusing capacity has been estimated indirectly, via measurements of CO_2 -diffusing capacity.⁹ These measurements have led to the conjecture that the O_2 -diffusing capacity of a normal placenta is sufficient to allow a virtually complete vein-to-vein PO_2 equilibration in the placental microcirculation, and that the uterine-umbilical vein PO_2 difference results entirely from shunting of uterine and umbilical blood flows across the placenta and from uneven maternal-to-fetal blood perfusion ratios within the placenta itself.⁹ However, the conjecture that placental O_2 transport is not diffusion-limited is based on the assumption that umbilical O_2 uptake is the only O_2 flux that generates the transplacental

PO_2 gradient. The more realistic assumption—that some of this gradient is caused by O_2 consumption by the placental barrier—leads to an alternative interpretation of experimental evidence. The importance of placental oxidative metabolism in determining the uterine-umbilical venous PO_2 difference and the uterine-to-umbilical blood flow ratio is best illustrated by contrasting two models of fetal oxygenation.

In the model that was used to explain the concept of venous equilibration (see Fig. 14-5), two bloodstreams flowing concurrently at the same rate are separated by a structurally homogeneous membrane that does not consume O_2 . The two streams have virtually the same hemoglobin content per milliliter of blood but are assumed to have the highly different oxyhemoglobin dissociation curves of fetal sheep and pregnant sheep homozygous for ovine hemoglobin B. The numerical example of this model assumes the O_2 -diffusing capacity to be high enough to produce almost complete venous PO_2 equilibration and a normal level of arterial and venous O_2 saturation of the fetal bloodstream.

In the second model (Fig. 14-6), the membrane is assumed to have an O_2 -diffusing capacity identical to that in the first model. In contrast to the first model, however, the membrane is assumed to consume O_2 at constant rate per unit of surface and to have a total O_2 consumption

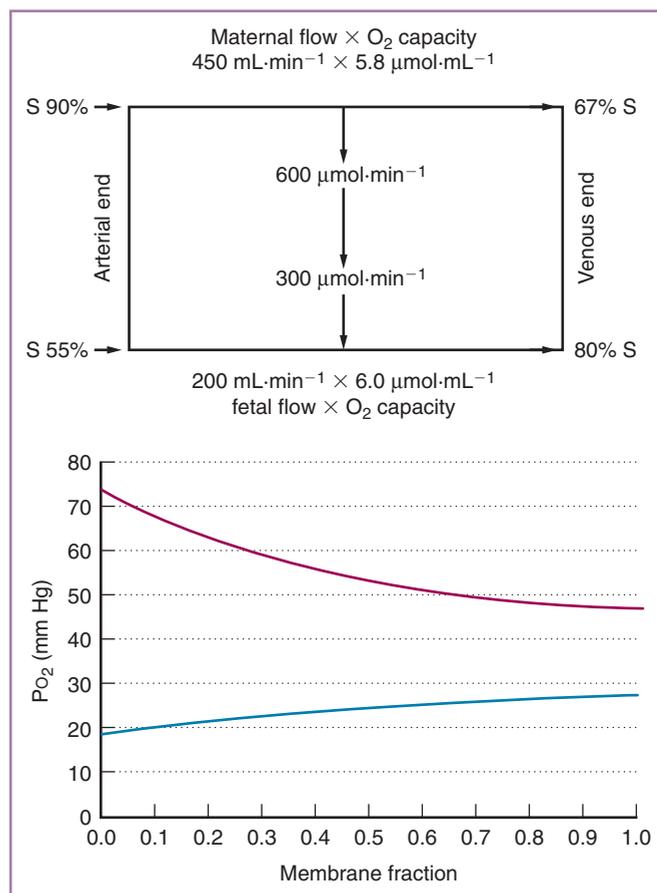

FIGURE 14-6 O_2 transport across a homogeneous membrane that consumes oxygen. Model of O_2 transport across a structurally and metabolically homogeneous membrane that is assumed to have the same O_2 -diffusing capacity as in the Figure 14-5 model, and to consume O_2 at a rate that is equal to fetal O_2 uptake. Oxygen consumption by the membrane requires a greater transmembrane PO_2 gradient and a greater maternal blood flow to provide the same level of fetal oxygenation as in the Figure 14-5 model. Red line, maternal; blue line, fetal.

that is equal to fetal O_2 uptake. Because it takes a smaller PO_2 difference to draw O_2 into the membrane than across the whole membrane, the PO_2 difference generated by membrane O_2 consumption is assumed to be only 75% of the PO_2 difference that is required to transport the same amount of O_2 from maternal to fetal blood. Fetal placental blood flow and oxygenation are as in the first model. It is apparent that O_2 consumption by the membrane requires a much larger vein-to-vein PO_2 difference (approximately 20 versus 6 mm Hg) and a markedly higher maternal-to-fetal flow ratio (2.25 versus 0.5).

The doubling of O_2 flux through the maternal surface of the membrane requires a disproportionately greater increase of maternal blood flow, because a proportional increase would have left the maternal PO_2 unchanged. The increase in the ratio of maternal flow to O_2 flux decelerates the decrease of maternal PO_2 from arterial to venous end and maintains the greater transplacental PO_2 difference that is required to maintain a normal level of fetal oxygenation.

Developmental Changes in Placental Oxygen Transport

Under normal physiologic conditions, the O_2 saturations and PO_2 of umbilical blood decline in the time interval between mid-gestation and two-thirds gestation and then show no further systematic change. In the fetal lamb, O_2 saturations decline, approximately, from 90% to 80% in the umbilical vein, and from 65% to 55% in the umbilical artery. These are remarkably small variations in view of the enormous and complex changes in O_2 uptake, placental blood flow, and placental structure that take place throughout pregnancy.

At mid-gestation, the placenta consumes, approximately, four times more O_2 than the fetus,¹⁰ and the placental villi show a smaller degree of branching than at later stages.¹¹ The hindrance to transplacental O_2 diffusion that is produced by these conditions is compensated for by a very high uterine blood flow. At this stage of development, the ratio of uterine blood flow to fetal O_2 uptake is about 6 mL/ μ mol of O_2 (500 mL \cdot min⁻¹/80 μ mol \cdot min⁻¹). From mid-gestation to two-thirds gestation, this ratio declines to about 1.7 (500/300). The two major factors that produce this change are (1) an elongation and branching of the placental villi without any increase in placental O_2 consumption, and (2) an increase in umbilical blood flow (approximately from 70 to 200 mL \cdot min⁻¹). The increase in placental villous surface without a commensurate increase in placental O_2 consumption suggests a radical change in placental energy metabolism. Unfortunately, there is no clue as to the nature of this change. The mathematical model presented in Figure 14-6 is meant to be a schematic representation of placental O_2 transport at two-thirds gestation when umbilical O_2 uptake has become about equal to placental O_2 consumption.

From two-thirds to near-term gestation, there is a further, large increase in umbilical O_2 uptake (approximately from 300 to 1000 μ mol \cdot min⁻¹). There is also an increase in placental O_2 consumption, which is, however, smaller than the increase in umbilical uptake (approximately from 300 to 600 μ mol \cdot min⁻¹). The increase in O_2 transport across the placenta is determined by synchronous increases in placental O_2 -diffusing capacity and in uterine and umbilical blood flows. Under normal physiologic conditions, these changes in diffusing capacity and flows maintain virtually constant the transplacental PO_2 difference.¹² In this final stage of development, the increase in O_2 -diffusing capacity results primarily from a process of placental differentiation that produces extremely thin regions of the placental epithelium. Presumably, the thinning of the epithelium involves also a local reduction in mitochondrial density per unit surface. In essence, the placental epithelial barrier progressively evolves into a structurally and meta-

bolically uneven barrier that tends to separate the respiratory gas exchange function from other functions that require a high rate of oxidative metabolism. A likely, concomitant process is that the regions of the barrier that acquire specialized functions become perfused at different rates by maternal and fetal blood, thus creating a more complex condition of placental O_2 transport than the one depicted in Figure 14-6.

It is important to note that the maternal and the fetal blood flow to the placental cotyledons are only a fraction of the uterine and the umbilical flows, respectively. In sheep, the fraction of uterine flow perfusing the cotyledons is approximately 80% from mid-gestation¹⁰ to term.¹³ The fraction of umbilical flow to the cotyledons is about 93%.¹⁴ For this reason alone, any model that represents the placenta as a structurally and metabolically homogeneous membrane that is perfused evenly at rates equal to the uterine and the umbilical flow is no more than an approximate representation of the real system at any developmental stage. It is not clear, however, whether conditions of physiologically significant uneven O_2 exchange are present in the placental cotyledons in early development or become a distinctive feature of placental function in the last third of gestation only.

The uterine-umbilical venous PO_2 difference varies widely among pregnancies. According to our present understanding of placental O_2 transport, this is the expression of variability in the ratio of the placental O_2 -diffusing capacity to the placental and fetal O_2 consumption. At comparable values of placental and fetal oxidative metabolism, the greater the O_2 -diffusing capacity of the placental membrane is, the smaller the vein-to-vein transplacental PO_2 difference is. Under conditions of normal placental development, variations in placental O_2 -diffusing capacity have the function of adapting placental O_2 transport to the PO_2 in the maternal circulation. For example, ewes who are homozygous for high- O_2 -affinity hemoglobin maintain a smaller PO_2 in the uterine circulation than ewes that carry the low- O_2 -affinity hemoglobin type.⁴ The placental membrane adapts to the low maternal PO_2 by developing a greater O_2 -diffusing capacity. This developmental change requires a smaller transmembrane PO_2 gradient to draw O_2 at a normal rate into and across the barrier. The result of this adaptation is a smaller uterine-umbilical venous PO_2 difference and a normal level of fetal oxygenation. There are conditions, however, that inhibit placental development to various degrees, widen the transplacental PO_2 gradient, and generate a state of chronic fetal hypoxia. An extreme example of this type of fetal hypoxia has been produced experimentally by exposing pregnant ewes to high environmental temperatures for most of gestation.¹⁵ Near term, these ewes carry severely hypoxic, growth-restricted fetuses. This form of fetal hypoxia is characterized by the presence of a uterine-umbilical venous PO_2 difference that is about twice the normal value. The umbilical venous PO_2 and O_2 saturation are about 20 mm Hg and 50%, respectively. This is a level of oxygenation that alters the distribution of fetal cardiac output, decreases O_2 consumption by some fetal tissues (e.g., skeletal muscle), and is close to the limit of fetal viability.

There is evidence that human fetal growth restriction is also associated with a uterine-umbilical venous PO_2 difference that is greater than normal (Fig. 14-7).¹⁶ Furthermore, the terminal villi in the placentas of severely hypoxic, growth-restricted human fetuses occupy a significantly smaller fraction of placental volume than normal¹⁷ and show signs of trophoblastic degeneration.¹⁸ Because in the differentiation of the placental barrier, the areas with the smallest interhemal distance are located preferentially in the terminal villi, these data support the hypothesis that the hypoxia of growth-restricted fetuses is the result of a disproportionate reduction of those regions of the placental barrier that facilitate the transplacental diffusion of oxygen.

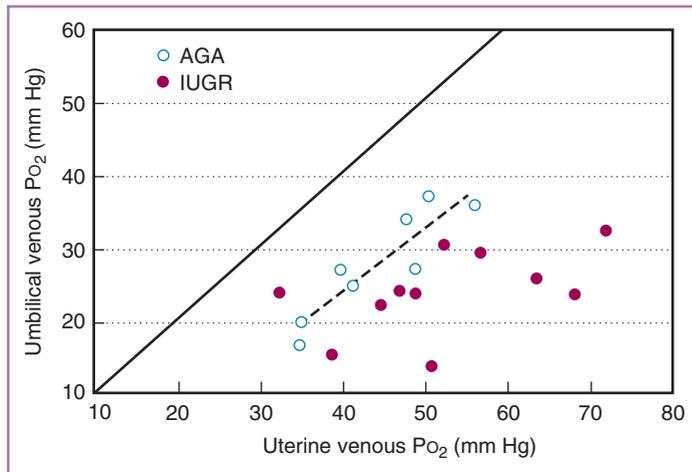

FIGURE 14-7 Uterine venous and umbilical venous partial pressures of oxygen. Relationship between uterine venous and umbilical venous partial pressure of oxygen (PO_2) in normal human pregnancies (*open circles*) and pregnancies with intrauterine growth restriction (IUGR) (*closed circles*). AGA, appropriate for gestational age. (From Pardi G, Cetin I, Marconi AM, et al: Venous drainage of the human uterus: Respiratory gas studies in normal and fetal growth retarded pregnancies. *Am J Obstet Gynecol* 166:699, 1992.)

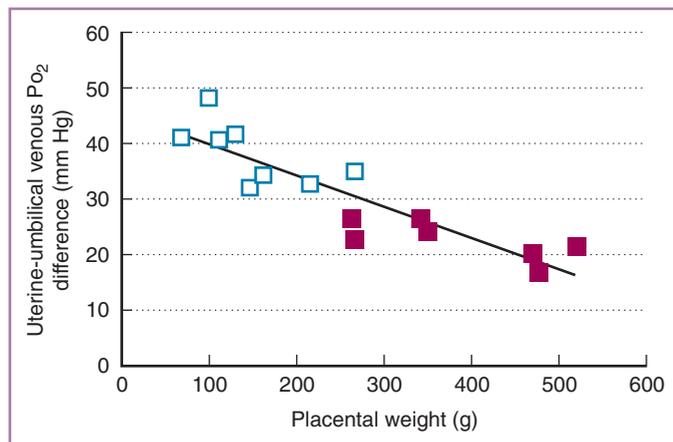

FIGURE 14-8 Uterine-umbilical venous PO_2 difference versus placental weight. Correlation of the uterine-umbilical venous PO_2 difference with placental weight in normal (*closed squares*) and growth-restricted (*open squares*) fetal sheep ($R^2 = 0.79$). (From Regnault TR, de Vrijer B, Galan HL, et al: Development and mechanisms of fetal hypoxia in severe fetal growth restriction. *Placenta* 28:714-723, 2007.)

Studies on placental respiratory gas exchange under normal physiologic conditions have shown that the uterine-umbilical venous PO_2 difference is inversely correlated to placental weight. This negative correlation becomes highly significant if the placentas of growth-restricted fetuses are included in the analysis (Fig. 14-8).¹⁵ A likely explanation for this finding is that the growth of placental mass and the differentiation of the placental epithelium are controlled, at least in part, by common factors. This explanation is supported by the results of a study on the effects of deleting, in mice, the placental-specific insulin-like growth factor 2 gene (*IGF2*).¹⁹ This deletion causes both a decrease in

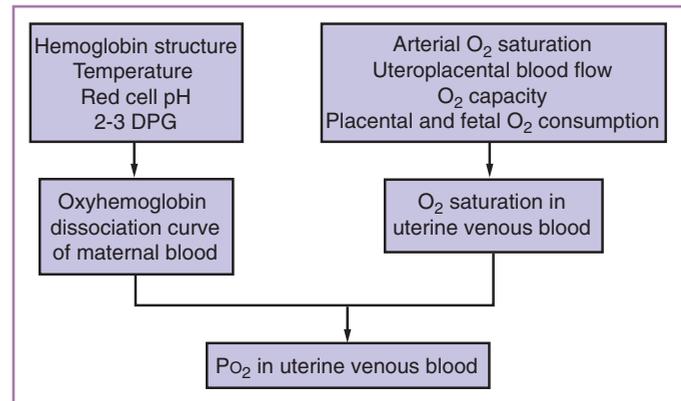

FIGURE 14-9 Factors that determine uterine venous partial pressure of oxygen (PO_2). 2-3 DPG, 2,3-diphosphoglycerate.

placental mass and an increase in the mean thickness of the trophoblast.

Factors That Determine Uterine Venous PO_2

The evidence in sheep, rhesus monkeys, and humans points to uterine venous PO_2 as being the primary determinant of umbilical venous PO_2 in these species. The factors that determine uterine venous PO_2 are shown in Figure 14-9, and of these, the immediate causative factors are the oxygen saturation and oxyhemoglobin dissociation curve of venous blood. The position of the oxyhemoglobin dissociation curve is shifted by pH, so that at any given saturation, the PO_2 is inversely related to pH (the Bohr effect). Because of the Bohr effect, maternal alkalosis can be detrimental to fetal oxygenation via its effect on uterine venous PO_2 (Fig. 14-10).

The oxygen saturation of uterine venous blood, S_V , is a function of four variables and can be calculated with the following equation:

$$S_V = S_A - \dot{V}O_2 / F [O_2 \text{ CAP}],$$

where S_A is the oxygen saturation of maternal arterial blood, $O_2 \text{ CAP}$ is the oxygen capacity of maternal blood, F is the uterine blood flow, and $\dot{V}O_2$ is the oxygen consumption rate of the gravid uterus. This equation, an application of the Fick principle,* is an approximation that neglects the small contribution of free oxygen to the oxygen content of blood. Implicit in the equation are the three main types of hypoxia listed in textbooks of physiology:

*Derivation of the equation for oxygen saturation of venous blood. Let $\dot{V}O_2$ = uterine O_2 consumption (mmol/min), F = uterine blood flow (mL/min), A = arterial oxygen content (mmol/mL), V = uterine venous oxygen content (mmol/mL), $[O_2 \text{ CAP}]$ = oxygen capacity (mmol/mL), S_A = oxygen saturation of arterial blood, and S_V = oxygen saturation of uterine venous blood. According to the Fick principle,

$$\dot{V}O_2 = F(A - V).$$

Divide both sides of the equation by oxygen capacity: $\dot{V}O_2/[O_2 \text{ CAP}] = F(A/[O_2 \text{ CAP}] - V/[O_2 \text{ CAP}])$. If we neglect the contribution of free oxygen to A and V , $A/[O_2 \text{ CAP}] = S_A$, and $V/[O_2 \text{ CAP}] = S_V$.

$$\text{Therefore, } \dot{V}O_2/[O_2 \text{ CAP}] = F(S_A - S_V) \\ \text{and } S_V = S_A - \dot{V}O_2/F[O_2 \text{ CAP}].$$

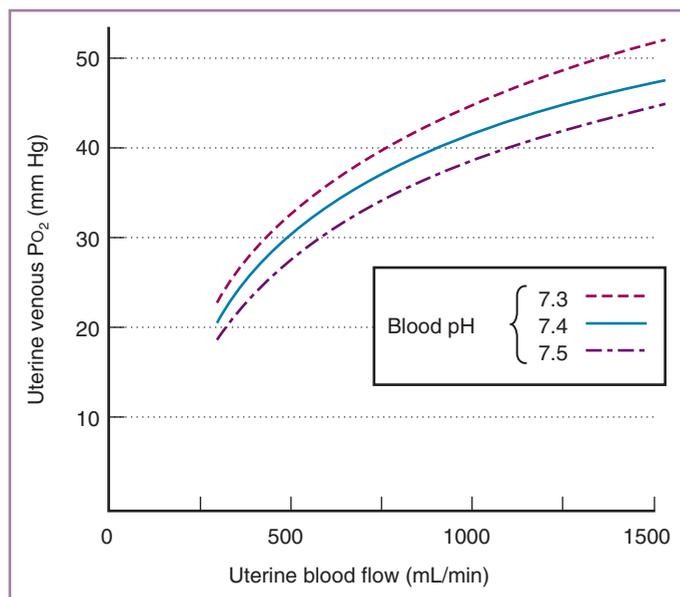

FIGURE 14-10 Uterine venous partial pressure of oxygen (PO_2) as a function of uterine blood flow in a pregnant patient close to term. The figure was constructed with the assumption that the following values were constant: maternal arterial PO_2 , 80 mm Hg; maternal oxygen capacity, 17.4 volumes percent; oxygen consumption rate of the gravid uterus, 30 $\text{mL}_{\text{STP}}/\text{min}$. STP, standard temperature and pressure.

- Low saturation of arterial blood (hypoxic hypoxia)
- Reduced oxygen capacity (anemic hypoxia)
- Reduction in blood flow (circulatory hypoxia)

These types of hypoxia, alone or in combination, decrease uterine venous saturation. A decrease in uterine venous oxygen saturation implies a decrease of uterine venous PO_2 and impairment of fetal oxygenation.

An important consequence of the inefficiency of a placenta—which is a venous equilibrater, consumes O_2 at a rapid rate, and has a low oxygen-diffusing capacity—is that it requires a relatively high uterine blood flow to provide a normal level of fetal oxygenation. For example, if we consider as valid the evidence that under normal physiologic conditions the umbilical venous PO_2 of a 35-week-old human fetus is about 30 mm Hg²⁰ and that uterine venous PO_2 must be at least 10 mm Hg higher than umbilical venous PO_2 ,¹⁶ according to Figure 14-10 the uterine blood flow in late human pregnancy should normally be about 1 L. Early estimates based on Doppler technology were considerably lower.²¹ However, using improved Doppler imaging, Konje and colleagues²² reported the mean blood flow carried by the two uterine arteries to be 942 mL/min at 36 weeks. Knowing the normal value of uterine blood flow is necessary to construct a correct model of fetal oxygenation.

Transport of Oxygen to Fetal Tissue

In recent years, improved techniques for blood flow measurement and umbilical blood sampling in utero have led to considerable progress in the exploration of human fetal physiology. The results of this effort, together with comparative data in sheep, allow us to construct a tenta-

TABLE 14-3 REPRESENTATIVE DATA FOR BLOOD OXYGEN TRANSPORT IN A 35-WEEK HUMAN FETUS AND A SHEEP FETUS AT A COMPARABLE DEVELOPMENTAL STAGE

	Human Fetus (35 wk)	Sheep Fetus (19 wk)
Blood O_2 capacity (mM)	9.4	6.7
Umbilical venous O_2 saturation (%)	70.0	81.0
Umbilical venous O_2 content (mM)	6.6	5.4
Umbilical venous PO_2 (mm Hg)	28.0	28.0
Umbilical arterial O_2 saturation (%)	40.0	56.0
Umbilical arterial O_2 content (mM)	3.8	3.8
Umbilical arterial PO_2 (mm Hg)	19.0	19.0
Cardiac output ($\text{mL}/\text{min}/\text{kg}$)	500.0	500.0
Umbilical blood flow ($\text{mL}/\text{min}/\text{kg}$)	120.0	216.0
Umbilical flow/cardiac output	0.24	0.43

tive picture of normal human fetal oxygenation and blood oxygen transport (Table 14-3).

In both the human and ovine fetuses, arterial PO_2 is about one-fourth the maternal arterial PO_2 at sea level. This is a consequence partly of the structural and functional characteristics of the placenta, which require that the oxygenation of fetal blood take place at a low PO_2 , and partly of the anatomy of the fetal circulation, which forms arterial blood by mixing the blood that returns from the placenta with deoxygenated blood returning from the fetal tissues.

Despite the very low PO_2 of its blood, the fetus is capable of transporting large amounts of oxygen from the placenta to the sites of oxygen consumption in the fetal body. Three major adaptations make this possible:

- The hemoglobin of fetal red blood cells has a high affinity for oxygen (i.e., it binds oxygen at low PO_2 values). This property enables the fetal red blood cells that circulate through the placenta to become highly saturated with oxygen.
- The fetus has a very high cardiac output relative to its body size and metabolic rate.
- The distribution of cardiac output between placenta and fetus and within the fetus creates a well-balanced oxygen uptake and delivery system.

Available data for the human fetus indicate that this adaptive strategy has some intriguing quantitative differences from the ovine model. At mid-gestation, the oxygen capacity of human fetal blood is approximately 6.5 mM; umbilical venous oxygen saturation and PO_2 are about 90% and 50 mm Hg, respectively.²³ In comparison, the mid-gestation ovine fetus has a somewhat lower oxygen capacity (5.7 ± 0.3 mM) and an equally high umbilical venous oxygen saturation ($89\% \pm 1\%$). Note that a 90% oxygen saturation is close to the highest value that can reasonably be expected for the oxygenation of blood by any respiratory organ.

As gestation progresses past mid-term, umbilical venous oxygen saturation and PO_2 decline concomitantly with an increase in oxygen capacity. These changes occur in both species, but those described in humans are larger,^{20,23} so that in late gestation the human fetus has blood with substantially greater oxygen capacity and about 10% lower umbilical venous oxygen saturation than the ovine fetus.

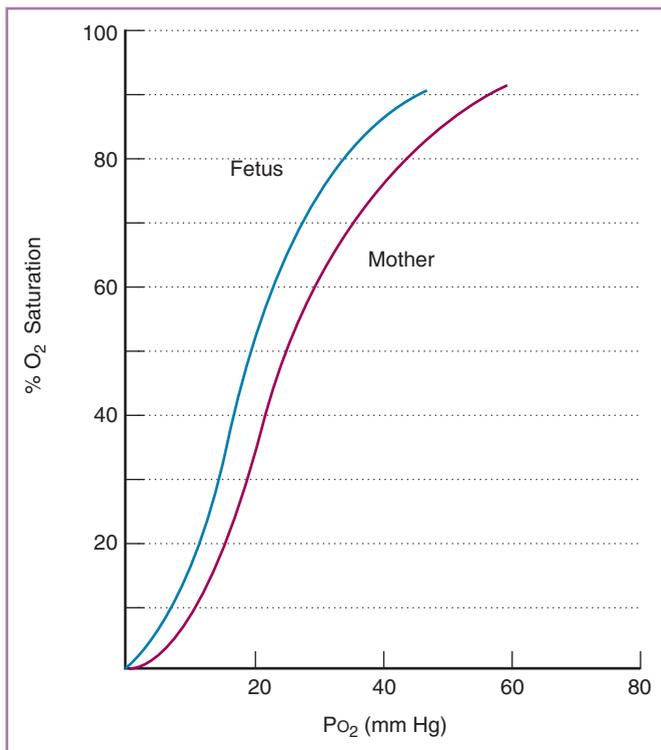

FIGURE 14-11 The oxyhemoglobin dissociation curves of maternal (red line) and fetal (blue line) human blood at pH 7.4 and 37° C. PO_2 , partial pressure of oxygen. (From Hellegers AE, Schrufer JJ: Nomograms and empirical equations relating oxygen tension, percentage saturation and pH in maternal and fetal blood. *Am J Obstet Gynecol* 81:377, 1961.)

Despite the difference in oxygen saturation, the two species have comparable umbilical venous PO_2 values because human fetal blood has slightly lower oxygen affinity than ovine fetal blood. Although the oxygen affinity of human fetal blood is not as high as in sheep, it still represents an important adaptation to the low PO_2 at which the human placenta oxygenates the fetus. Figure 14-11 compares the oxyhemoglobin dissociation curves of human adult and fetal blood.²⁴ At a PO_2 of 30 mm Hg and blood pH 7.4, fetal blood is 73% saturated with oxygen; adult blood is only 60% saturated.

In addition to umbilical venous PO_2 and oxygen saturation, we must consider oxygen content, which is the product of oxygen saturation and capacity. The umbilical venous blood of the late-gestation human fetus has a higher oxygen content than that of the sheep fetus because the higher oxygen capacity more than compensates for the lower saturation.

The next two important factors to be considered are umbilical blood flow and fetal cardiac output. The human umbilical blood flow is approximately 120 mL/min/kg fetal bodyweight,²⁵ which is about 40% lower than umbilical blood flow measured in sheep.³ Initial attempts to measure human fetal cardiac output suggested that it is also relatively small, but further investigations indicate that cardiac output is as high in the human as in the sheep fetus and approximately equal to 500 mL/min/kg fetal bodyweight.²⁶⁻²⁸ Therefore, there seems to be a major difference between the two species in the distribution of fetal cardiac output. In fetal sheep, umbilical blood flow represents approximately 40% of cardiac output; in the late-gestation human fetus, umbilical blood flow is less than 30% of cardiac output (see Table

14-3). This large difference may result, in part, from errors of measurement. It seems clear, however, that in comparison with the ovine fetus, a high blood oxygen capacity (i.e., high hemoglobin content and hematocrit) and a low ratio of umbilical blood flow to cardiac output are distinctive normal characteristics of the human fetus. Umbilical blood flow and oxygen capacity are interrelated. In anemic human fetuses, umbilical blood flow becomes greater than 120 mL/min/kg fetal bodyweight and can be as high as in the sheep fetus.²⁹

The function of the fetal circulation as an oxygen delivery system depends on an appropriate balance between umbilical blood flow and fetal somatic blood flow. It can be understood intuitively that directing too much cardiac output into the somatic circulation would impair the umbilical uptake of oxygen, and that directing too much cardiac output into the umbilical circulation would impair the supply of oxygen to fetal organs. It may seem that, theoretically, the optimal balance is to split the distribution of cardiac output evenly between the umbilical and somatic circulations. However, the experimental evidence shows a balance tilted toward the somatic circulation. The enormous growth of the human fetal brain is probably the major factor that creates the demand for a smaller umbilical flow in the human than in the ovine fetus. At term, the human fetus and the ovine fetus weigh about the same, but the mass of the fetal human brain is about eight times greater. A larger cerebral mass implies a greater oxygen demand and requires a greater percentage of cardiac output directed to the fetal upper body at the expense of the fetal lower body and the umbilical circulation. The high O_2 capacity of human fetal blood can be viewed as a compensatory mechanism that allows the human fetus to maintain a relatively low umbilical blood flow without compromising umbilical O_2 uptake.

Because of its low blood PO_2 , the fetus is more hypoxic than the neonate. Normally, however, the fetus has access to all the oxygen it needs and does not use anaerobic glycolysis as a terminal source of energy.³⁰ Furthermore, the low level of PO_2 in fetal arterial blood is physiologically useful because it is an essential component of the mechanisms that keep the ductus arteriosus open and the pulmonary vascular bed constricted. To counteract the pathologic connotation of the word *hypoxia*, it is advisable to use the expression *physiologic hypoxia* to refer to the normal state of fetal oxygenation.

In the ordinary usage of the term, fetal hypoxia means any decrease below normal in the level of fetal oxygenation. Such a decrease can come about in different ways, most commonly as a reduction in the PO_2 of umbilical venous blood, which in turn determines a decrease of fetal arterial PO_2 , in the oxygen capacity of fetal blood (anemic hypoxia, elevated levels of carbon monoxide), or in the perfusion rate of the umbilical circulation.

The circulation of an unanesthetized, otherwise healthy fetus reacts to an acute decrease in umbilical venous and arterial PO_2 in a predictable manner.^{31,32} As the PO_2 falls, blood flow is increased to the central nervous system (CNS) and the heart, although cardiac output and placental blood flow tend to remain constant. As a consequence, acute fetal hypoxia is characterized by a redistribution of cardiac output favoring the CNS and heart at the expense of other parts of the fetal body.

The fraction of cardiac output directed to the CNS and heart increases hyperbolically as the arterial oxygen content decreases (Fig. 14-12). The functional meaning of this relationship is that to mount a successful defense against hypoxia, the fetus must keep constant (or nearly so) the flow of oxygen to the CNS and heart (i.e., the product of blood flow times the oxygen content per milliliter of arterial blood). The limit of a successful circulatory defense against acute hypoxia is reached when the perfusion rate of the CNS and the heart has reached

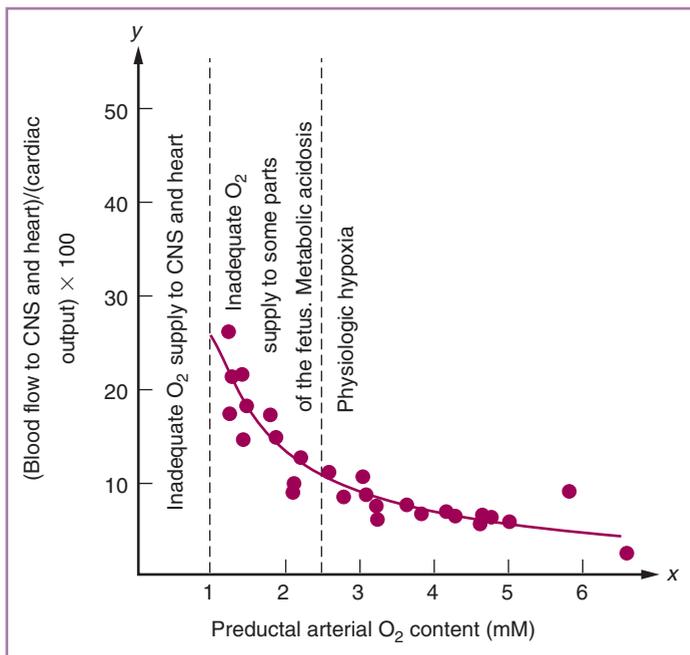

FIGURE 14-12 Hyperbolic relationship between the oxygen content in the preductal arteries of a fetal lamb and the percentage of cardiac output directed to the heart and the central nervous system (CNS). The curve was drawn according to the equation $y \times x = 0.26$. (From Sheldon RE, Peeters LLH, Jones MD Jr, et al: Redistribution of cardiac output and oxygen delivery in the hypoxemic fetal lamb. *Am J Obstet Gynecol* 135:1071, 1979.)

its maximum. In the fetal lamb, this limit is attained when the oxygen content in the supraductal arteries is approximately 1 mM. At this level, the flow of blood per gram of tissue is extremely high in the brain (approximately 4 mL/min/g) and in the heart (approximately 7 mL/min/g). Furthermore, the combined CNS and heart flow has become 26% of fetal cardiac output (see Fig. 14-12).³¹ The circulations of the human and ovine fetus react similarly to acute hypoxia. Under normal physiologic conditions, however, the large oxygen demand of the human fetal brain requires a larger contribution of cardiac output to cerebral perfusion than that of the fetal lamb. As a consequence, in response to acute hypoxia the human fetus may not be able to produce a percentage increase in cerebral blood flow as dramatic as in a species with a small brain.

Between the region of oxygenation that defines physiologic hypoxia and the limit below which there is an insufficient oxygen supply to the CNS and heart, there is a broad range (approximately between 2.5 and 1 mM arterial oxygen content in the fetal lamb) in which the supply of oxygen to some parts of the fetal body other than the CNS and heart (e.g., skeletal muscle) cannot sustain a normal level of O₂ consumption.³³

Oxygen Therapy

The inhalation of oxygen by a pregnant patient can dramatically increase the PO₂ of maternal arterial blood but causes only a small increase in fetal arterial PO₂ (Table 14-4).^{34,35} This observation seems to contradict the empirical knowledge that oxygen therapy can be an effective measure for the improvement of fetal oxygenation. Indeed, some investigators have claimed that maternal oxygen inhalation cannot ameliorate fetal hypoxia because its effect on fetal PO₂ is “neg-

TABLE 14-4 PO₂ OF MATERNAL AND UMBILICAL BLOOD AT DIFFERENT LEVELS OF MATERNAL OXYGENATION

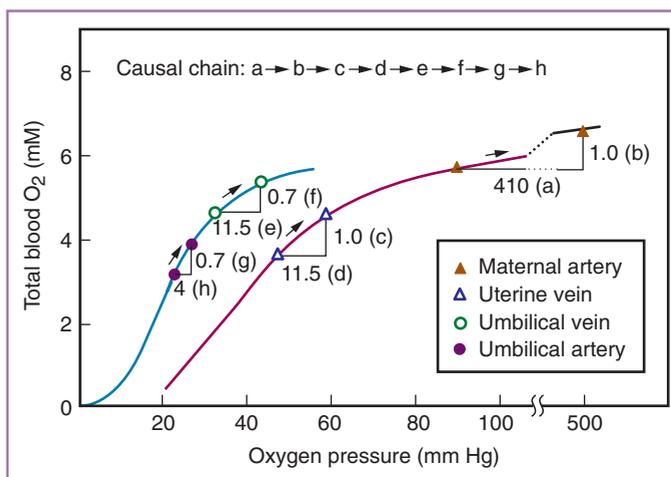

FIGURE 14-13 Oxygen therapy. Example of the relationship between oxygen content and partial pressure of oxygen in maternal (red line) and fetal (blue line) blood before and after maternal inhalation of 100% oxygen. (From Meschia G: Transfer of oxygen across the placenta. In Gluck L [ed]: *Intrauterine Asphyxia and the Developing Fetal Brain*. Chicago, Year Book Medical, 1977.)

ligible.” Others have claimed that the discrepancy of PO₂ changes in mother and fetus is the consequence of severe placental vasoconstriction in response to the high PO₂ of maternal blood. To dispel these misconceptions, it is necessary first to understand why fetal arterial PO₂ increases much less than maternal arterial PO₂ and then to focus attention on the effect that oxygen therapy has on the oxygen content of fetal blood.

The venous equilibration model of placental exchange and the characteristics of the maternal and fetal oxyhemoglobin dissociation curves readily explain the “small” effect of oxygen therapy on fetal PO₂. In the example shown in Figure 14-13,³⁶ the oxygen contents of maternal and fetal blood are plotted against PO₂:

- The inhalation of 100% oxygen by the mother causes the PO₂ of maternal arterial blood to increase from 90 to 500 mm Hg (step a).

- This increase in PO_2 causes an increase of maternal arterial oxygen content equal to 1 mM (step b). These changes in arterial PO_2 and oxygen content do not cause any appreciable change in the uterine blood flow.
- If we assume they do not increase the uterine oxygen consumption rate—a correct assumption if fetal oxygen supply was already adequate before oxygen therapy—the law of conservation of matter requires that uterine venous oxygen content also increase 1 mM (step c).
- The increase in uterine venous oxygen content causes the uterine venous PO_2 to increase 11.5 mm Hg (step d). Note that the “S” shape of the maternal oxyhemoglobin dissociation curve and the different positions of the arterial and venous points on this curve determine that an equal change of oxygen content is associated with a markedly smaller change of PO_2 in the uterine vein than in the maternal arteries. Note also that the assumption of a constant oxygen consumption rate maximizes the increase in venous PO_2 . If the oxygen consumption of the gravid uterus were to increase in response to oxygen therapy, the increase of venous PO_2 would be less than indicated.
- Given an increase of 11.5 mm Hg in the uterine venous PO_2 , the umbilical venous PO_2 will increase by an approximately equal value (step e).
- The increase in umbilical venous PO_2 is associated with an increase in umbilical venous oxygen content (step f), whose magnitude is dictated by the slope of the oxyhemoglobin dissociation curve and by the position of the umbilical venous point on that curve.
- In this example, the oxygen content of umbilical venous blood increases 0.7 mM. If we assume no appreciable change in umbilical blood flow or oxygen uptake, it follows (again by application of the law of conservation of matter) that the oxygen content in the umbilical artery must also increase 0.7 mM (step g).
- Because the arterial point is positioned on the steep part of the fetal oxyhemoglobin dissociation curve, an increase of 0.7 mM in oxygen content is associated with a PO_2 increase of only 4 mm Hg (step h).

The conclusion of this chain of events is that a PO_2 change of 410 mm Hg in maternal arterial blood results in a PO_2 change of 4 mm Hg in umbilical arterial blood.

If we focus our attention on fetal PO_2 changes by excluding other considerations, we might be tempted to conclude that maternal oxygen therapy has no appreciable effect on fetal oxygenation. However, oxygen therapy can cause similar increments in the oxygen content of maternal and fetal blood. In the example, an increase of 1 mM in maternal blood was associated with an increase of 0.7 mM in fetal blood. Under somewhat different circumstances, the oxygen content of fetal blood can actually increase more than the oxygen content of maternal blood (Fig. 14-14).³⁶

Oxygen therapy is commonly used in the treatment of acute fetal hypoxia. It may be valuable also in the treatment of chronic fetal hypoxia. In two studies, 55% oxygen was administered for several days to pregnant patients with intrauterine growth restriction.^{37,38} There were significant increases in umbilical venous PO_2 and oxygen saturation and a significant improvement in Doppler flow patterns.

Finally, it is important to consider the issue of oxygen toxicity. Breathing oxygen at high concentrations can be harmful to the lungs of the mother. Because of this concern, breathing 100% oxygen at

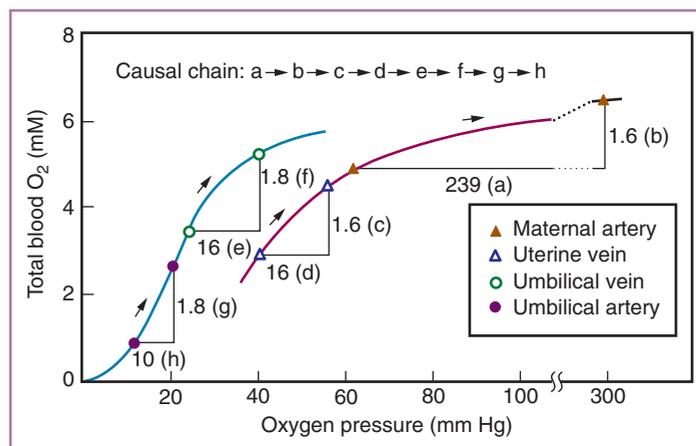

FIGURE 14-14 Example of the pronounced effect of oxygen therapy on fetal oxygen content in a case of fetal hypoxia secondary to maternal hypoxia. Red line, maternal; blue line, fetal. (From Meschia G: Transfer of oxygen across the placenta. In Gluck L [ed]: Intrauterine Asphyxia and the Developing Fetal Brain. Chicago, Year Book Medical, 1977.)

atmospheric pressure must be limited to a few hours only. Breathing 50% oxygen at atmospheric pressure is considered safe. However, the question of whether pregnancy alters the tolerance of the mother to hyperoxia has not been addressed. In general, there is no concern that maternal hyperoxia would increase fetal PO_2 to toxic levels, as long as the oxygen is administered at atmospheric pressure and for the purpose of treating fetal hypoxia.

Placental Carbon Dioxide Transfer

Carbon dioxide is an end product of fetal metabolism. In the fetal lamb, the respiratory quotient (i.e., the moles of CO_2 produced per mole of oxygen consumed) is approximately 0.94. The CO_2 produced by the fetus diffuses from the umbilical circulation into the placenta and from the placenta into the maternal blood, which brings it to the lungs for excretion. The diffusional transfer of CO_2 from fetus to mother requires the PCO_2 of fetal blood to be higher than the PCO_2 of maternal blood. In chronic sheep preparations, umbilical venous PCO_2 is approximately 5 mm Hg higher than uterine venous PCO_2 . The factors responsible for determining the magnitude of the PCO_2 gradient between fetal and maternal blood have not been analyzed in detail. A consequence of the high diffusibility of CO_2 across the placenta is that respiratory disturbances of acid-base balance in the mother cause—with a delay of a few minutes only—analogue disturbances in the fetus, as long as the two organisms are in communication via a well-perfused placenta. An abnormally low fetal PCO_2 (fetal respiratory alkalosis) is always secondary to a low maternal PCO_2 . However, an abnormally high fetal PCO_2 (fetal respiratory acidosis) can be caused by a high maternal arterial PCO_2 , inadequate gas exchange across the placenta, or a combination of these two conditions.

There are probably substantial differences among mammals in the permeability of the placental barrier to bicarbonate ions. The epitheliochorial placenta of sheep has a very low permeability to bicarbonate and to other small anions, such as chloride ions and ketoacids. If maternal metabolic acidosis or alkalosis develops, the bicarbonate concentration of fetal blood remains normal for several days; however, the hemochorial placenta of the rabbit or rhesus monkey is much more permeable to chloride ions than an epitheliochorial placenta. This

suggests that the hemochorial placenta is permeable to bicarbonate and other ions, in which case metabolic disturbances of acid-base balance in the mother would cause analogous disturbances in the fetus. Unfortunately, there is no exact information, in the human or any other species with a hemochorial placenta, about the rate at which a metabolic disturbance of acid-base balance in the maternal compartment is transmitted to the fetal compartment.

Chapter 15

Fetal Lung Development and Surfactant

Alan H. Jobe, MD, PhD

In the recent past, lung immaturity in the preterm newborn often resulted in death. With intensive clinical management, lung function no longer limits the survival of most preterm newborns. That management includes the use of antenatal corticosteroids to mature the fetal lung, improvements in neonatal ventilatory techniques, and surfactant treatments. Understanding the process of lung maturation involves anatomy, physiology, and cell and molecular biology. Although the anatomy and physiology of lung development in the human and in experimental animals have been characterized, the cell biology and genetics are now revealing the mechanisms underlying the developmental program.

Hyaline membranes were described in association with respiratory deaths early in the twentieth century. However, there was no substantial increase in the understanding of lung immaturity until Avery and Mead correlated respiratory failure with decreased surfactant levels in saline extracts of the lungs of infants who died of respiratory distress syndrome (RDS) in 1959.¹ Once the association between atelectasis with hyaline membranes and surfactant levels was appreciated, a large research effort was focused on the surfactant system. The first direct clinical benefit was the development by Gluck and colleagues in 1971 of the lecithin-to-sphingomyelin ratio using amniotic fluid to predict the risk of RDS in preterm infants.² The usefulness of phosphatidylglycerol measurements for lung maturity testing then was recognized.³ The maturational effects of corticosteroids on developing systems were apparent by the late 1960s, and in 1972 Liggins and Howie demonstrated a decreased incidence in RDS with maternal corticosteroid treatments.⁴ The subsequent development of surfactant treatment for RDS and other neonatal lung diseases has had a major beneficial impact on outcomes.⁵ Further progress in the pulmonary outcomes of infants will result from new information about how antenatal and postnatal abnormalities contribute to lung development, injury, and repair.

Lung Structural Development

Embryonic Stage

The lung first appears in the embryo at about 26 days as a ventral bud off the esophagus just caudal to the laryngotracheal sulcus.⁶ The grooves between the lung bud and the esophagus deepen, and the bud elongates within the surrounding mesenchyme and divides to form the future mainstem bronchi (Fig. 15-1).⁷ Several factors that determine lung bud formation have been identified using transgenic mouse models. Deletion of fibroblast growth factor 10 (FGF-10) or a com-

pound deletion of the zinc finger DNA-binding proteins Gli2 and Gli3 prevent lung development by disrupting tracheal development (Table 15-1).^{8,9} Subsequent dichotomous branching of the trachea gives rise to the conducting airways and lobar structures of the lungs. Branching is controlled by the underlying mesoderm because removal of the mesenchyme stops branching, and transplantation of the mesenchyme from a branching airway to a more proximal airway or the trachea induces budding in the new location. Lobar airways are formed by about 37 days with progression to segmental airways by 42 days and subsegmental bronchi by 48 days in the human.⁶

Some of the diffusible factors responsible for airway branching have been identified.^{8,9} Several members of the large family of fibroblast growth factors acting through specific fibroblast growth factor receptors modulate airway branching and parenchymal development. For example, overexpression of FGF-7 (also known as keratinocyte growth factor) results in lung tumors similar to cystic adenomatoid malformations. Several factors are associated with the development of tracheo-esophageal fistula in transgenic mice. These and other genes have very precise spatial and temporal expression patterns that choreograph lung structural development. Newly developed techniques to turn on or turn off specific genes in mouse models will result in a more complete understanding of early lung development.

Pseudoglandular Stage

The pseudoglandular period, from about the 6th to 17th week of human gestation, is characterized by progressive division to generate 15 to 20 generations of airways depending on airway segment length and lobar position.¹⁰ The developing airways are lined with simple cuboidal cells that contain large amounts of glycogen. Epithelial differentiation is centrifugal in that the most distal tubules are lined with undifferentiated cells, with progressive differentiation in the more proximal airways. Pulmonary arteries grow in conjunction with the airways, and the principal arteries are present by 14 weeks. The pulmonary microvasculature develops in the mesenchyme around the developing airways by the processes of angiogenesis by the sprouting of new vessels from preexisting vessels, and of vasculogenesis, in which primitive vascular plexuses fuse and then connect with vessels under control of factors such as vascular endothelial growth factor⁸ (VEGF). Pulmonary venous development occurs in parallel by both angiogenesis and vasculogenesis, but with a different pattern that demarcates lung segments and subsegments. By the end of the pseudoglandular stage, airways, arteries, and veins have developed in a pattern corresponding to that found in the adult. The diaphragm separates the chest from the abdomen during this stage of lung development, and failure to close results in diaphragmatic hernia and lung hypoplasia.

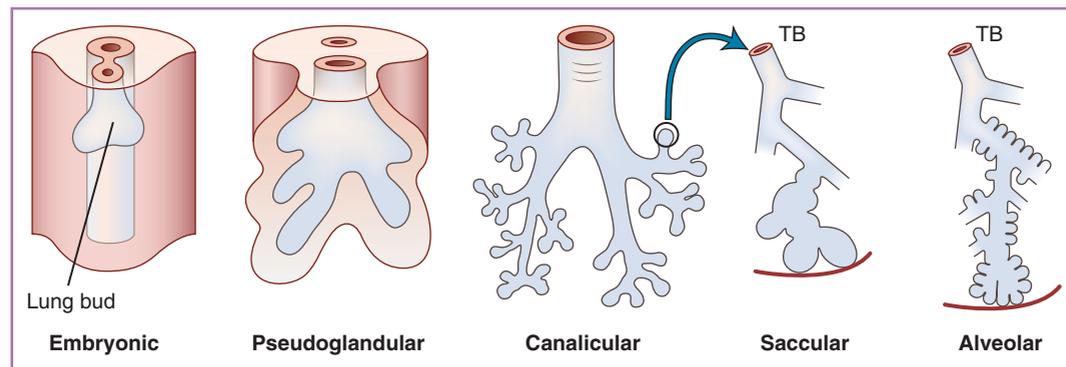

FIGURE 15-1 Morphologic development of the human lung. Schematic representations of stages of development. TB, terminal bronchiole. (Courtesy of Jeffrey Whitsett, Cincinnati Children's Hospital.)

TABLE 15-1 LUNG DEVELOPMENT IN THE HUMAN FETUS

Stage of Development	Fetal Age (wk)	Structural Events	Regulators of Lung Growth and Differentiation	Associated Abnormalities
Embryonic	3-6	Lung bud formation, trachea, lobar and segmental bronchi	TTF-1, FGF-10, Shh, Gli	TE fistula, pulmonary agenesis, hypoplasia, asymmetries
Pseudoglandular	6-16	Subsegmental bronchi, terminal bronchi, mucous glands, cartilage, smooth muscle, early vasculature and epithelial differentiation	TTF-1, FGFs, FOXa1/a2	Sequestration, abnormal lobation, cystic adenomatoid malformation, lymphangiectasias, congenital diaphragmatic hernia
Canalicular	16-26	Respiratory bronchioles, acinar saccules, thinning of capillary-epithelial space, type I and type II epithelial cells	Glucocorticoid receptors, VEGF	Pulmonary hypoplasia, alveolar-capillary dysplasia
Saccular	26-36	Division of acinar saccules, microvascular expansion, increase in gas-exchange surface area	Glucocorticoid receptors, VEGF	Pulmonary hypoplasia, pulmonary hypertension
Alveolar	32 wk to 2 yr	Septation of saccules and alveoli, maturation of type II cells, surfactant	Glucocorticoid receptors, retinoic acid receptors, inflammatory mediators	SP-B, SP-C, and ABCA3 transporter deficiencies, pulmonary hypertension

FGF-10, fibroblast growth factor 10; FOXa1/a2, forkhead box a1/a2; Shh, sonic hedgehog homolog; TTF-1, thyroid-specific transcription factor 1; VEGF, vascular endothelial growth factor.

Canalicular Stage

The canalicular stage, between about 16 and 26 weeks' gestation, represents the transformation of the preivable lung to the potentially viable lung that can exchange gases. The three major events during this stage are the "birth" of the acinus, epithelial differentiation with the development of the potential air-blood barrier, and the start of surfactant synthesis within recognizable type II cells.¹¹ The acinus is the tuft of distal airways originating from a terminal bronchiole. Its initial development is the critical first step for the development of the future gas exchange surface of the lung. The initially poorly vascularized mesenchyme surrounding the airways becomes more vascular and more closely aligned with the airway epithelial cells. The capillaries initially form a double capillary network between future airspaces. These capillaries subsequently fuse to form a single capillary bed between the future gas exchange surfaces, with close apposition to the saccular walls to form a structure by about 19 weeks similar to the thin air-blood barrier in the adult lung. If the double capillary network does not fuse, the infant will have severe hypoxemia and the histopathologic findings of alveolar-capillary dysplasia. The total surface area occupied by the air-blood barrier increases exponentially through the canalicular

stage, with a resultant fall in the mean wall thickness and with an increased potential for gas exchange. Epithelial differentiation is characterized by proximal-to-distal thinning of the epithelium by transformation of cuboidal cells into thin cells that line wide tubes. The tubes grow both in length and in width with attenuation of the mesenchyme, which is simultaneously vascularized. After about 20 weeks' gestation in the human fetus, these cuboidal cells rich in glycogen begin to have lamellar bodies in their cytoplasm, indicating the initiation of surfactant production.

Saccular Stage

The saccular stage is the period of lung development that is present in most potentially viable preterm fetuses from about 26 weeks to 36 weeks of gestation. The saccule is the terminal structural element of the fetal lung, which divides or septates through perhaps three generations with formation of respiratory bronchioles, and a further three generations to form alveolar ducts before the initiation of "secondary" septation of these saccules to form alveoli.⁶ During this saccular stage of lung development, airspace number increases from about 65,000 at 18 weeks to 4 million by 32 to 36 weeks of gestation (Fig. 15-2). Micro-

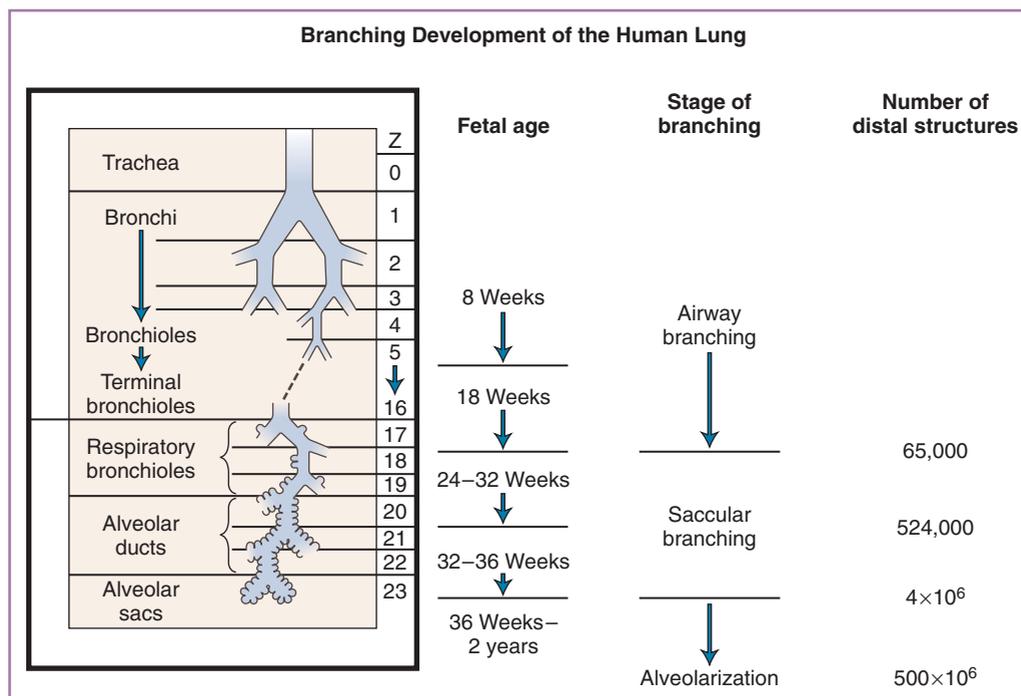

FIGURE 15-2 Airway branching, fetal age, and number of branches during lung development. Airway branching results in about 16 generations of airways by about 18 weeks' gestation. Branching of distal saccular structures yields respiratory bronchioles and alveolar ducts in the saccular lung by about 32 weeks' gestation. Alveolarization continues from 32 to 36 weeks until 2 years of age. (Modified from Burri PW: Development and growth of the human lung. In Fishman AP, Fisher AB [eds]: Handbook of Physiology: The Respiratory System. Bethesda, MD, American Physiology Society, 1986, p 1.)

vascularity continues to increase, as does the gas-exchange surface area of the lung. The fetal lung is sensitive to glucocorticoid stimulation of surfactant and lung structural changes and to the development of pulmonary hypoplasia. Very little is known about the modulators of saccular septation. Saccular septation and the associated vascularization are the critical stages of lung development that may be influenced by common obstetric interventions.

Alveolar Stage

Alveolarization is initiated at 32 to 36 weeks from the terminal saccules by the appearance of septa composed of capillaries, elastin fibers, and collagen fibers (see Fig. 15-1). The saccules and new alveoli rapidly septate to generate about 100 million alveoli at term and about 500 million alveoli in the adult human.^{12,13} The rate of alveolar formation is maximal between about 36 weeks' gestation and several months after birth and may be complete by about 2 years of age. The important concept is that alveolar development is a late fetal event that is at its maximal rate during the stages of fetal development after early preterm labor and delivery. Once alveoli are formed, the lung subsequently loses alveoli with age, although under some circumstances the adult lung may be able to develop new alveoli.¹⁴ However, if alveolarization is disrupted during the period of rapid accumulation between about 32 weeks' gestation and term, then there may be adverse short-term and long-term effects on lung function in the newborn.

A number of clinical interventions and agents are known to disrupt normal alveolarization in developing animals (Table 15-2). Hyperoxia, hypoxia, and mechanical ventilation all can interfere with alveolarization.¹⁵ The preterm infant that is mechanically ventilated will be exposed to these factors as well as to nutritional deficits.¹⁶ Recent

TABLE 15-2 MODULATORS OF ALVEOLARIZATION

Factors That Delay or Interfere with Alveolarization

Mechanical ventilation of the preterm infant
 Glucocorticoids
 Proinflammatory cytokines (TNF- α , TGF- α , IL-11, IL-6)
 Chorioamnionitis
 Hyperoxia or hypoxia
 Poor nutrition
 Nicotine

Factors That Stimulate Alveolarization

Vitamin A (retinoic acid)
 Thyroxine

IL, interleukin; TGF- α , transforming growth factor- α ; TNF- α , tumor necrosis factor- α .

pathology from infants with very low birth weight who have died of bronchopulmonary dysplasia (BPD) demonstrates an arrest of alveolar development with lungs that contain fewer and larger alveoli.¹⁷ These lungs also demonstrate less airway injury, inflammation, and fibrosis than the lungs of infants who died from bronchopulmonary dysplasia in earlier eras.

New concepts about inflammatory mediators are being developed that link the clinical observations that chorioamnionitis can be associated with altered lung development.¹⁸ In transgenic mouse models, the overexpression of proinflammatory cytokines during the period of postnatal alveolarization disrupts alveolar formation. These same cyto-

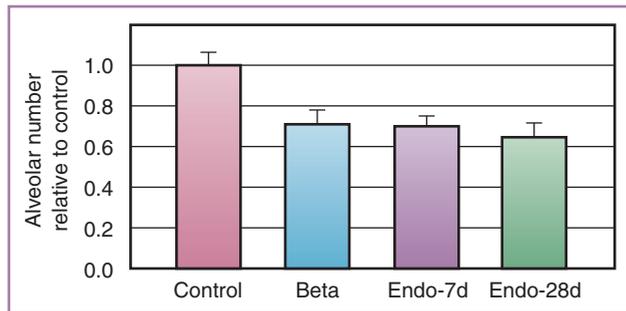

FIGURE 15-3 Effect of maternal betamethasone (Beta) or intra-amniotic endotoxin (Endo) on alveolar number in preterm lambs. The betamethasone treatment (0.5 mg/kg) was given 7 days before preterm delivery at 125 days' gestation. Endotoxin (*Escherichia coli* 055:B5) (20 mg) was given by intra-amniotic injection 6 days before preterm delivery at 125 days, or continuously from day 80 to day 108 at a rate of 0.6 mg/day into the amniotic fluid using an Alzet pump. The interventions decreased alveolarization of the fetal lung. (Data from Willet KE, Jobe AH, Ikegami M, et al: Antenatal endotoxin and glucocorticoid effects on lung morphometry in preterm lambs. *Pediatr Res* 48:782, 2000; and Moss TJM, Newnham JP, Willet KE, et al: Early gestational intra-amniotic endotoxin: Lung function, surfactant and morphometry. *Am J Respir Crit Care Med* 165:805, 2002.)

kines are elevated in amniotic fluid, cord blood, and tracheal aspirate samples of infants exposed to chorioamnionitis before preterm delivery. In an experimental model of chorioamnionitis caused by the intra-amniotic injection of endotoxin, alveolar numbers were decreased after preterm delivery in sheep (Fig. 15-3).^{19,20}

Another clinically relevant observation is that glucocorticoids can cause an arrest in alveolarization. Glucocorticoids cause permanent abnormalities in alveolar and vascular development in mice and rats.¹⁴ Maternal glucocorticoids given to the monkey at the sacular stage of lung development decrease the mesenchyme and make the lung appear more mature, but at term the lung has a lower gas volume and fewer alveoli.²¹ In sheep, single or repetitive weekly maternal glucocorticoid treatments cause a decrease in alveolar number and an increase in alveolar size after preterm birth (see Fig. 15-3).²² However, the alveolar numbers were normal at term, demonstrating that recovery from an inhibition of alveolar development is possible. A concern is that many infants with very low birth weight who are exposed to chorioamnionitis also are exposed to antenatal and postnatal glucocorticoid therapy.

Pulmonary Hypoplasia

Although embryonic developmental anomalies occasionally result in unilateral pulmonary atresias and abnormal lung segmentation syndromes, pulmonary hypoplasia syndromes are much more common. Pulmonary hypoplasia diagnosed by low lung weight was found in 15% to 20% of an unselected autopsy series.²³ The diagnosis of pulmonary hypoplasia by the anatomic criteria of decreased airway numbers and decreased radial alveolar counts is time consuming and not routine. Measurements of lung DNA content relative to body weight also can identify infants with pulmonary hypoplasia. However, generally the diagnosis is made clinically on the basis of the severity of respiratory failure and the clinical associations. The fetus must maintain the appropriate volume of fetal lung fluid in the airways and have the normal frequency and amplitude of fetal breathing move-

TABLE 15-3 CLINICAL ASSOCIATIONS WITH PULMONARY HYPOPLASIA

Thoracic Compression

- Renal agenesis (Potter syndrome)
- Urinary tract outflow obstruction
- Oligohydramnios before 28 weeks' gestational age
- Extra-amniotic fetal development

Decreased Intrathoracic Space

- Diaphragmatic hernia
- Pleural effusions
- Abdominal distention sufficient to limit chest volume
- Thoracic dystrophies

Decreased Fetal Breathing

- Intrauterine central nervous system damage
- Fetal Werdnig-Hoffmann syndrome
- Other neuropathies and myopathies

Other Associations

- Primary pulmonary hypoplasia
- Trisomy 21
- Multiple congenital anomalies
- Erythroblastosis fetalis

ments for the lung to grow normally.²⁴ Fetal lung fluid volume can be decreased either by external chest compression (e.g., oligohydramnios) or by space occupation in the chest cavity (e.g., diaphragmatic hernia). Conditions associated with pulmonary hypoplasia are listed in Table 15-3. Thoracic compression syndromes are most destructive to lung growth during the canalicular period of human lung development from 16 to 24 weeks' gestation. Oligohydramnios not associated with renal anomalies does not invariably result in pulmonary hypoplasia; however, the earlier it is in gestation, the more severe and the longer the oligohydramnios lasts, the more likely it is that severe pulmonary hypoplasia will occur.²⁵ Some infants delivered because of premature preterm rupture of membranes after many weeks of oligohydramnios can have good lung function.²⁶ Pulmonary hypoplasia, despite maintenance of apparently normal fetal lung fluid and amniotic fluid volumes, can occur in infants with severe central nervous system damage from infectious or developmental neuropathies and myopathies.

Diaphragmatic hernia is the most common cause of pulmonary hypoplasia resulting from lung compression. The lung on the side of the diaphragmatic hernia is often severely hypoplastic, but the contralateral lung also is hypoplastic, although less so. Studies in animal models indicate that maturation of the surfactant system is delayed in the hypoplastic lungs, and surfactant components are decreased in amniotic fluid from infants with diaphragmatic hernia.²⁷ Attempts to surgically correct the diaphragmatic hernia in utero have seldom succeeded. Obstruction of the trachea will distend the fetal lung with fetal lung fluid and stimulate lung growth. Although the lung grows larger, the constant stretch can result in decreased numbers of type II cells and decreased surfactant.²⁸ As a general rule, the fetal lung develops abnormally if it is compressed, collapsed because of loss of fetal lung fluid, or overstretched.

Infants with diaphragmatic hernia and with less severe degrees of pulmonary hypoplasia can be supported with mechanical ventilation. Attempting to achieve normal gas exchange and oxygenation with excessive mechanical ventilation results in severe lung injury. Gentle

approaches to mechanical ventilation together with the selective use of extracorporeal membrane oxygenation and delayed surgical correction of diaphragmatic hernias is resulting in survivals of 80% or better. Infants with trisomy 21 or other syndromes may have anomalous lung development or may have abnormal fetal breathing patterns that may result in pulmonary hypoplasia.

Fetal Lung Fluid

The fetal airways are filled with fluid until delivery and the initiation of ventilation. Quantitative information about fetal lung fluid is from the fetal lamb, with sonographic and pathologic correlates available for the human. The fetal lung close to term contains enough fluid to maintain the airway volume approximately at the same volume as the functional residual capacity once air breathing is established. This volume is about 25 mL/kg body weight in the fetal lamb. The composition of fetal lung fluid is unique relative to other fetal fluids.²⁹ The chloride content is high, and the bicarbonate and protein contents are low. The fetal epithelium is essentially impermeable to protein. The fetal lung fluid is in equilibrium with fetal partial pressure of carbon dioxide values of about 45 mm Hg, which results in a low pH in fetal lung fluid. This electrolyte composition is maintained by transepithelial chloride secretion with bicarbonate reabsorption. However, there are species differences in fetal lung fluid, and bicarbonate and pH are higher in the primate. Active chloride transport by epithelial cells results in passive water movement into the fetal airspaces, with a net production rate for fetal lung fluid of 4 to 5 mL/kg/hr.³⁰ The production of fetal lung fluid is about 400 mL/day for a 4-kg fetus. In humans, about half of this fluid is swallowed and about half mixes with the amniotic fluid. The pressure in the fetal trachea exceeds that in the amniotic fluid by about 2 mm Hg, generating an outflow resistance that maintains the fetal lung fluid volume. The secretion of fetal lung fluid is primarily an intrinsic metabolic function of the developing alveolar and airway epithelium, because changes in vascular hydrostatic pressures, tracheal pressures, and fetal breathing movements do not greatly affect fetal lung fluid production.

Although the presence of fetal lung fluid is essential for normal lung development, its clearance is equally essential for normal neonatal respiratory adaptation. Fetal lung fluid production can be completely stopped and fluid adsorption initiated in near-term fetal sheep by infusions of epinephrine at concentrations that approximate the levels of epinephrine present during labor.³¹ The epinephrine-responsive change in the airspace epithelium from fluid secretion to absorption is absent in preterm fetal sheep and can be induced by short-term cortisol and triiodothyronine infusions.³² In term guinea pigs, the Na⁺ channel blocker amiloride delays fluid clearance and causes respiratory distress, demonstrating that Na⁺,K⁺ adenosine triphosphatase function is essential for the clearance of airway fluid after birth.²⁹

Fetal lung fluid production may decrease in the days just before labor. Fetal lung fluid volume decreases in fetal sheep to about 65% of the maximal volumes present during fetal life.³⁰ During active labor and delivery, another 30% of the fluid is cleared from the airways and alveoli, leaving only about 35% of the fetal lung fluid to be adsorbed and cleared from the lungs with breathing. Most of the fluid moves rapidly into the interstitial spaces and then directly into the pulmonary vasculature, with less than 20% of the fluid being cleared by pulmonary lymphatics. Clearance of the fluid from the interstitial spaces occurs over many hours. Alveolar fluid volume in the normal lung is only about 0.3 mL/kg. The sequence of prelabor, labor, and delivery is an important regulator of the fetal lung fluid volume present at the initiation of air breathing.

Cesarean delivery of fetuses who have not experienced labor can result in decreased lung compliance, early respiratory distress, and transient tachypnea of the newborn.^{33,34} The magnitude of the potential problem can be appreciated by the following estimates. Assume the apneic term newborn born without labor has a fetal lung fluid volume of 25 mL/kg, a normal blood volume of 80 mL/kg, and a hematocrit of 50%. The fetal lung fluid, which contains essentially no protein, would be equivalent to 62% of the plasma volume. Cesarean delivery, intubation, and ventilation could result in a crystalloid volume challenge of 25 mL/kg, which could destabilize cardiopulmonary function. Although this scenario is the extreme, many subtle abnormalities and a few severe difficulties of neonatal adaptation result from the presence of large amounts of alveolar and interstitial fluid in the lungs of infants.

Surfactant

Lipids

Surfactant from lungs of all mammalian species contains 70% to 80% phospholipids, about 8% protein, and about 8% neutral lipids, primarily cholesterol (Fig. 15-4). The phosphatidylcholine species of the phospholipids contribute about 70% by weight to surfactant and are about 80% of the phospholipids.³⁵ The composition of the phospholipids in surfactant is unique relative to the lipid composition of the lung or other organs. About 50% of the phosphatidylcholine species are saturated, in that most of the fatty acid esterified to the glycerol-phosphorylcholine backbone is the 16-carbon saturated fatty acid palmitic acid. The other major phosphatidylcholine species of surfactant has a fatty acid with one double bond in the 2-acyl position of the molecule.

Saturated phosphatidylcholine is the principal surface-active component of surfactant. The acidic phospholipid, phosphatidylglycerol, is 4% to 15% of the phospholipids in surfactant from different species. The composition of the phospholipids in the surfactant lipoprotein complex changes during late gestation. Surfactant phospholipids from the immature fetus or newborn contain relatively large amounts of phosphatidylinositol, and these amounts decrease as phosphatidylglycerol appears with lung maturity.³⁶ Although phosphatidylglycerol is a convenient marker for lung maturity, its presence is not necessary for normal surfactant function.

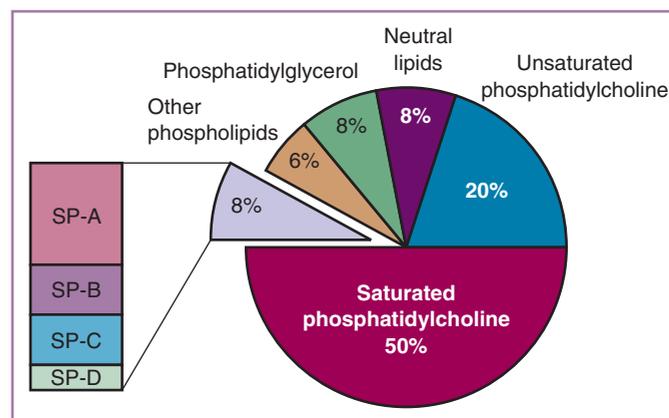

FIGURE 15-4 Composition of surfactant. The major component is saturated phosphatidylcholine. The surfactant proteins (SP) contribute about 8% to the mass of surfactant.

Proteins

Much of the protein isolated with surfactant from alveolar lavages is serum protein that is not specific to surfactant. However, four surfactant proteins have been characterized and their functions in part elucidated.³⁷ Two of the proteins (SP-A and SP-D) have related structures and are classified as collectins because they bind carbohydrate lectins in a calcium-dependent manner.

The 26-kDa monomer of SP-A is heavily glycosylated and assembled as a six-tetramer complex of about 650 kDa.³⁸ The protein has a collagen-like domain that facilitates tetramer formation, and a carbohydrate recognition domain. SP-A is expressed predominantly in type II cells and Clara cells in the late-gestation and mature lung. SP-A appears in fetal lung fluid and amniotic fluid in parallel with the surfactant phospholipids during late gestation. It is secreted constitutively and separately from the surfactant complex contained in the lamellar bodies. Once in the airspace, SP-A associates with surfactant and is required for tubular myelin formation. SP-A may contribute to the biophysical function of surfactant primarily by making surfactant less sensitive to inactivation by edema fluid and inflammatory products in the injured lung. Mice that lack SP-A have essentially normal surfactant function and metabolism unless the lung is injured.

SP-A functions primarily as an innate host defense protein in the alveolus and airways.³⁸ The ability of SP-A to bind carbohydrates and to interact with immune cells in the lungs contributes to host defense. It binds endotoxin avidly, and it also binds a wide range of gram-positive and gram-negative organisms, fungi (such as *Aspergillus fumigatus*), and other organisms such as mycobacteria and *Pneumocystis carinii*. Macrophages have receptors for SP-A, and SP-A promotes phagocytosis and killing of microorganisms by alveolar macrophages. SP-A also acts as an opsonin for the phagocytosis of viruses, such as herpes simplex, influenza A, and respiratory syncytial virus. Mice that lack SP-A have less effective clearance and killing of bacteria and viruses, and infections are more likely to become systemic.³⁹ The defect in host defenses can be corrected by treating SP-A-deficient mice with SP-A.

Another component of the host defense role of SP-A is modulation of the inflammatory response to infection. Nitric oxide production by macrophages is increased by SP-A to promote pathogen killing. SP-A also downregulates the general inflammatory response of the lung that generates tumor necrosis factor- α and other proinflammatory cytokines.

Two closely related genes express SP-A in humans, and no genetically based deficiency state has been identified. However, genetic polymorphisms in SP-A have been linked to an increased risk of RDS.⁴⁰ Infants born with low ratios of SP-A to surfactant phospholipid are at increased risk of death and bronchopulmonary dysplasia.⁴¹ SP-A levels are also low in preterm baboon models of BPD, in infants with respiratory syncytial virus pneumonia, and in patients with acute RDS.

SP-D has similarities in structure and function to SP-A, but distinct differences also are apparent.³⁸ The 43-kDa monomer of SP-D forms tetramers by collagen domains and then associates into a 560-kDa multimer. The carbohydrate recognition domain of SP-D binds endotoxin, gram-negative organisms, and a variety of other lung pathogens with a specificity that overlaps with SP-A. SP-D is minimally associated with surfactant lipids. The protein is present in alveolar lavage fluid at 10% to 30% of the level of SP-A. SP-D is expressed in the lung in type II cells, Clara cells, and other airway cells and glands. Expression of SP-D in the lung increases from late gestation to achieve adult levels after term, and glucocorticoids increase SP-D expression.

SP-D has the characteristics of an innate host defense protein. It binds bacteria and fungi, aggregates viruses, and promotes opsoniza-

tion and phagocytosis by macrophages. It also may modulate the proinflammatory responses of leukocytes in the lung. In contrast to SP-A, SP-D increases with acute lung injury. Mice that lack SP-D have increased tissue and alveolar pools of surfactant lipids and develop emphysema.⁴² Mice that are SP-D deficient have a greater inflammatory response when given respiratory syncytial virus. No SP-D deficiency has been identified in humans, and its contribution to the pathogenesis of BPD and lung infections in newborns has not been defined.

SP-B is a small, 79-amino-acid homodimer of about 18 kDa that comprises about 2% of surfactant by weight.³⁸ The essential function of SP-B is its absolute requirement for normal packaging of the surfactant phospholipids into lamellar bodies for secretion. In the absence of SP-B, type II cells have no lamellar bodies and SP-C is incompletely processed. Therefore, functionally, SP-B deficiency also results in SP-C deficiency. Mice and humans that lack SP-B die soon after birth with a severe RDS-like syndrome.⁴³ Surfactant treatment is not effective, presumably because there are no pathways for reprocessing of the surfactant components.

Deficiency of SP-B most frequently occurs because of a frame-shift mutation, although multiple compound mutations have been described. The gene frequency of this frame-shift maturation is 1 per 1000 to 3000 individuals.⁴⁴ Deficiency of SP-B from all mutations accounts for about 30% of term infants who die of severe RDS at birth as a result of possible genetic causes for the respiratory failure. An antenatal diagnosis of SP-B deficiency can be made using amniotic fluid. Some mutations result in low expression that may increase with glucocorticoid treatment. Infants with low expression may have a chronic progressive lung disease indistinguishable from bronchopulmonary dysplasia. Acute lung injury and inflammation resulting in release of tumor necrosis factor in the lungs depresses SP-B levels.

SP-C is a 35-amino-acid, 4.5-kDa monomer that is about 2% of surfactant by weight.³⁷ This extremely hydrophobic protein promotes surfactant film adsorption. The SP-C sequence is highly conserved across species, and messenger RNA is expressed in the developing tips of the branching airways during early lung development. During late gestation, SP-C is expressed, processed, and secreted with SP-B and the surfactant lipids in lamellar bodies only by type II cells. A deficiency of SP-C in mice results in no lung developmental abnormalities or striking abnormalities in surfactant function.⁴⁵ However, the mice get a progressive interstitial lung disease as they age. SP-C deficiency in humans can also cause a progressive interstitial lung disease that can present in infancy and may make the individual susceptible to developing acute RDS.⁴⁶ The clinical spectrum of genetically based SP-C abnormalities in humans has not been well defined yet. Acute lung injury will decrease the expression of SP-C, but how this may affect lung function is not known.

Deficiency of the ABCA3 transporter has recently been described as a cause of severe lethal RDS in term infants resulting from surfactant deficiency.⁴⁷ This transporter is a member of a family of ATP-binding cassette transporters that localize to the limiting membranes of lamellar bodies in type II cells. Its deficiency seems to disrupt lipid transport and lamellar body formation, resulting in severe surfactant deficiency. This genetically based deficiency disease in term infants is more common than are SP-B or SP-C deficiencies.

Surfactant Metabolism

Type II cells and macrophages are the cells responsible for the major pathways involved in surfactant metabolism (Fig. 15-5). The synthesis and secretion pathways in type II cells are complex sequences of bio-

FIGURE 15-5 Diagram of surfactant metabolism. The lipid-associated surfactant proteins B (SP-B) and SP-C (solid red arrows) track with the lipid from synthesis to secretion of lamellar bodies. SP-A is secreted and combines to form tubular myelin with SP-B, SP-C, and the lipids. The surface film is shown as a monolayer of lipids with SP-B. The hypophase of bilayer lipids is a reservoir of surfactant that can add to the monolayer. SP-B and SP-C leave the monolayer without lipids and are catabolized by macrophages. Lipids leave the monolayer as vesicles and are either catabolized or recycled back to type II cells.

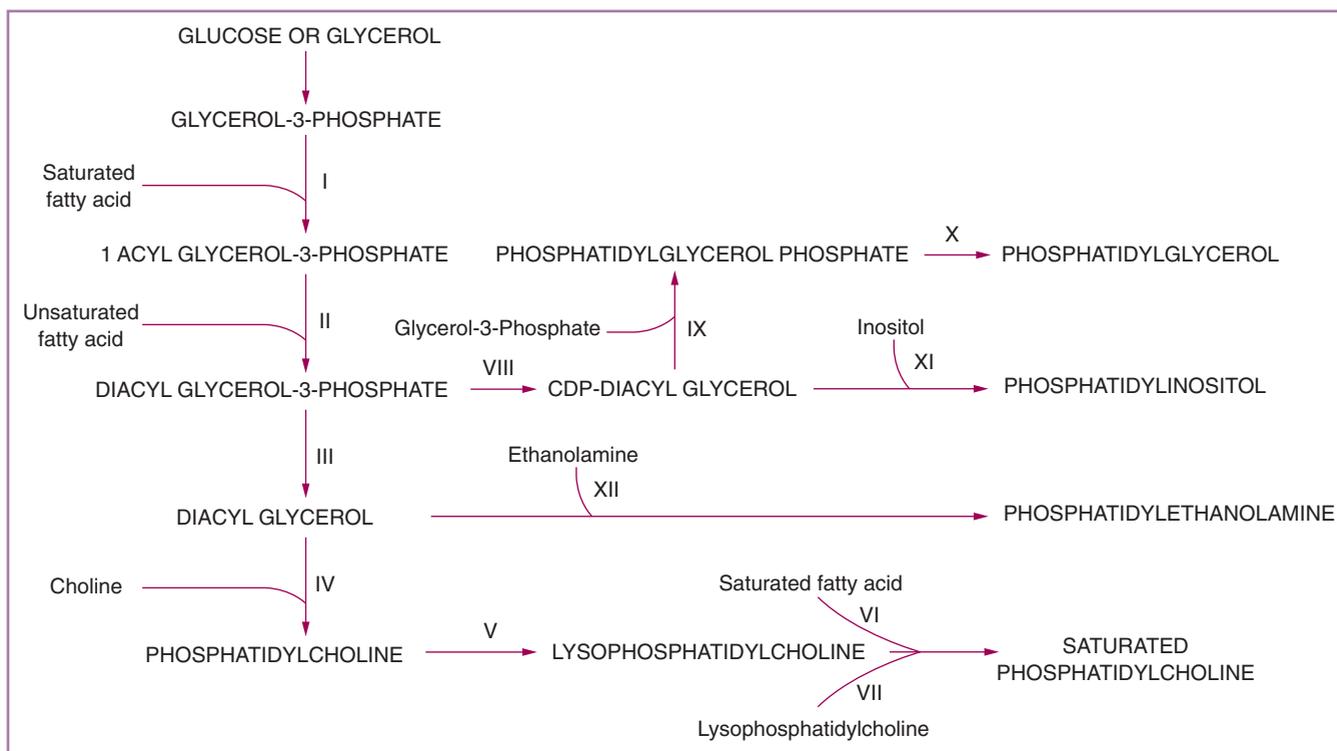

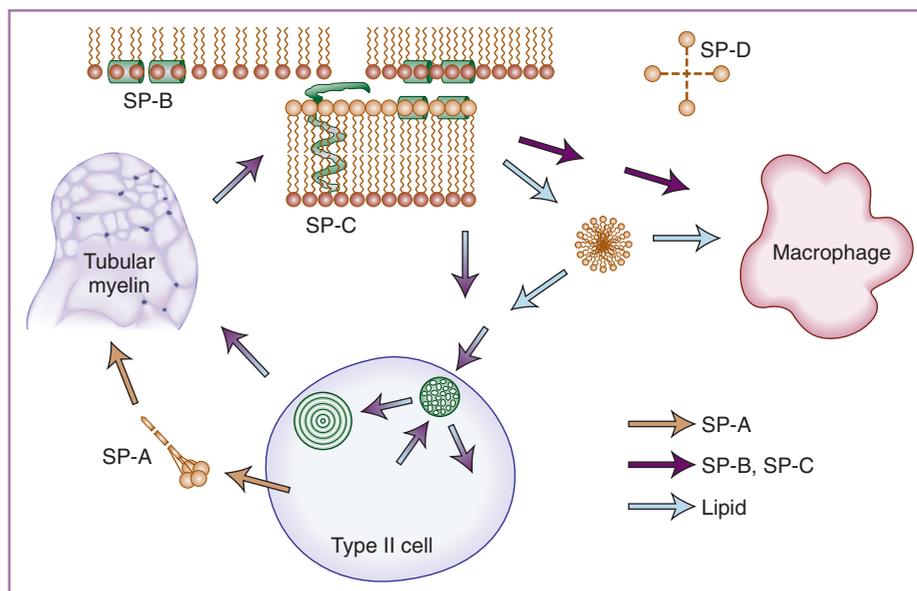

FIGURE 15-6 Biosynthesis of lung phospholipids. The major pathways and precursors for the synthesis of saturated phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylglycerol are outlined. The enzymes specific for each step are indicated by roman numerals: I, glycerophosphate acyltransferase; II, 1-acyl-glycerolphosphate phosphotransferase; III, phosphatidic acid phosphatase; IV, cytidine-5'-diphospho (CDP)-choline diacylglycerol phosphotransferase; V, phospholipase A₂; VI, lysophosphatidylcholine acyl transferase; VII, lysophosphatidylcholine-lysophosphatidylcholine acyl transferase; VIII, phosphatidate cytidyltransferase; IX, glycerophosphate phosphatidyltransferase; X, phosphatidylglycerol phosphatase; XI, CDP-inositol diacylglycerol phosphotransferase; XII, ethanolamine diacylglycerol phosphotransferase.

chemical events that result in lipid, SP-B, and SP-C release in lamellar bodies to the alveolus by exocytosis. Specific enzymes within the endoplasmic reticulum use glucose, phosphate, and fatty acids as substrates for phospholipid synthesis. The uniqueness of a phospholipid is determined by the fatty acid side chains esterified to the glycerol carbon

backbone and by the head group (e.g., choline, glycerol, inositol) linked to the phosphate. The interrelated pathways for the synthesis of lung phospholipids are outlined in Figure 15-6, and the enzymes discussed in the next paragraph are identified by roman numerals on that figure.

The three-carbon backbone of each phospholipid enters the pathway as glycerol-3-phosphate. The *de novo* synthetic pathway then proceeds through two sequential acyltransferase reactions. A saturated fatty acyl-coenzyme A (usually palmitic acid) is esterified to the 1-acyl position of glycerol-3-phosphate by glycerol-phosphate acyltransferase (I). Then the 1-acyl-glycerol-phosphate phosphotransferase (II) esterifies either an unsaturated or a saturated fatty acid to the 2-acyl position, generating diacylglycerophosphate (phosphatidic acid), which is the common precursor of the phospholipids. Phosphatidic acid is then either dephosphorylated to diacylglycerol by phosphatidic acid phosphatase (III) or converted to cytidine-5'-diphosphodiacylglycerol by phosphatidate cytidyltransferase (VIII). Cytidine-5'-diphosphodiacylglycerol is the common precursor of phosphatidylglycerol and phosphatidylinositol. Phosphatidylglycerol is synthesized by a two-step pathway involving the enzymes glycerol-phosphate phosphatidyltransferase (IX) and phosphatidylglycerol phosphatase (X). The diacylglycerol is the direct precursor of both phosphatidylethanolamine and phosphatidylcholine after the transfer of ethanolamine or choline from the cytidine-5'-diphosphoethanolamine or cytidine-5'-diphosphocholine to the diacylglycerol by the appropriate phosphotransferase (IV, XII). However, the resulting phosphatidylcholines are largely 1-acyl saturated, 2-acyl unsaturated.

A remodeling of some of the 2-acyl-unsaturated phosphatidylcholines from the *de novo* synthetic pathway occurs in the type II cell before packaging of the resulting saturated phosphatidylcholine into lamellar bodies for secretion. The direct re-acylation of lysophosphatidylcholine with palmitoyl-coenzyme A (enzyme VI) is the important pathway for saturated phosphatidylcholine synthesis in type II cells.⁴⁸

Although the overall synthetic pathways are known, the details of how the components of surfactant condense to form the surfactant lipoprotein complex containing the phospholipids SP-B and SP-C in lamellar bodies remain obscure. Lipids and the hydrophobic surfactant proteins are essential to lamellar body formation, because the lamellar bodies are absent or abnormal from type II cells that lack SP-B or the ABCA3 transporter. The development and maturation of the ability of the immature lung to process surfactant lipids from synthesis to secretion are essential if the fetus is to ventilate successfully after birth.

Once the type II cell has matured sufficiently to have surfactant stores, secretion can be stimulated.⁴⁹ Type II cells respond to beta agonists by increased surfactant secretion. Purines such as adenosine triphosphate are more potent stimulators of surfactant secretion than beta agonists and may be important for surfactant secretion at birth. Surfactant secretion also occurs with mechanical stimuli, such as lung distention and hyperventilation. The surfactant secretion that occurs with the initiation of ventilation after birth probably results from the combined effects of elevated catecholamines and lung expansion.

After Avery and Mead¹ observed that saline extracts of the lungs of infants with RDS had high minimum surface tensions, decreased alveolar and tissue surfactant pools were documented in developing animals. In general, surfactant pool sizes correlate with lung compliance during development, although other factors, such as structural maturation of the lung, also influence compliance measurements. Infants with RDS have surfactant pool sizes on the order of 2 to 10 mg/kg of bodyweight.⁵⁰ The quantity is similar to the amount of surfactant found in the alveoli of healthy adult animals and humans, but much less than the amount of surfactant recovered from healthy term animals, which have surfactant pool sizes of 100 mg/kg of bodyweight.

The rate of increase in the pool size of alveolar surfactant after preterm birth has been measured in ventilated preterm monkeys recovering from RDS.⁵¹ The surfactant pool size increases from about 5 mg/kg toward the 100 mg/kg value measured in term monkeys

within 3 to 4 days. Although there are no comparable pool size measurements for humans, the concentration of saturated phosphatidylcholine in airway samples from infants recovering from RDS increased over a 4- to 5-day period to become comparable with values for normal or surfactant-treated infants.⁴¹ This slow increase in pool size explains why the uncomplicated clinical course of RDS lasts from 3 to 5 days. The explanation for why surfactant pool sizes increase slowly after preterm birth is apparent from measurements of the kinetics of surfactant secretion and clearance in the newborn.⁵² Incorporation of precursors into lung phosphatidylcholine is rapid. However, there are long delays between synthesis and the movement of surfactant components from the endoplasmic reticulum through the Golgi to lamellar bodies for eventual secretion. The time lag from surfactant phospholipid synthesis to peak secretion of labeled surfactant is about 40 hours in term newborn lambs. Ventilated preterm baboons with RDS that are developing BPD have small alveolar pool sizes of surfactant, a low percentage secretion of *de novo* synthesized lipids, and decreased surfactant function.⁵³ The peak time for secretion of surfactant lipids labeled with ¹³C-glucose was about 70 hours in infants with RDS (Fig. 15-7).⁵⁴

The slow increase in the alveolar surfactant pool from *de novo* synthesis is balanced in the term and preterm lung by slow catabolism and clearance.⁵⁵ Radiolabeled surfactant phospholipids given into the airspaces of term lambs are cleared from the lung with a half-life on the order of 6 days. This slow lung clearance is in striking contrast with the more rapid catabolism characteristic of the adult lung, with half-life values on the order of 12 hours. Preterm ventilated baboons that are developing BPD degrade a treatment dose of surfactant with a half-life of about 2 days.⁵³ The biologic half-life of surfactant lipids in infants with RDS was about 35 hours (see Fig. 15-7).⁵⁶ Although the measurements of surfactant metabolism in preterm infants are limited, the consistency of the values between infants with RDS and the preterm animal models clearly indicates that the preterm lung requires a number of days to achieve normal surfactant pool sizes and metabolism.

Surfactant does not remain static in the airspaces. The surfactant phospholipids move from the airspaces back to type II cells, where they are taken up by an endocytotic process into multivesicular bodies (see Fig. 15-5).⁵⁵ In the term and preterm lung, about 90% of the phospholipids are recycled back to lamellar bodies and re-secreted to the airspace. In the adult lung, this process is about 25% efficient. The phospholipids are recycled as intact molecules without degradation and resynthesis. In the adult lung, macrophages catabolize about 50% of the surfactant. There are few macrophages in the preterm lung at birth, but their numbers increase with postnatal age, inflammation, and injury.

An understanding of the dynamics of surfactant metabolism is further complicated by form transitions of surfactant within the alveolar space.⁵⁵ Surfactant phosphatidylcholine moves from secretion as lamellar bodies to a tubular myelin pool that is the reservoir in the hypo-phase from which the surface film is maintained. SP-A is essential for this transition. Area compression of the surface film is then thought to concentrate saturated phosphatidylcholine by squeezing out other lipids and surfactant proteins. New surfactant adsorbs into the surface film and "used" surfactant leaves in the form of small vesicles, which then are cleared from the airspaces.

Physiologic Effects of Surfactant on the Preterm Lung

The effects of surfactant on the preterm surfactant-deficient lung can be demonstrated by the pressure-volume relationships during quasi-

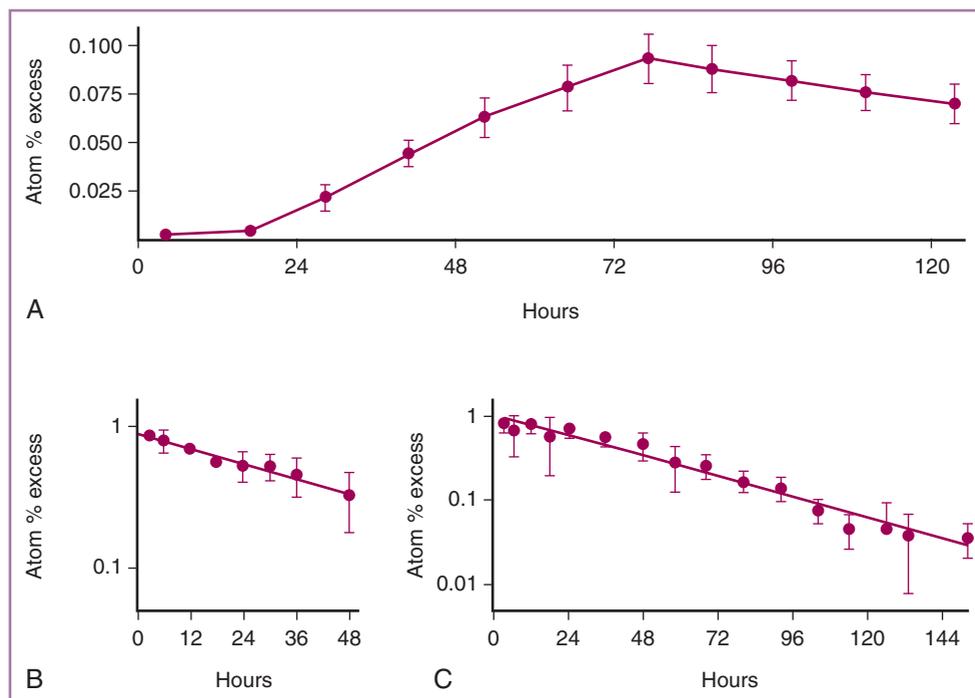

FIGURE 15-7 Measurements of surfactant metabolism in preterm infants with respiratory distress syndrome using stable isotopes. **A**, Curve for the ^{13}C labeling of palmitate in phosphatidylcholine recovered from airway aspirates of 11 preterm infants who received ^{13}C -glucose infusion for the first 24 hours of life. The time to maximal enrichment expressed as atom % excess ^{13}C was 77 ± 8 hours. The half-life after peak enrichment was about 100 hours. **B** and **C**, Loss of ^{13}C dipalmitoyl phosphatidylcholine from treatment doses of surfactant given to eight preterm infants at a mean age of 4.6 hours (**B**), and for a second dose of surfactant given at a mean age of 37 hours (**C**). The half-life of the label in the airway aspirates was about 34 hours. (Data in **A** from Bunt JE, Carnielli VP, Darcos Wattimena JL, et al: The effect in premature infants of prenatal corticosteroids on endogenous surfactant synthesis as measured with stable isotopes. *Am J Respir Crit Care Med* 162:844, 2000; data in **C** from Torresin M, Zimmermann LJ, Cogo PE, et al: Exogenous surfactant kinetics in infant respiratory distress syndrome: A novel method with stable isotopes. *Am J Respir Crit Care Med* 161:1584, 2000.)

static inflation and deflation.⁵ The pressure needed to open a lung unit is related to the radius of curvature and surface tension of the meniscus of fluid in the airway to that unit. With surfactant deficiency, surface tensions are high and variable. The uninflated lung contains fluid-filled airways with different radii. The units served by airways with larger radii and with lower surface tensions “pop” open first, making lung inflation nonuniform with surfactant deficiency. Preterm surfactant-deficient rabbit lungs do not inflate until pressures exceed 25 cm H_2O (Fig. 15-8).

Surfactant treatment results in a striking decrease in the opening pressure to about 15 cm H_2O . Because the treatment does not alter the radii of the airways, the decreased opening pressure results from adsorption of the surfactant to the menisci. Inflation is more uniform because low surface tensions make aeration of airways less dependent on airway size. More units are opening at lower pressures, and there is less overdistention of the units that do open. Inflation is less uniform in the surfactant-deficient lung.

A striking effect of surfactant on the surfactant-deficient lung is the 2.5 times increase in maximal volume at 35 cm H_2O airway pressure (see Fig. 15-8). Pressures higher than 35 cm H_2O rupture the surfactant-deficient control lungs and result in little further volume accumulation. This difference in the lung gas volume caused by surfactant treatment is lung volume that will increase the surface area of the lung

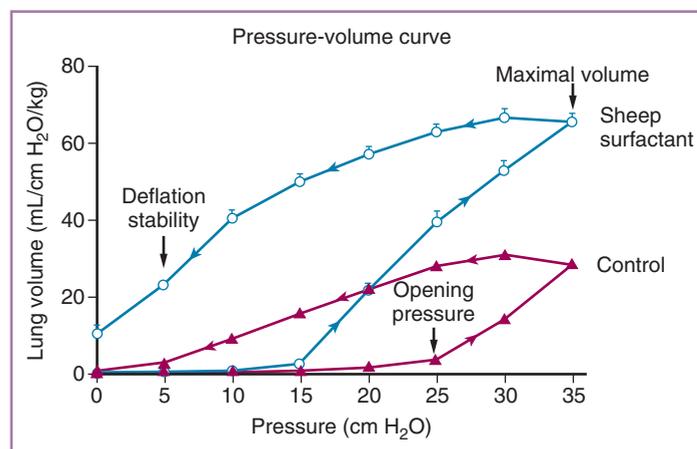

FIGURE 15-8 Pressure-volume relationships for the inflation and deflation of surfactant-deficient and surfactant-treated preterm rabbit lungs. The arrowheads on the curves indicate the direction of the inflation-deflation sequence. The control lungs are from 27-day preterm rabbits. Surfactant deficiency is indicated by the high opening pressure, the low maximal volume at a distending pressure of 35 cm H_2O , and the lack of deflation stability at low pressures on deflation. In contrast, treatment of 27-day preterm rabbits with a natural surfactant strikingly alters the pressure-volume relationships.

and provide better gas exchange. Surfactant also stabilizes the lung on deflation. The surfactant-deficient lung collapses completely at low transpulmonary pressures. The surfactant-treated lung retains about 36% of the lung volume on deflation to 5 cm H₂O pressure.

Surfactant for Respiratory Distress Syndrome

Fujiwara and associates first reported in 1980 that airway instillation of surfactant improved oxygenation in infants with severe RDS.⁵⁷ Surfactant for RDS became available for general clinical use in 1990 after extensive clinical trials.⁵⁸ Three surfactants prepared from pig or cow lungs are currently in use in the United States. They are not equivalent to natural surfactant in composition or function because they have altered surfactant protein and phospholipid compositions and somewhat different biophysical characteristics. However, the metabolic characteristics of surfactant in the preterm are favorable for surfactant treatment.⁵ In the infant with RDS, alveolar and tissue pool sizes are small, and the alveolar pool increases slowly after birth. Treatment acutely increases both the alveolar and tissue pools because the exogenously administered surfactant is taken up into type II cells and processed for re-secretion. The surfactant given as treatment becomes substrate for the preterm lung to metabolize and can improve the function of the surfactant used for treatment.⁵⁹ The surfactant used for treatment remains in the lungs and is not rapidly degraded (see Fig. 15-7). Treatment doses of surfactant do not feedback inhibit the endogenous synthesis of saturated phosphatidylcholine or the surfactant proteins. No adverse metabolic consequences of surfactant treatment on the endogenous metabolism of surfactant or other lung functions have been identified. There are no clinically important differences between the surfactants used clinically to treat RDS.

Surfactants have been evaluated as treatment in two situations: for preterm infants at risk for RDS immediately after birth, and for infants with established RDS.⁶⁰ Either treatment strategy effectively decreases the severity of respiratory symptoms and infant mortality. The choice of treatment strategy probably does not influence complications or outcomes for larger infants with RDS, but early treatment may benefit the very immature infant weighing less than 1 kg at birth.

In the initial trials, delivery room treatment was compared with treatment many hours after birth. In clinical practice, the two treatment strategies now are less distinct because treatment is given as soon after birth as is practical and when some respiratory distress is apparent.⁶¹ A surfactant treatment should not interfere with neonatal resuscitation and initial stabilization. Clinical treatment strategies also include the use of continuous positive end-expiratory pressure with surfactant treatments to avoid mechanical ventilation.⁶²

The clinical trials consistently showed that mortality from RDS and overall infant mortality rates decreased with surfactant treatment (Fig. 15-9).⁶⁰ Surfactant treatments also decrease the incidence of pneumothorax, oxygen requirements, and ventilatory requirements over the first several days of life. A disappointment has been the lack of a consistent decrease in the incidence of BPD in surfactant-treated survivors of RDS. Presumably, infants whose lives are saved by surfactant treatment are those most likely to develop BPD, thus in part explaining the lack of decrease of this chronic lung disease. Fortunately, the severity of BPD has decreased despite the survival of more immature infants. Although isolated trials report either increases or decreases in the occurrences of common neonatal problems, such as patent ductus arteriosus and intraventricular hemorrhage, surfactant treatments do not seem to affect the nonpulmonary complications of prematurity.

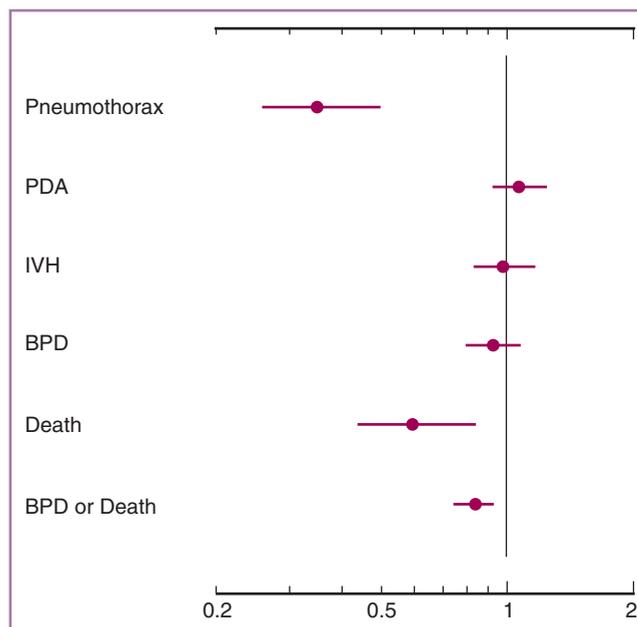

FIGURE 15-9 Meta-analysis of eight randomized controlled trials of surfactant for the treatment of respiratory distress syndrome. Results are given as odds ratios and 95% confidence intervals for 988 randomized patients. BPD, bronchopulmonary dysplasia; IVH, intraventricular hemorrhage; PDA, patent ductus arteriosus. (Data from Soll RF, Morley C: Prophylactic versus selective use of surfactant for preventing morbidity and mortality in preterm infants. *Cochrane Database Syst Rev* [2]:CD000510, 2001.)

Infants with primarily surfactant deficiency should respond well to surfactant. Reasons for poor responses are injury to the preterm lung by inflammation or ventilatory injury before surfactant treatment, unrecognized pulmonary hypoplasia, or very immature lung structure. Antenatal corticosteroid treatments before preterm birth seem to act synergistically with surfactant to improve outcomes for infants by improving respiratory function and decreasing pneumothorax and intraventricular hemorrhage.⁶³ Multiple beneficial interactions between antenatal corticosteroids and postnatal surfactant treatments can be demonstrated in experimental models.⁶⁴ The corticosteroid exposure makes the endogenous surfactant less resistant to inhibition by proteins and inflammatory mediators. The corticosteroid-induced increases in airspace volume and decreased permeability of the airway epithelium decreases the dosage of exogenous surfactant needed to improve lung function and decreases surfactant inactivation. Other effects of corticosteroids on fluid clearance and inflammation also probably contribute to improved clinical responses. The availability of surfactant treatments is not a reason to withhold antenatal corticosteroid treatment to women at risk of preterm delivery.

Induced Lung Maturation

Normally, lung maturation does not occur until after 36 or 37 weeks' gestation in an infant destined to deliver at term. However, the incidence of RDS is only about 30% at 30 weeks' gestation, and infants as early as 25 weeks' gestation often do not have severe RDS.⁶² Therefore, spontaneous "early maturation" is frequent and is thought to result from fetal stress inducing endogenous fetal cortisol and other hormones that result in early lung maturation responses. Clinical experi-

ence and recent results in transgenic mouse models suggest that endogenous cortisol is not as absolutely required for normal lung development as previously thought.⁶⁵ Explants of mid-gestation fetal human lung differentiate and develop mature type II cells and surfactant in the absence of glucocorticoids. Infants born at term without hypothalamic-pituitary function generally have normal lungs. The simplest interpretation of these observations is that the fetal human lung can develop without cortisol. However, some maternal cortisol crosses the placenta to the fetus, as demonstrated by experiments with transgenic mice. Disruption of the corticotropin-releasing hormone (CRH) gene (*Crh*^{-/-}) results in adult mice with very low plasma corticosterone levels that require corticosterone supplementation to reproduce.⁶⁶ CRH^{-/-} fetuses from CRH^{-/-} mice die after birth with lungs that have an arrest in thinning of the saccules, although the surfactant system matures relatively normally. Corticosterone supplementation in the water of the CRH^{-/-} dam prevents the delayed lung development in CRH^{-/-} fetuses, because the glucocorticoid leaks from dam to fetus. The lungs of CRH^{-/-} fetuses develop normally in CRH⁺ dams because corticosterone is transferred to the fetus during the circadian peak in maternal glucocorticoid secretion.⁶⁷ Low levels of fetal glucocorticoid exposure are sufficient to support normal lung maturation.

The clinical issues regarding diagnosis and induction of fetal lung maturation are developed in Chapter 23. However, a few points pertaining to basic mechanisms are pertinent at this juncture. Pharmacologic induction of early lung maturation is the rationale for the clinical use of antenatal glucocorticoids in women at risk for preterm delivery. Numerous animal models and the clinical trials demonstrate that glucocorticoids can induce maturation of lung and other organs. However, the fetal stress presumed to accompany fetal growth restriction, preeclampsia, or premature rupture of membranes is not consistently associated with a decrease in the incidence of RDS in the clinical literature.⁶⁸ Thus, the link between presumed fetal stress and early lung maturation is not apparent.

A provocative clinical observation is that histologic chorioamnionitis is associated with a decreased incidence of RDS in preterm infants.⁶⁹ This observation has been explored in fetal sheep using intra-amniotic injections of endotoxin, the proinflammatory cytokine interleukin (IL)-1 α , and live *Ureaplasma* organisms as inflammatory stimuli.⁷⁰⁻⁷³ Endotoxin induces chorioamnionitis and lung inflammation followed by a change in lung structure comparable to the maternal betamethasone effect. The surfactant system is stimulated more by inflammatory mediators than by maternal betamethasone (Fig. 15-10).⁷¹⁻⁷³ Fetal plasma cortisol is not increased by the inflammatory stimuli, demonstrating that the lung maturational effect is not mediated by cortisol. In fetal sheep, maternal betamethasone causes fetal growth restriction and thymic involution, and both adverse effects are prevented if the fetus also is exposed to intra-amniotic endotoxin.⁷⁴ These results with inflammatory mediators and the clinical observations indicate that inflammatory pathways are contributing to the early lung maturation that frequently accompanies preterm birth.

Although many hormones influence lung maturation in experimental systems (Table 15-4), the only lung maturational agent other than corticosteroid that has been systematically evaluated in the human is thyrotropin-releasing hormone (TRH). The rationale for the use of TRH is that thyroid hormone induces lung maturation when given to the fetus, and the combined use of thyroid hormone and corticosteroid stimulates surfactant synthesis in vitro in human lung explants and lung tissues from other animals more rapidly and to a greater extent than either agent alone. Thyroid hormones are not a good choice for maternal treatment, because high and toxic maternal doses would be required to achieve placental transfer. TRH does cross

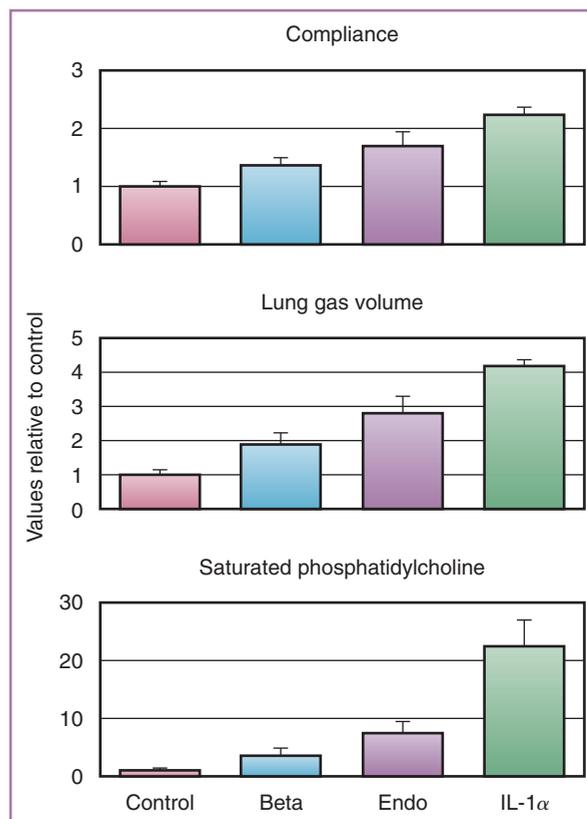

FIGURE 15-10 Induction of lung maturation. Relative effects on lung compliance, lung gas volume measured at 40 cm H₂O pressure, and the amount of saturated phosphatidylcholine in alveolar washes 7 days after fetal exposure to 0.5 mg/kg maternal betamethasone (Beta), 10 mg intra-amniotic endotoxin (Endo), or 150 mg recombinant ovine interleukin 1 α (IL-1 α). The endotoxin or IL-1 α stimulus improved lung function and increased surfactant. (Data from Jobe AH, Newnham JP, Willet KE, et al: Endotoxin-induced lung maturation in preterm lambs is not mediated by cortisol. *Am J Respir Crit Care Med* 162:1656, 2000; and Willet K, Kramer BW, Kallapur SG, et al: Intra-amniotic injection of IL-1 induces inflammation and maturation in fetal sheep lung. *Am J Physiol* 282:L411, 2001.)

the placenta, and maternal TRH elevates fetal triiodothyronine, thyroxine, and prolactin levels. However, three large trials found no beneficial effect of maternal TRH, and one trial suggested some acute risks and concerns about longer-term outcomes for infants who received TRH.⁷⁵ TRH cannot be recommended to induce early lung maturation.

Chapter 16

Evidence-Based Practice in Perinatal Medicine

George A. Macones, MD

All those who drink of this remedy recover in a short time, except those whom it does not help, who die. Therefore, it is obvious that it fails only in incurable cases.

—GALEN (CIRCA 100 AD)

Evidence-Based Medicine in Perspective

Many of the improvements in medical care for women in the past 30 years have come about as a result of carefully designed studies of interventions aimed at improving health. Before this time, physicians relied on anecdote and personal experience to guide patient care.

Evidence-based medicine is a style of practice best described as “integrating individual clinical expertise with the best-available external clinical evidence from systematic research.”¹ Thus, contrary to what many believe, evidence-based medicine combines understanding of the literature with individual expertise. It is this blend of evidence and clinical intuition that makes evidence-based medicine so attractive and essential to the practice of modern medicine.

Why is evidence-based medicine important in maternal-fetal medicine? First, the practice of evidence-based medicine allows us to provide the best care to our patients. Instances in obstetrics are easily found where an incomplete or improper assessment of the evidence has led to problems with care. The classic example is the emergence of electronic fetal heart rate monitoring (see Chapter 22). This device, novel when it was introduced, generated new information that was widely expected to lead to improved perinatal outcomes. Unfortunately, electronic fetal monitoring was widely implemented before evidence of benefit existed, and it became firmly rooted in obstetrics in the United States and many other countries. As has been well documented, it is uncertain whether continuous electronic fetal monitoring confers any benefit beyond that of intermittent auscultation in low-risk patients, and it has been a major contributing factor in the rise in the rate of cesarean delivery.

Second, clinical research is growing exponentially, as evidenced by the number of medical journals, research publications, and scientific societies. Some have estimated that 1000 articles are added to MEDLINE per day. In addition, clinical research has gained in importance, with programs at the National Institutes of Health and other funding agencies focused on clinical research. With the volume and rapid access to such information (for both physicians and patients),

it is essential for practicing clinicians to be able to assess the medical literature to determine a best course of action for an individual patient.

Finally, in perinatal medicine we are today faced with several important yet unanswered questions:

- What (if any) treatment should we recommend for women with a short cervix seen on an ultrasound scan?
- Can preeclampsia be prevented or reduced through prenatal screening and treatment programs?
- Should we screen women for inherited thrombophilias if they have a history of poor pregnancy outcome? If so, how should we treat those who are positive?

How do we, as physicians and researchers, reach sound decisions for such questions? We start by learning to assess the quality of available medical evidence. In this chapter, we review the principles that serve as a basis for learning to interpret clinical research, including clinical research study designs, measures of effect, sources of error in clinical research (systematic and random), and screening and diagnosis. This will provide the reader with the information that will advance the journey toward becoming an evidence-based medicine practitioner.

Types of Clinical Research Studies

Several study designs are reported in the medical literature.

Descriptive Studies

Case reports and case series are simply descriptions of either a single case or a number of cases, and these are termed descriptive studies.² Often they focus on an unusual disease, an unusual presentation of a disease, or an unusual treatment for a disease. In case reports and case series, there is no control group. Because of this, drawing any

inference on causality is impossible. Such studies are useful mainly for hypothesis *generation*, rather than hypothesis *testing*. However, case reports and case series can be very valuable in the scientific process, because many important observations were initially made by a single case or series of cases. For example, in the early 1980s, physicians in California noted an unusual respiratory illness in homosexual men. The astute observation of these physicians led to the discovery of the acquired immunodeficiency syndrome epidemic in the United States.

Observational Studies

The two main types of observational studies are case-control studies and cohort studies.^{2,3,4} These study designs attempt to assess the relationship between an exposure and an outcome (Table 16-1).

In case-control studies, subjects are identified on the basis of disease rather than on exposure. Groups of subjects with and without disease are identified, and then exposures of interest are retrospectively sought. Comparisons of the distribution of exposures are then made between cases and controls. Case-control studies are useful for the study of rare conditions. Advantages of case-control studies include efficient use of time, low cost, and the ability to assess the impact of multiple exposures. However, case-control studies cannot be used to calculate an incidence of disease given a particular exposure, and they carry substantial potential for confounding and bias.

Cohort studies identify subjects on the basis of exposure and then assess the relationship between the exposure and the clinical outcome of interest. Cohort studies can be either retrospective or prospective. In a retrospective cohort study, the exposed population is identified after the event of interest has occurred. In a prospective cohort study, exposed and unexposed subjects are followed over time to see if the outcome of interest occurs. Cohort studies are useful in the study of rare exposures. The advantages of cohort studies are that the incidence of disease in exposed and unexposed individuals can be assessed, and there is less potential for bias (especially if prospective). The main disadvantage of prospective cohort studies is that they can be time-consuming, sometimes requiring years to complete (if prospective), and are thus often expensive.

A clinical example may help to contrast these study designs. The relationship between anticonvulsant use in pregnancy and the occurrence of neural tube defects could be assessed with either a case-control or a cohort study. In a case-control study, one would identify a group of cases of fetuses or neonates with neural tube defects and a group of controls (i.e., children without a neural tube defect). The maternal record could be reviewed to determine whether exposure to anticonvulsants has occurred. To study this question with a cohort study, one would first identify a population of women taking anticonvulsants in pregnancy and a group not taking anticonvulsants, and then follow

both groups through pregnancy and delivery to determine the frequency of neural tube defects in each group.

Cohort studies can be either prospective or retrospective, whereas case-control studies are almost always retrospective. The advantage of a prospective cohort study is that the type and amount of data being collected can be determined by the investigator, based on the research question. In a retrospective cohort study, one almost always relies on inpatient or outpatient records for data collection, so the study is limited by the type and quality of the data included in these sources. For example, suppose an investigator is interested in the relationship between maternal cocaine use and fetal growth restriction. In a prospective cohort study, one would have the opportunity for a very accurate assessment of this exposure, perhaps by obtaining a hair sample. A retrospective study would have to rely on what was recorded in the medical record, which is most likely based on patient self-report.

There is a common misconception that an analysis performed using data prospectively collected and contained in a database is equivalent to a prospective cohort study. In fact, unless the research question was defined a priori (i.e., before the start of data collection), this is best termed a *retrospective secondary analysis of prospectively collected data*. In many cases, such analyses are more similar to a retrospective cohort study, because important clinical information may not have been collected as completely or systematically as it could have been had the research question been specified in advance.

Interventional Studies

The randomized clinical trial is the gold standard of clinical research design.⁵ In a clinical trial, eligible consenting participants are randomly allocated to receive different therapies. Differences in clinical outcomes are then compared on the basis of the treatment assignment. Clinical trials are powerful because the likelihood of confounding and bias influencing the results is minimized. However, clinical trials are logistically difficult and expensive, and they can take years to complete. There are also concerns about whether the results of clinical trials can be generalized—that is, applied to clinical practice with the expectation that the same results will occur. Specifically, people who consent to be part of a trial may differ from those who do not consent in that they may be more likely to comply with an intervention or have a generally more healthy lifestyle than persons who decline to enter the study. In addition, well-performed clinical trials often have strict inclusion and exclusion criteria, with strict follow-up procedures. In real-life clinical situations, such rigor in follow-up rarely occurs. Standards for reporting prospective randomized trials have been developed to ensure that results from all trial participants are reported. These have been published as the CONSORT statement.⁶

Despite these concerns, clinical trials provide the best evidence to guide practice. An excellent example of a practice-guiding clinical trial was the screening and treatment study of bacterial vaginosis (BV) in pregnancy performed by the Maternal-Fetal Medicine Units (MFMU) Network.⁷ A variety of studies from around the world suggested that symptomatic and asymptomatic BV was associated with spontaneous preterm birth.⁸⁻¹⁰ In addition, secondary analyses of data from clinical trials with high-risk women suggested that screening and treating BV in pregnancy might reduce the occurrence of spontaneous preterm delivery.^{11,12} Many assumed that screening and treating all pregnant women might reduce the incidence of preterm birth if applied to all pregnant women. To answer this question, the MFMU Network performed a placebo-controlled clinical trial comparing treatment with metronidazole to placebo for women who screened

TABLE 16-1 COMPARISON OF CASE-CONTROL STUDIES AND COHORT STUDIES

Case-Control Studies	Cohort Studies
Good for rare disease	Good for common disease
Study multiple exposures	Study multiple outcomes
Done quickly	Long follow-up
Inexpensive	Expensive (prospective)
No incidence data	Can directly calculate incidence
Prone to bias	Less prone to bias

positive for BV in pregnancy.⁷ This study demonstrated that treating asymptomatic BV in pregnancy did not affect the occurrence of preterm birth.

Another benefit of randomized clinical trials is that subgroup analyses from such data can be used to generate hypotheses for future research. One example is the study cited earlier by Hauth and colleagues.¹¹ After the primary analysis of their randomized clinical trial of metronidazole and erythromycin to reduce the risk for preterm birth in women with a prior preterm birth or other historical risk factors demonstrated a reduction of preterm birth, a secondary analysis found that the benefit was limited to women with BV. This secondary analysis (and a similar secondary analysis of another randomized clinical trial¹²) should have prompted a new randomized trial of antibiotic treatment, for which women would be enrolled if they had both BV and a historical risk for preterm birth.

Other Study Designs

Two other study designs deserve mention: meta-analysis and decision analysis. Both are valuable tools for the evidence-based medicine practitioner.

Meta-Analysis

In a meta-analysis, the results of a series of randomized clinical trials (or observational studies) can be statistically combined to obtain a *summary estimate* for the effect of a given treatment.¹³ Meta-analyses are also termed systematic reviews, and they should be differentiated from other, less data-driven review articles in which authors present their own interpretation of data. The strength of a meta-analysis comes from its being an analysis of combined results from multiple clinical trials, thereby increasing the “power” to detect differences in treatment. This is an especially important methodology in obstetrics, as we have few large randomized clinical trials to guide our treatments. Numerous meta-analyses have been performed for topics in obstetrics,^{14,15} many

in the Cochrane Database of Systemic Reviews.¹⁶ Two such analyses (Figs. 16-1 and 16-2) are taken from the Cochrane Library meta-analysis of the effect on neonatal outcome of antibiotics given antenatally to women with preterm prematurely ruptured amniotic membranes.¹⁷ In Figure 16-1, a comparison of neonatal infectious complications between those who received antibiotics and those who did not is made, and the data are pooled for all available studies. Each of 11 randomized trials that met inclusion criteria for this analysis is listed, with the number of subjects and the frequency of the outcome in the treatment and control groups noted. The relative risk and 95% confidence interval (see Assessing Random Error, later) for each study, weighted for their sample size, are shown. The total number of subjects with the outcome of interest is summed and the combined relative risk and 95% confidence interval calculated. In this example, a number of small trials show a nonsignificant trend in favor of antibiotic treatment. The pooled (i.e., statistically combined) relative risk was 0.67, with a 95% confidence interval from 0.52 to 0.85. The point estimate (i.e., the relative risk) suggests that the “best guess” is that antibiotics reduce the risk for neonatal infection by 33%. The confidence interval suggests that the data are consistent with as much as a 48% reduction in risk ($1 - 0.52$) or as little as a 15% ($1 - 0.85$) reduction in risk. Even the upper bound of the confidence interval suggests a protective effect of antibiotics on neonatal infection.

Compare this summary graph with that for the effect of antibiotics on perinatal death in women with preterm premature rupture of membranes (see Fig. 16-2). Here, the pooled estimate yields a point estimate relative risk of 0.89, with a 95% confidence interval from 0.67 to 1.18. The point estimate suggests that the best estimate is that antibiotics reduce the occurrence of perinatal death by 11%. The confidence interval suggests that the data are consistent with as much as a 33% reduction in perinatal death or an 18% increase in perinatal death with antibiotics. Because the confidence interval crosses a relative risk of 1.0, the data are consistent with “no difference” between the groups.

A notable limitation of meta-analysis is that clinical trials on the same general topic seldom enroll populations or employ treatments that are the same. Thus, at times, meta-analysis can seem like mixing apples with oranges.^{13,18-20} It is incumbent on the reader to make such a determination. Guidelines for publication of quality meta-analyses have been promulgated by the QUOROM statement, proposed by a consortium of journal editors²¹ and, like the CONSORT statement, they are subscribed to by the *American Journal of Obstetrics and Gynecology*, *Obstetrics and Gynecology*, and general medical journals such as *The Lancet*, the *New England Journal of Medicine*, and the *Journal of the American Medical Association*.

Two other issues are pertinent to the subject of meta-analyses. First, performing a meta-analysis requires significant methodological skill, so not all meta-analyses are of the same quality. The Cochrane Library, for example, includes very high quality meta-analyses on a number of obstetric topics. Second, there is debate about the role of meta-analyses when large clinical trials are available. This issue was raised in a recent meta-analysis of antiplatelet agents for the secondary prevention of preeclampsia.²² The authors suggested that antiplatelet agents may reduce the risk for preeclampsia and for birth before 34 weeks of gestation. In this meta-analysis, out of five studies that enrolled over 1000 women in each treatment arm, four did not show a reduction in the risk for preeclampsia with antiplatelet therapy. How do we reconcile the role of large clinical trials with the role of meta-analyses in guiding our practice? Although opinions vary, I believe that a single, well-performed randomized clinical trial in a generalizable population provides stronger evidence than a meta-analysis (where heterogeneous studies must be combined). On the other hand, meta-analyses that include large studies may provide insight into the efficacy of treatment in subgroups of subjects.

Decision Analysis

Decision analysis is a methodology in which the component parts of a complex decision are identified and analyzed in a theoretical model. Decision models often use the existing literature to compare different therapeutic strategies for a clinical dilemma. The ultimate goal of any decision analysis is to reach a clinical decision. Importantly, decision models are often the foundation for formal economic analysis, such as cost-effectiveness analysis.²³ Decision and economic analyses are fairly common in the obstetric literature. Such analyses have been

published on group B streptococci screening,²⁴ indomethacin use for preterm labor,²⁵ tocolysis at advanced gestational ages,²⁶ and thromboprophylaxis at cesarean delivery.²⁷ Interested readers should consider reading review articles on this subject.^{23,28}

Sources of Error in Clinical Research

Broadly speaking, two types of error can occur in clinical research studies: *systematic* error and *random* error.^{3,4} Systematic error is generally introduced by the investigator in the study design. Sources of systematic error include confounding and bias.²⁹⁻³¹ Random error is assessed using various methods for hypothesis testing, as described later. As readers of clinical research, our goals are to understand and to try to interpret the role of these errors in the studies we read.

Confounding

Confounding is a type of systematic error that can be present in observational research studies.^{29,31,32} Confounding occurs when two factors are associated with each other and the effect of one factor on a given outcome is distorted by the effect of the other factor. Importantly, randomized clinical trials of sufficient size generally cannot be confounded, because randomization itself should lead to an equal distribution of confounding factors between various treatment groups.⁵

An example that illustrates possible confounding comes from observational studies of indomethacin for tocolysis. Norton and colleagues³³ performed a matched retrospective cohort study of infants delivered at less than 30 weeks. These authors identified 57 infants whose mothers were exposed to indomethacin delivered at or before 30 weeks' gestation, and 57 infants whose mothers did not receive indomethacin. Infants born to mothers treated with indomethacin before delivery had a higher rate of necrotizing enterocolitis and grades II to IV intraventricular hemorrhage, an observation also noted in other observational studies.³⁴⁻³⁶ However, the proper interpretation of observational studies requires that potential sources of systematic error such as confounding and bias be considered. In this example, it is possible that confounding may explain the association between indo-

methacin and the neonatal morbidity observed in this observational study.³⁷ Specifically, because indomethacin is generally not a first-line tocolytic in practice, it is likely that this drug was used mainly in subjects who failed first-line tocolysis. If failing first-line tocolysis is itself a risk factor for adverse neonatal outcome, then the association between indomethacin and adverse neonatal outcome can be confounded. Thus, a principal question in the interpretation of these studies is whether patients who are failing first-line tocolysis are themselves at higher risk for adverse neonatal outcomes (whether exposed to indomethacin or not) than those who respond to first-line tocolysis. Existing data suggest that women whose labor does not stop after first-line tocolysis have an increased risk for adverse neonatal consequences because of the well-established relationship between tocolytic failure and subclinical and intra-amniotic infection, both of which are associated with adverse neonatal outcome.

Because of the relationships between refractory preterm labor and subclinical infection, and between subclinical infection and major neonatal morbidity,³⁸⁻⁴⁰ it is uncertain whether the association between indomethacin and adverse neonatal outcome in these retrospective observational studies is a “true” association or a spurious association resulting from confounding. We hypothesize that in the observational studies, exposure to indomethacin may be nothing more than a sign of inflammation-driven preterm labor, which itself is associated with major neonatal complications.³⁷

Bias

Bias is defined as a “process at any stage of inference tending to produce results that depart systematically from true results.”⁴¹ Bias usually occurs at the study design stage.^{30,31} There are two main types of bias to consider. *Selection* bias occurs when an error is made in the selection of a study population. For example, a recent study by Nicholson and colleagues⁴² sought to determine the association between “preventive” induction and a reduced rate of cesarean birth. The authors designed a retrospective cohort study, comparing outcomes of women managed by physicians who use preventive induction, to outcomes of women managed by physicians who do not use preventive induction. The results suggest that those cared for by physicians who use preventive induction have, surprisingly, lower cesarean rates. However, the physicians who practiced preventive induction in this study were trained in family medicine, whereas those who practiced without preventive induction were trained as obstetric/gynecologic specialists. Because it is likely that these two groups of physicians cared for different types of patients and probably had differences in clinical management, the possibility of selection bias exists. Such bias cannot be controlled for analytically. In this example, the authors correctly acknowledged the possibility of selection bias as an explanation for their findings.

Information bias occurs when a systematic error is made in the measurement of exposure or outcome information. A *recall* bias is a type of information bias that occurs when subjects recall past events differently, and the difference is related to the exposure status or the disease outcome. Recall bias occurs commonly in observational studies of teratogenesis. In a case-control study to assess whether exposure to medications is associated with cleft lip,⁴³ cases of cleft lip were ascertained after delivery occurred. Controls were women who delivered children without a birth defect. Mothers of cases and controls were asked about medication use during the pregnancy. The question that should be asked when reading such a study is whether women who have delivered a child with a birth defect are more likely to recall medication use than a woman who has delivered a normal child. To the extent that there is differential recall, there may be significant recall

bias that would lead to an inflated estimate of the relationship between medications and cleft lip.

Assessing the Role of Systematic Error in Clinical Research

Clinicians must be able to assess the role of systematic error in clinical research. Although a detailed discussion is beyond the scope of this chapter, there are several useful maxims for reading clinical research:

1. Systematic error is of greater concern for observational studies than for clinical trials. Because of randomization, confounding seldom occurs in clinical trials.⁴⁴
2. Retrospective observational studies are often more likely to be biased than prospective studies (although bias can still occur in prospective observational studies).
3. In any observational study, one should always carefully read the methods section and consider whether there is the potential for bias.
4. Even if one believes a study to have a serious bias, the study should not automatically be discarded. It is important to consider not just the *presence* of bias but also the *direction* of the bias.³¹ Consider again the example of the case-control study of medications and cleft palate just described. Now assume that the results of the study suggested no association between medications and cleft palate. Given the study design, concern about recall bias is appropriate, but in this case the recall bias would have led to an overestimate of the association between medications and cleft lip. Because the study showed *no* association, it is unlikely that the recall bias would lead to a change in the overall interpretation of the results of the study.
5. Likewise, confounding should always be considered as an explanation of observed results. Readers should consider whether relevant confounding factors were measured and, if they were unmeasured, the direction of the possible confounding. There are statistical techniques to adjust for measured confounding factors, such as multivariate analysis and logistic regression.⁴⁵ In modern observational clinical research, it is unacceptable to report only unadjusted associations when measured confounders can be adjusted for, using appropriate statistical techniques.

Assessing Random Error: Hypothesis Testing and Measures of Effect in Clinical Research

In clinical research, one is often interested in whether an exposure is significantly associated with an outcome, or whether an intervention can improve a given outcome. Commonly, interpretation of the results of clinical research is focused on the assessment of a significance test, such as a probability value. This type of testing provides information on the role of chance (i.e., random error) to explain the observed results in a given study. Although assessing the role of random error is important when reading medical literature, it is equally important to assess the role of systematic error (i.e., bias and confounding) in clinical research.

Let us consider a recent randomized trial that was designed to assess whether vitamin C and E supplementation in pregnancy would reduce the incidence of preeclampsia and perinatal complications.⁴⁶ To answer this question, the authors randomly allocated 935 women to active treatment with vitamins, and 942 to placebo (Table 16-2). The association between treatment with vitamins C and E and preeclampsia can be expressed in several ways: by probability value, by relative risk with

TABLE 16-2 VITAMINS C AND E TO PREVENT PREECLAMPSIA

	Preeclampsia		Total
	Yes	No	
Vitamins C and E	56	879	935
Placebo	47	895	942
Total	103	1774	1877

Data from Rumbold AR, Crowther CA, Haslam RR, et al: Vitamins C and E and the risks of preeclampsia and perinatal complications. *N Engl J Med* 354:1796-1806, 2006.

95% confidence intervals, and by several other measures of effect, including odds ratio and risk difference.

Probability Value

A probability value is defined as the likelihood of obtaining the observed differences in the sample if there is no true difference in the population. For example, a probability value of 0.05 means that there is a 5% probability of achieving the observed difference if in fact the null hypothesis of no true difference is true. Thus, the smaller the probability value, the smaller the possibility of chance as the explanation for an observed difference. In the MFMU Network example⁷ (in which treatment with metronidazole was compared to placebo for women who screened positive for BV in pregnancy), the probability value was 0.95, indicating a high likelihood that chance explained the small difference in the rate of preterm birth between the groups.

Traditionally, a probability value of less than 0.05 has indicated “significance,” whereas a probability value of more than 0.05 has indicated “no significance.” In fact, many journals still allow probability values to be reported in this way. However, with the definition of a probability value in mind (see preceding paragraph), readers should wonder whether a probability value of 0.049 is different from a probability value of 0.051. Clearly, there is more to the interpretation of a probability value than the absolute number.

Relative Risk with 95% Confidence Intervals

A relative risk is defined as the incidence of the outcome in the exposed group divided by the incidence of disease in the unexposed (untreated) group. Thus, in the vitamin study (see Table 16-2), the relative risk was as follows:

$$\text{Relative risk} = \frac{56/935}{47/942} = \frac{0.06}{0.05} = 1.20$$

A relative risk of 1.0 means that the incidence of the outcome is identical in the exposed and unexposed subjects. A relative risk of less than 1.0 means that the incidence of the outcome is less in the exposed group, whereas a relative risk of more than 1.0 means that the incidence is greater in the exposed group.

The point estimate is the best estimate of the association between an exposure and an outcome, but it does not give information about the stability or statistical precision of the estimate. Clearly, the precision of such an estimate is related to the power of the study. The precision of a relative risk or other measure of effect is often described as a 95% confidence interval.⁴⁷ A 95% confidence interval is interpreted as follows: If a study is without bias, there is a 95% chance that the true point estimate lies within the bounds of the confidence interval. The

narrower the confidence interval is, the greater is precision in the estimate. The wider the confidence interval is, the less certainty there is in the estimate.

Confidence intervals also provide information about statistical significance. In general, if a relative risk of 1.0 falls within the bounds of the 95% confidence interval for a given association, then the corresponding probability value will be more than 0.05. Likewise, if a relative risk of 1.0 is *not* included in the bounds of a 95% confidence interval, then the corresponding probability value will most likely be less than 0.05.

Other Measures of Effect

An odds ratio is another popular measure of effect that can be calculated from either observational studies or clinical trials.⁴⁸ Odds ratios are good approximations of relative risks in cases where the disease of interest is rare. They are most commonly calculated in case-control studies when the calculation of a relative risk is impossible because the denominator is not known. Odds ratios are also the output for most statistical packages when multivariable logistic regressions are performed. In general, relative risks are preferred over odds ratios when data are available to calculate a relative risk, such as in cohort studies or clinical trials.

Using the example from Table 16-2, the odds ratio for the association between vitamin treatment and preeclampsia is as follows:

$$\text{Odds ratio} = \frac{56 \times 895}{879 \times 47} = 1.21$$

An odds ratio is interpreted in exactly the same manner as a relative risk. Thus, an odds ratio of 2.0 would be interpreted as a twofold increase in risk, whereas an odds ratio of 0.5 would mean a 50% reduction in risk. The 95% confidence intervals are also interpreted in the same fashion as those for relative risks. Remember that the preferred measure of effect to calculate in clinical trials and cohort studies is a relative risk (or risk difference). Odds ratios can be used as surrogates for relative risks when the disease in question is rare.

The risk difference is the simple arithmetic difference in incidence between groups and can be calculated from clinical trial data or from cohort studies (but not from case-control studies). In the case of the vitamin study data (see Table 16-2), the risk difference is 0.06 – 0.05 = 0.01.

A risk difference is interpreted differently from a relative risk or an odds ratio. A risk difference of zero means that there is no difference in the incidence of disease between groups. A positive risk difference means that the incidence of the outcome is greater in the experimental group, whereas a negative risk difference means that the incidence of the outcome is greater in the control group. In the example of vitamin C and E treatment to prevent preeclampsia, the risk difference means that there is a 1.0% increase in the risk for preeclampsia in those exposed to vitamins C and E. The 95% confidence interval includes zero, which signifies that the data are consistent with there being no difference in the incidence between groups (and corresponds to a probability value of more than 0.05).

The measure of effect that is appropriate is largely determined by the aims of the study and the study design.⁴⁸

Approach to Assessing Random Error

Approaching the analysis of research data can seem a daunting task. However, apprehension can be minimized by forming a clear plan at the start or in the planning phase of a research study. The following

are some key steps to consider in the analysis of clinical research data.

STEP 1. GRAPH AND SUMMARIZE

Graph and summarize (e.g., means, range, standard deviation) all outcomes and exposures. This simple process allows the researcher to see a snapshot of the data to appreciate the distribution of a variable (e.g., is it a normal distribution?) and to identify implausible data elements.

STEP 2. PERFORM UNIVARIATE DATA ANALYSES

This critical step provides the foundation for the next steps: stratified and multivariable analysis. Univariate analysis allows assessment of associations between any given single exposure and outcome. The choice of the statistical test (or tests) in univariate analysis will vary with the design of the study and the type of outcome and exposure. An important design criterion that influences the univariate statistical test employed is whether or not the study is matched. *Matching* refers to the process of making a study group and comparison group comparable with respect to extraneous factors. A matched study design must be followed by a matched analysis.

There are several commonly used univariate statistical tests:

- Chi-square and Fisher’s exact tests: These tests are used when both the outcome and exposure of interest are binary (yes/no). These tests compare the observed distribution of numbers in the cells of a 2 × 2 table, and they compare them to the expected distribution. Chi-square and Fisher’s exact tests are used when data are unmatched. If the study is matched, then the appropriate test is the McNemar test.
- Student *t* test: A *t* test is used to compare means between two groups. For example, if one wished to compare the mean maternal age of women who develop preeclampsia with the age of those who do not, a *t* test would be appropriate. A *t* test can be either paired (for matched data) or unpaired (for unmatched data).

STEP 3. PERFORM STRATIFIED ANALYSIS

Stratified analysis is a way to assess confounding factors and effect modification. This can help to identify the variables to be included in multivariable analysis. The following is an example of a stratified analysis for a hypothetical case-control study to assess the association between alcohol use and preeclampsia. Table 16-3 is a 2 × 2 table generated from this case-control study.

The unadjusted odds ratio is 2.26; 95% confidence interval (CI), 1.2 to 4.2. This unadjusted analysis suggests that alcohol use increases the risk for preeclampsia, but in an observational study, confounding factors that may distort the relationship between alcohol and pre-

TABLE 16-3 2 × 2 TABLE FROM CASE-CONTROL STUDY TO ASSESS ALCOHOL USE AND PREECLAMPSIA			
	Preeclampsia +	Preeclampsia –	Total
Alcohol +	71	52	—
Alcohol –	29	48	—
Total	100	100	200

eclampsia must be considered. One possible confounding factor is parity, because it may be associated with both alcohol use and preeclampsia. To assess whether parity confounds the association between alcohol use and preeclampsia, a stratified analysis can be performed to assess the alcohol-preeclampsia association separately in multiparous and in nulliparous women. This stratified analysis of this hypothetical dataset generates Tables 16-4 and 16-5.

In addition to these stratum-specific odds ratios, a stratified analysis also generates a Mantel-Haenszel summary odds ratio, which in this case is 1.0; 95% CI, 0.42 to 2.34. The proper interpretation of this summary odds ratio is that it represents the association between alcohol use and preeclampsia, after adjusting for the effect of parity. Thus, in this hypothetical example, although the unadjusted odds ratio suggested an association, the adjusted results did not. Stated differently, parity confounds the association between alcohol and preeclampsia.

A stratified analysis is thus a key step in assessing potential confounders, but it is limited because one can stratify only one or two factors simultaneously. Therefore, stratified analysis is more useful to assess potential confounders that should be included in multivariable models.

STEP 4. PERFORM MULTIVARIABLE ANALYSIS

A multivariable analysis is essential for observational studies, and it can be used occasionally in interventional studies. It allows assessment of the independent effects of many exposures on an outcome, while controlling for confounding factors. The performance of a multivariable analysis is complex and beyond the scope of this chapter. It is generally useful to consult with a biostatistician or with someone who has significant expertise in this area.

Sample Size and Power

So far, we have focused mainly on the assessment of type I (or alpha) error in clinical research, defined as the probability of rejecting the null hypothesis when in fact the null is correct. Type II (or beta) error is

TABLE 16-4 ALCOHOL-PREECLAMPSIA ASSOCIATION IN NULLIPAROUS SUBJECTS			
	Preeclampsia +	Preeclampsia –	Total
Alcohol +	8	16	—
Alcohol –	22	44	—
Total	30	60	90

Odds ratio = 1.0 (95% confidence interval, 0.33 to 2.9).

TABLE 16-5 ALCOHOL-PREECLAMPSIA ASSOCIATION IN MULTIPAROUS SUBJECTS			
	Preeclampsia +	Preeclampsia –	Total
Alcohol +	63	36	—
Alcohol –	7	4	—
Total	70	40	110

Odds ratio = 1.0 (95% confidence interval, 0.23 to 4.2).

defined as the probability of accepting the null hypothesis when in fact it is false. In a study with type II error, the results are falsely reported as negative, and thus a true difference is missed. This typically occurs when the sample size is insufficient.

This concept of a false-negative study emphasizes the importance of sample size estimation and statistical power (*power* is defined as 1 minus the beta error). Sample size estimates should be performed prior to any observational or interventional study. The following are the key components of a sample size estimate for cohort studies or clinical trials, and for case-control studies (that have a binary outcome).

Sample size estimate for cohort study or clinical trial

Alpha error
Beta error
Incidence of outcome in unexposed subjects
Ratio of exposed to unexposed subjects
Minimum detectable relative risk

Sample size estimate for case-control study

Alpha error
Beta error
Prevalence of exposure in controls
Ratio of controls to cases
Minimum detectable odds ratio

Some of these components deserve discussion. First, alpha error, by tradition, is set at 0.05, reflecting the intent to perform a study whose results will be falsely declared to be positive less than 5% of the time. Second, beta error is usually set somewhere between 0.05 and 0.20, reflecting the intent to identify a true relationship at least 80% of the time when a relationship truly exists, and, simultaneously, a willingness to miss finding a true relationship 20% of the time. This means that such a study is described as having 80% to 95% power. Third, the incidence of exposure or the prevalence of exposure can generally be estimated from the literature or from pilot data. Last, the minimum detectable odds ratio or relative risk is that meant to be clinically relevant. In practice, there is a tradeoff between wanting to detect as small a difference as possible and wanting to maintain a reasonable sample size (from a logistical and cost perspective).

Sample size estimates should be performed before beginning a research study and should be reported as part of the study's design. As readers of the literature, we should be especially cognizant of sample size and statistical power in cases of a negative study.

Assessing Research on Screening and Diagnosis

Screening and diagnostic tests are an integral part of clinical medicine. For example, measurement of fundal height, a screening test for fetal growth disturbances and amniotic fluid abnormalities, is a routine part of prenatal care. If the fundal height measures significantly less than anticipated, a diagnostic test, in this case an ultrasound examination, is performed. The same sequence of screening followed by diagnostic testing occurs commonly in obstetric practice—for example, a family history (screening test) that leads to a “targeted” ultrasound (which may be diagnostic for some disorders or a screening test for others) and eventually to amniocentesis (diagnostic test). Because such testing dominates our clinical lives, it is essential that physicians understand the principles of screening and diagnostic tests.⁴⁹ Only by understand-

ing the difference between screening and diagnostic testing can physicians make rational decisions about the proper interpretation of test results, and about whether a new test should be incorporated into clinical practice.

Screening versus Diagnosis

Screening has been defined as “the presumptive identification of an unrecognized disease or defect by the application of tests, examination or other procedures which can be applied rapidly. . . . A screening test is not meant to be diagnostic. Persons with positive or suspicious findings must be referred to their physicians for diagnosis and treatment.”⁴¹ Thus, screening tests are those that are widely applied to a population and require follow-up with a diagnostic test (if an individual screens positive). In general, a successful screening program must meet the following criteria:

- The condition screened for must have a significant burden on health.
- There must be effective early treatment for those who screen positive.
- The test must be sufficiently sensitive and specific (see later).
- The screening test must be inexpensive and easy to perform.
- The screening test must be safe and acceptable to patients.

Cervical cytology screening for premalignant lesions of the cervix is an example of a successful screening program that fulfills all of these criteria. In contrast, although cytomegalovirus infection of the fetus and neonate creates a significant burden of disease, a screening program for this virus has no value because there is no successful intervention. Similarly, although cervicovaginal fetal fibronectin screening can identify as many as 60% of women destined for preterm birth before 28 weeks,⁵⁰ there is currently no effective intervention that could be applied to screen-positive women to reduce the risk for preterm delivery.⁵¹

Sensitivity, Specificity, and Predictive Values

It is critical to understand the characteristics of both screening and diagnostic tests. Sensitivity and specificity are characteristics inherent in the test and are independent of the prevalence of the disease.^{49,52} Sensitivity is the probability, expressed as a percentage, that if the disease is present, the test is positive. The numerator is the number of subjects with the disease who have a positive test, and the denominator is the total number of diseased subjects.

Specificity is the probability, expressed as a percentage, that if the disease is absent, the test is negative. The numerator is the number of subjects without disease who have a negative test, and the denominator is the total number of nondiseased subjects. Although the sensitivity and specificity of a test are important considerations when deciding whether or not to order a test, we become more interested in the predictive values when the test results have returned. Predictive values, unlike sensitivity and specificity, depend on the prevalence of the outcome in the population tested.

A positive predictive value (PPV) is the probability that if the test is positive, the subject has the disease. The numerator is the number of subjects with the disease who have a positive test, and the denominator is the total number of those with a positive test. A negative predictive value (NPV) is the probability that if the test is negative, the subject does not have the disease. The numerator is the number of subjects

TABLE 16-6 FETAL FIBRONECTIN (FFN) TO PREDICT DELIVERY WITHIN 7 DAYS OF TESTING

	Delivery, <7 Days		Total
	Yes	No	
FFN +	20	130	150
FFN –	3	610	613
Total	23	740	763

Prevalence = 23/763 = 3%.

Sensitivity = 20/23 = 87%; specificity = 610/740 = 82%.

PPV = 20/150 = 13%; NPV = 610/613 = 99.5%.

NPV, negative predictive value; PPV, positive predictive value.

Data from Peaceman AM, Andrews WW, Thorp JM, et al: Fetal fibronectin as a predictor of preterm birth in patients with symptoms: A multicenter trial. *Am J Obstet Gynecol* 177:13, 1997.

without disease who have a negative test, and the denominator is the total number of those with negative tests. Given the same sensitivity and specificity, the PPV will increase and the NPV will decrease as the prevalence rises. Likewise, as the prevalence decreases, the PPV decreases and the NPV increases.

These abstract concepts are best demonstrated with a clinical example. Peaceman and colleagues⁵³ performed a prospective cohort study at multiple centers to assess whether cervicovaginal fetal fibronectin could be used as a diagnostic test in women with symptoms of preterm labor; fetal fibronectin has also been assessed in other studies as a screening test.⁵⁰ In the Peaceman study, women with symptoms of early preterm labor were enrolled, and cervicovaginal swabs for fibronectin testing were obtained. Treating physicians and patients were blinded to the results of the fibronectin test, a strength of the study. The outcomes assessed were the occurrence of delivery within 7 days, within 2 weeks, and before 37 weeks' gestation. The results of the analysis of delivery within 7 days (Table 16-6) may be used as an example to illustrate sensitivity, specificity, and PPV and NPV.

Some would look at these results and the high NPV and suggest that fetal fibronectin is a useful tool in this setting to rule out an imminent delivery. Another way of looking at these same data would be to look closely at the low prevalence of delivery within 7 days (3%). After reading this article, the following questions emerge: Is it appropriate to use a diagnostic test in such a low prevalence group? And, more importantly, what would be the impact of testing a higher-prevalence population (i.e., a population with a greater chance of preterm birth within 7 days)?

Physicians may look at these results differently. Some may argue that the treatment for preterm labor has risk, is of questionable efficacy, and is overused. Thus, a test that could avoid overtreatment with tocolytics might be helpful. Others could argue that the very high NPV with fetal fibronectin was obtained only when testing patients with a very low prevalence of preterm delivery and that no diagnostic test is needed in such a low-prevalence population. Furthermore, when this test is used in a higher-prevalence group, the NPV will decrease, making it much less useful. The value of a test with these characteristics is thus population dependent, according to the prevalence of preterm birth and the prevailing pattern of clinical care regarding tocolytic drugs for women with minimal symptoms.

For example, let us assume the population tested could be selected by adding clinical data to define a group with a higher prevalence of delivery within 7 days. Table 16-7 illustrates the effect of the increased prevalence on PPV and NPV. Remember that the sensitivity and speci-

TABLE 16-7 FETAL FIBRONECTIN (FFN) TEST TO PREDICT DELIVERY WITHIN 7 DAYS OF TESTING: HYPOTHETICAL ANALYSIS OF A HIGH-PREVALENCE GROUP

	Delivery < 7 Days		Total
	Yes	No	
FFN +	99	117	216
FFN –	15	532	547
Total	114	649	763

Prevalence = 114/763 = 15%.

Sensitivity = 99/114 = 87%; specificity = 532/649 = 82%.

PPV = 99/216 = 45%; NPV = 532/547 = 97%.

NPV, negative predictive value; PPV, positive predictive value.

ficity stay constant regardless of the disease prevalence. As expected, the PPV increases somewhat, and the NPV is decreased to 97%. Another way of looking at the NPV is that 3% of those with a negative test will go on to deliver within 7 days. Is this rate of false-negative testing acceptable for a patient who presents at 24 weeks with symptoms of preterm labor? Once again, the answer is determined by patient- and physician-related factors that are unique to the clinical setting.

Likelihood Ratios

Likelihood ratios, another method to describe test performance, can be used to calculate post-test probabilities, just like predictive values. In literature from the United States, predictive values are commonly reported, whereas likelihood ratios are preferred in many European and South American journals. A likelihood ratio is defined as the probability of the test result in the presence of outcome, divided by the probability of the result in those without the outcome. Separate likelihood ratios are calculated for positive tests and negative tests. Likelihood ratios express how many times more (or less) likely a test result is to be found in those with the outcome compared with those without the outcome.

As an example, the positive likelihood ratios from the data on delivery within 7 days in the previously cited Peaceman study⁵³ can be calculated as shown here, by dividing the proportion of women with a positive test who did deliver within 7 days, by the proportion of women with a positive test who did not deliver within 7 days:

$$\text{Positive likelihood ratio} = \frac{20/23}{130/740} = \frac{0.87}{0.18} = 4.8$$

Likelihood ratios can also be used to calculate a post-test probability (PPV), which is what we use in clinical practice. To do this, however, the pretest probability (prevalence) must be converted to pretest odds using the following formula:

$$\begin{aligned} \text{Odds} &= \text{probability of event} / (1 - \text{probability of event}) \\ \text{Probability} &= \text{odds} / (1 + \text{odds}) \end{aligned}$$

Using the Peaceman data for a positive test, the prevalence of delivery within 7 days is 3%. In odds, this translates to 0.031. Then, we can calculate the post-test odds using the formula

$$\text{Pretest odds} \times \text{likelihood ratio} = \text{post-test odds}$$

In this case, the post-test odds are $0.031 \times 4.8 = 0.1488$. When the post-test odds are converted to a post-test probability (i.e., a PPV), the result is $0.1488/1.1488 = 13.0\%$, the same as the PPV calculation we saw in Table 16-6.

Thus, looking at the positive and negative likelihood ratios is another way to assess the utility of a test, and these ratios can be used to convert pretest probabilities to post-test probabilities. For the latter issue, this can be somewhat cumbersome, and many individuals prefer to simply use a 2×2 table to calculate predictive values.

Receiver Operating Characteristic Curves

Although test results may be categorical (i.e., positive or negative), they are more often expressed in clinical medicine as a point on a continuum. As clinicians, we evaluate test results and try to discriminate “normal” from “abnormal.” Although it would be ideal to have tests that are simultaneously very sensitive and specific, this is seldom the case. Thus, we are faced with selecting thresholds that trade between degrees of sensitivity and specificity. A graphic method that makes these tradeoffs explicit and aids in the selection of cut points is the *receiver operating characteristic (ROC) curve*. The sensitivity is placed on the y axis versus 1 minus the specificity (the false-positive rate) on the x axis for the entire range of cut points. Tests that discriminate well tend to generate a curve that occupies the upper left corner of the graph. Poorly discriminating tests generate a curve that falls along the diagonal that follows from the lower left corner to the upper right corner. A 45-degree line along this diagonal describes a nondiscriminating test, which is one that has no threshold value.

ROC curves have three primary uses: to select a cut point for an individual test, to assess the overall accuracy of the individual test, and to compare the overall accuracy of two tests for the same condition. The last is most often done by calculating and comparing the area under the ROC curve.

A recent example of the clinical use of ROC curves in selecting an appropriate cut point was published by Owen and colleagues⁵⁴ and focused on mid-trimester transvaginal cervical length measurements to predict preterm birth before 35 weeks' gestation in high-risk women. To assess this question, the authors performed a multicenter prospective study of transvaginal ultrasound cervical measurements every 2 weeks in 183 women with a prior birth at less than 32 weeks. Figure 16-3 shows a comparison of ROC curves for shortest observed cervical length to the cervical length at the first examination, for the prediction of spontaneous preterm birth before 35 weeks' gestation. Figure 16-3 suggests the following:

1. The shortest observed cervical length is a better discriminator than the initial cervical length for the prediction of spontaneous preterm birth at less than 35 weeks.
2. Although the shortest observed cervical length is better than the initial examination, neither test is particularly discriminating (as evidenced by the fact that neither curve is very close to the left upper corner of the graph).
3. The optimal cut point for the shortest observed cervical length is 25 mm. At this level, however, the sensitivity is only about 70%, with a false-positive rate of about 20%.

Iams and colleagues⁵⁵ reported a study of several tests to predict preterm birth in pregnant women. Cervical examinations by digital examination (expressed as a Bishop score) and by ultrasound (expressed as the length of the cervical canal) were compared with monitored

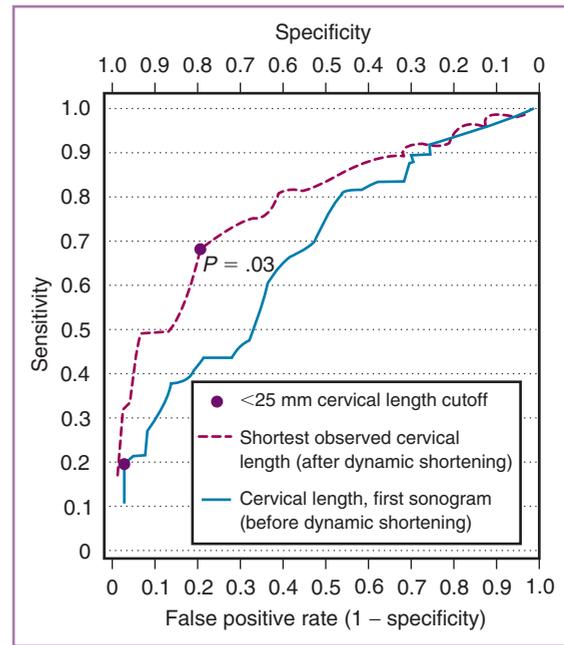

FIGURE 16-3 Comparison of ROC curves for cervical length. Receiver operating characteristic (ROC) curves of cervical length cutoffs for the prediction of spontaneous preterm birth before 35 weeks' gestation. (From Owen J, Yost N, Berghella V, et al: Mid-trimester endovaginal sonography in women at high risk for spontaneous preterm birth. *JAMA* 286:1340, 2000.)

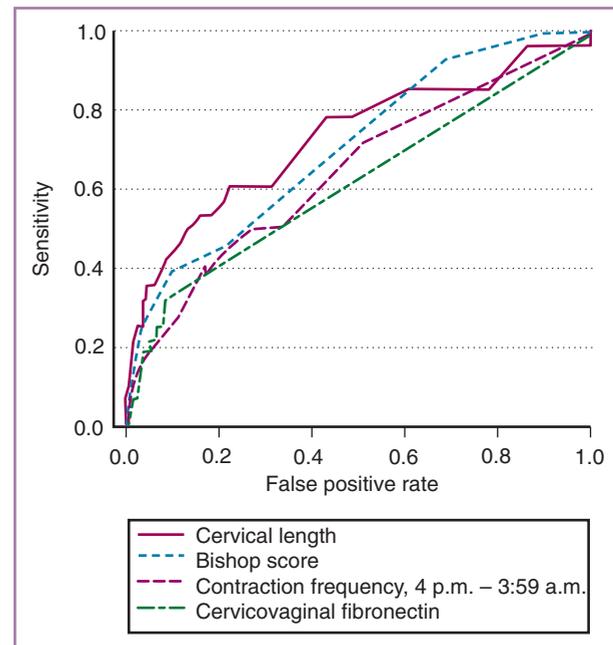

FIGURE 16-4 Comparison of tests to predict preterm birth. Receiver operating characteristic curves for cervical length, Bishop score, frequency of contractions, and presence or absence of fetal fibronectin in cervicovaginal secretions at 27 to 28 weeks in the prediction of spontaneous preterm delivery (less than 35 weeks). (From Iams JD, Newman RB, Thom EA, et al, for the National Institute of Child Health and Human Development Network of Maternal-Fetal Medicine Units: Frequency of uterine contractions and the risk of spontaneous preterm delivery. *N Engl J Med* 346:250, 2002.)

uterine contraction frequency and fetal fibronectin in cervicovaginal secretions using ROC curves. The performance of each test was displayed on a common graph of their ROC curves (Fig. 16-4). Cervical length by ultrasound, though far from an ideal test, had the “best” performance, as the uppermost line of the curves displayed.

Summary

This overview of study design and methods to analyze and report data in perinatal medicine can serve as a starting point to integrate research data appropriately into clinical care. As with any skill, it is mastered by frequent repetition and especially by analyzing and presenting one’s own data with one of the methods described.

Chapter 17

Prenatal Diagnosis of Congenital Disorders

Ronald J. Wapner, MD, Thomas M. Jenkins, MD, and Nahla Khalek, MD

Prenatal diagnosis, a term once considered synonymous with invasive fetal testing and karyotype evaluation, now encompasses pedigree analysis, population screening, fetal risk assessment, genetic counseling, and fetal diagnostic testing. Although prenatal evaluation of the fetus for genetic disorders can have a huge impact on individual families, most screening and testing is done for events that occur in less than 1% of pregnancies. In this chapter, we describe different modalities available for in utero fetal diagnosis of congenital disorders, the approach to screening ongoing pregnancies for genetic disease, and the counseling requirement for each.

Screening for Fetal Genetic Disorders

Detecting or defining risk for disease in an asymptomatic low-risk population is the goal of screening. As opposed to diagnostic testing, intended to identify or confirm an affected individual, screening is intended to identify populations who have an increased risk for a specific disorder, and for whom diagnostic testing may be warranted. An ideal perinatal genetic screening test should fulfill the following criteria:

- Identify common or important fetal disorders
- Be cost-effective and easy to perform
- Have a high detection rate and a low false-positive rate
- Be reliable and reproducible
- Test for disorders for which a diagnostic test exists
- Be positive early enough in gestation to permit safe and legal options for pregnancy termination if desired

Sensitivity and specificity are two key concepts in screening test performance (see Chapter 16). Sensitivity is the percentage of affected pregnancies that are screen positive. Specificity is the percentage of individuals with unaffected pregnancies who screen negative. The reciprocal of specificity is the false-positive rate. Sensitivity and specificity are independent of disease frequency, and they describe the anticipated performance of a screening test in the population. Alternatively, positive and negative predictive values are dependent on disease prevalence and are vital in the interpretation of the test result for an individual patient. These latter two values represent, respectively, the likelihood that a person with a positive or negative test does or does not have an affected pregnancy. The impact of the prevalence of

the disease on the positive and negative predictive values is described in Chapter 16 and is shown in Tables 16-6 and 16-7.

Use of screening tests requires that cutoff values for “positive” tests be set. Performance of the test depends on this cutoff; for example, increased detection rate can be obtained by lowering the cutoff threshold, but the concomitant lowered specificity would result in more false-positive results. Table 17-1 shows the performance of second-trimester maternal serum screening for Down syndrome based on various cutoffs.¹ A receiver operating curve can be used as a statistical method to find the “best” balance between sensitivity and specificity. A line diagram is plotted with sensitivity on the vertical axis and the false-positive rate plotted horizontally (Fig. 17-1). The greater the area under the curve (toward the upper left corner), the better the test’s performance is, with increasing sensitivity and a reduced false-positive rate.

When screening for Down syndrome, cutoff values are important for laboratories that provide the testing and for clinicians who interpret the results. When viewed from the patient’s perspective, reporting tests as positive or negative can be confusing. Receipt of a “positive” result of 1 in 250 may lead to a choice of a diagnostic test that carries a risk of complications, whereas a “negative” result of 1 in 290 may provide greater reassurance than intended, when in fact the actual risk of Down syndrome is similar for both patients. Often, explaining the significance of a positive or negative result before the screening test is performed will assist patients in understanding their results. Many centers report the absolute risk to the patient to further help in interpretation. Regardless of the counseling approach, understanding the concept of screening is difficult for many patients. From the perspective of the laboratory or clinician, selection of a cutoff that is too high or too low will lead to overutilization or underutilization of diagnostic tests and the consequent risk of procedure-related pregnancy loss or false reassurance, respectively.

Likelihood Ratios

The impact of a positive screening test depends on the pretest (a priori) risk of an affected pregnancy. Likelihood ratios are statistical means to modify an individual’s risk based on known data for a population. For binary risk factors that are either present or absent, likelihood ratios are determined by comparing the frequency of positive tests in affected pregnancies to the frequency in normal pregnancies. This is calculated as the sensitivity of the test divided by its false-positive rate (likelihood ratio = sensitivity/false-positive rate). For tests that use continuous variables (such as serum marker measurements), likeli-

TABLE 17-1 DOWN SYNDROME DETECTION: FALSE-POSITIVE RATES (FPR) AT DIFFERENT CUTOFF VALUES

Triple Screen Cutoff	Detection Rate	FPR	Quadruple Screen Cutoff	Detection Rate	FPR
1:200	57	4.3	1:200	60	3.5
1:250	61	5.6	1:250	64	4.5
1:300	64	6.8	1:300	67	5.5
1:350	67	8.1	1:350	69	6.5
1:400	69	9.3	1:400	72	7.6

Data from Huang T, Watt H, Wald N: The effect of differences in the distribution of maternal age in England and Wales on the performance of prenatal screening for Down's syndrome. *Prenat Diagn* 17:615, 1997.

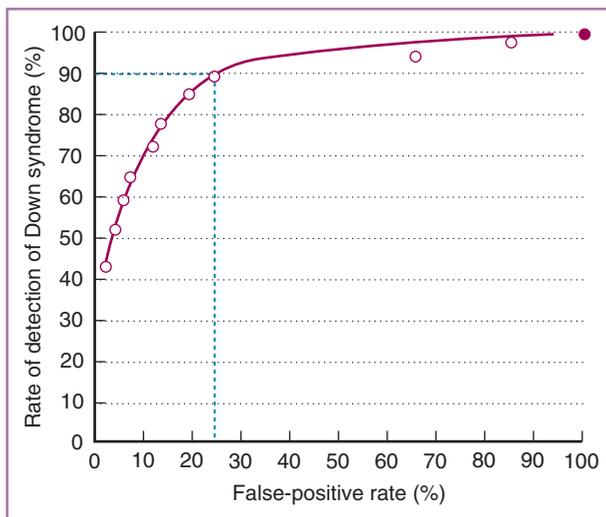

FIGURE 17-1 Receiver operating curve demonstrating sensitivity for Down syndrome detection versus false-positive rate. Cutoff points for sensitivity versus false-positive rate are determined by these curves. (From Haddow JE, Palomaki GE, Knight GJ, et al: Reducing the need for amniocentesis in women 35 years of age or older with serum markers for screening. *N Engl J Med* 330:1114, 1994.)

hood ratios are calculated from the log gaussian distributions of normal and affected pregnancies. Once a likelihood ratio is determined, it can be used to modify the a priori risk (Table 17-2). If more than one likelihood ratio is available and is independent of other parameters, it also can be used to modify risk. In this way, multiple factors (such as maternal age, serum analytes, and ultrasound findings) can be simultaneously used to modify risk.

Antenatal Screening for Down Syndrome

There has been a general consensus in the United States that invasive testing for Down syndrome should be offered to women with a second-trimester risk of 1:270 or higher (liveborn risk of 1:380). The cutoff

TABLE 17-2 ADJUSTING THE RISK FOR DOWN SYNDROME USING LIKELIHOOD RATIOS FOR BINARY ULTRASOUND MARKERS

A priori risk of Down syndrome (age or serum screen)	1:1000
Positive ultrasound marker for Down syndrome	
Rate in Down syndrome population (sensitivity of marker)	10%
Rate in general population (FPR of marker)	1.0%
Likelihood ratio (sens/FPR)	10.0
Adjusted risk for Down syndrome	
(A priori risk \times likelihood ratio) = $1/1000 \times 10$	1:100

FPR, false-positive rate; sens, sensitivity.

level and subsequent public policy was determined more than 25 years ago and was based on a maternal age risk of 35 years at delivery. The factors considered in determining this value included the prevalence of disease, a perceived significant increase in the trisomy 21 risk after this age, the risk of invasive testing, the availability of resources, and a cost-to-benefit analysis. Since that time, a number of additional screening tests for Down syndrome have become available that challenge the validity of maternal age as a single indication for invasive testing.

Maternal Age as a Screening Test

The association of Down syndrome with advancing maternal age was first reported in 1909.² Fifty years later, karyotype analysis was developed and correlated the Down syndrome phenotype with an extra G chromosome.³ This led to the development of genetic amniocentesis, through which the prenatal diagnosis of Down syndrome became feasible. To standardize the use of this emerging technology, a consensus report from the National Institutes of Health in 1979 suggested that amniocentesis be routinely offered to women aged 35 years or older at delivery. At that time, maternal age risks of Down syndrome were available only in 5-year groupings. Using these data, the age of 35 seemed a natural cutoff, because women in the 30- to 34-year grouping had a risk of 1:880, and the risk for women aged 35 to 40 was almost fourfold higher. This cutoff was based on a number of factors, including the availability of experienced operators and cytogenetics laboratories, the cost-to-benefit ratio, and the balance between procedure-related losses and the possibility of a positive finding. This cutoff continues to be used, and the second-trimester risk of 1:270 or liveborn risk of 1:380 remains the standard value for offering women invasive testing.

The risk for Down syndrome is now recognized to be continuous, which emphasizes the arbitrary nature of an absolute age threshold of 35. In addition to maternal age, the risk of trisomy 21 depends on the gestational age at which testing is performed, because only 69% of first-trimester and 76% of second-trimester Down syndrome pregnancies are viable (Table 17-3).⁴ Currently, more than 80% of diagnostic procedures to determine fetal karyotype performed in the United States are performed solely for "advanced maternal age," yet 70% of affected pregnancies are born to women outside this group. With many women delaying childbirth until later in life, more than 14% of pregnant women in the United States are being offered testing based on age alone. In Switzerland and the United Kingdom, almost 15% of births now occur in women older than 35.

TABLE 17-3 RISK FOR DOWN SYNDROME BASED ON MATERNAL AND GESTATIONAL AGES

Maternal Age (yr)	Gestational Age			
	12 Wk	16 Wk	20 Wk	Liveborn
20	1/1068	1/1200	1/1295	1/1527
25	1/946	1/1062	1/1147	1/1352
30	1/626	1/703	1/759	1/895

45	1/16	1/18	1/19	1/23

Data from Hook EB: Rates of chromosome abnormalities at different maternal ages. *Obstet Gynecol* 58:282, 1981.

Second-Trimester Maternal Serum Screening

Serum screening may be used to identify the 70% of Down syndrome pregnancies in women less than 35 years of age. This approach is derived from a 1984 report of lower maternal serum α -fetoprotein (MSAFP) levels in women carrying a Down syndrome fetus. Women with Down syndrome pregnancies had a median MSAFP value of 0.75 multiples of the unaffected median (MoM).^{5,6} Using this deviation to calculate a likelihood ratio, the age-related risk for Down syndrome could be modified. When the standard 1:270 cutoff was used, approximately 25% of Down syndrome pregnancies among women less than 35 years of age were screen-positive.⁷⁻⁹

Elevated human chorionic gonadotropin (hCG) (mean, 2.3 MoM) and reduced levels of unconjugated estriol (mean, 0.7 MoM) were subsequently linked to an increased risk of trisomy 21.^{6,10,11} hCG or reduced levels of unconjugated estriol used alone to modify the maternal age risk has a Down syndrome detection rate of only 20% to 30%. However, because they are independent variables, they can be analyzed simultaneously with maternal age and AFP to form a composite risk calculation (frequently called a triple screen).

The sensitivity of the triple screen for Down syndrome detection in women younger than 35 years ranges between 57% and 67% if the false-positive rate is held constant at 5%.¹²⁻¹⁵ Overall, the odds of having an affected pregnancy with a positive screen are approximately 1 in 33 to 1 in 62, depending on the age range of the population studied,^{16,17} an improvement over the 1:100 odds when maternal age is the sole screening parameter. Because of the impact of maternal age on the risk analysis, screening women who will be 35 years of age or more increases the sensitivity using the same cutoffs to approximately 87% but with a false-positive rate of nearly 25%.^{13,18}

Inhibin A, a protein produced initially by the corpus luteum and later by the placenta, is now routinely included in second-trimester Down syndrome screening resulting in a "quad screen." Inhibin A levels

are elevated in Down syndrome pregnancies (1.3 to 2.5 MoM) and do not vary with gestational age in the second trimester. There is, however, a small correlation with hCG levels, making the added sensitivity for Down syndrome detection less robust.¹⁹ Detection rates when a quad screen of α -fetoprotein (AFP), hCG, unconjugated estriol, and inhibin A are used are about 75% (screen positive rate, 5%) in the population under age 35 years.²⁰ For women older than 35, the detection rate is approximately 92% with a screen-positive rate of 13%.

Other analytes or combinations of analytes have been tested to further increase sensitivity. Hyperglycosylated hCG excreted in maternal urine has been tested as a marker for Down syndrome. One study of nearly 1500 women (1448 control subjects and 39 Down syndrome pregnancies) reported a sensitivity of 96% of affected pregnancies with a 5% false-positive rate and 71% detection with a 1% false-positive rate when a combination of hyperglycosylated hCG, urine β -core hCG fragment, MSAFP, and maternal age was used.²¹ This detection rate, however, has not been duplicated by others.

With the addition of extra markers, the potential benefit must be balanced against the cost. With each additional marker, costs to society can balloon into the millions because of the number of pregnancies tested each year with only a minimal improvement in detection. The relative cost and value of raising the sensitivity or lowering the false-positive rate a few percentage points is an ongoing debate.

Abnormal Second Trimester Maternal Serum Markers in Pregnancies with a Normal Karyotype

Unexplained Elevated Maternal Serum α -Fetoprotein

When an elevated MSAFP is reported in pregnancies in which the gestational age is correctly assigned and the fetus is structurally normal, and the amniotic fluid AFP (AFAFP) is normal, the biologic explanation is almost always a breach in the maternal-fetal interface. This leads to higher AFP levels in the maternal circulation. Not surprisingly, women with unexplained elevation in AFP levels have been found to have increased risk of obstetric complications, including fetal growth restriction, fetal death, prematurity, oligohydramnios, abruptio placentae, and preeclampsia. Table 17-4 summarizes the numerous reports; the higher the MSAFP level is, the greater the risk. Crandall and colleagues²² studied 1002 women with MSAFP values greater than 2.5 MoM and stratified them by the degree of elevation. In those with a normal ultrasound and amniocentesis, the risk of adverse outcome was 27% overall but varied with the degree of elevation. Adverse outcome occurred in 16% when the MSAFP was 2.5 to 2.9 MoM, 29% when it was 3.0 to 5.0 MoM, and 70% when it was greater than 5.0 MoM. Waller and coworkers²³⁻²⁵ investigated 51,008 women screened with MSAFP in California to evaluate the predictive value of high MSAFP compared with low levels. The risk of delivery before 28 weeks was 0.4% with low values (<0.81 MoM) and 3.2% for those with high values (>2.5 MoM), an eightfold difference. The rates for delivery before 37 weeks were 2.6% for the low MSAFP group and 24.3% for the high MSAFP group. Notably, women with MSAFP values greater than 2.5 MoM had a 10.5-fold increase in preeclampsia and a 10-fold increased risk of placental complications, suggesting that an elevated value in the absence of an anomaly may derive from a fetal-maternal hemorrhage of sufficient volume to have clinical significance. This observation may explain the elevation in MSAFP, but to date no management protocol has been demonstrated to improve outcome in these cases.

TABLE 17-4 STUDIES EVALUATING THE RELATION OF UNEXPLAINED ELEVATIONS OF MSAFP AND POOR PREGNANCY OUTCOME

Unexplained Elevated Human Chorionic Gonadotropin Levels

The risk for adverse pregnancy outcome with elevated hCG levels appears to be independent of those associated with elevated AFP. Studies have shown that unexplained elevated hCG (greater than 2.0 MoM) is associated with an increased risk of preeclampsia, preterm birth, low birth weight, fetal demise, and possibly hypertension.²⁶ It appears that the higher the hCG is, the greater the risk.

Elevated Human Chorionic Gonadotropin and Maternal Serum α -Fetoprotein

The combination of elevated MSAFP and hCG levels occurs rarely but may have an overall pregnancy complication rate exceeding 50%. A study of 66 singleton and 33 multiple pregnancies with an MSAFP of more than 2 MoM and an hCG of more than 3.0 MoM found that 60% of singletons and 81% of twins had at least one of several obstetric complications, including preeclampsia, preterm birth, growth restriction, placental abnormalities, and fetal death.²⁷ Confined placental mosaicism for chromosome 16 has been reported to be associated with extremely high levels of both analytes, as well as with similarly poor outcomes.^{28,29}

Low Second-Trimester Maternal Serum Estriol

Low maternal serum unconjugated estriol levels have been linked to adverse pregnancy outcomes.^{30,31} Very low or absent estriol levels of

0.0 to 0.15 MoM suggest biochemical abnormalities of the fetus or placenta, including placental steroid sulfatase deficiency, Smith-Lemli-Opitz syndrome, congenital adrenal hypoplasia, adrenocorticotropic deficiency, hypothalamic corticotropin deficiency, and anencephaly.

Smith-Lemli-Opitz syndrome is an autosomal recessive disorder resulting from a defect in $3\alpha\beta$ -hydroxysteroid- α 7-reductase, altering cholesterol synthesis and resulting in low cholesterol levels and the accumulation of the cholesterol precursor 7-dehydrocholesterol in blood and amniotic fluid. Because cholesterol is a precursor of estriol, the defect results in reduced or undetectable levels of estriol in maternal serum and amniotic fluid. Smith-Lemli-Opitz syndrome is characterized by low birth weight, failure to thrive, and moderate to severe mental retardation. It is associated with multiple structural anomalies, including syndactyly of the second and third toes, microcephaly, ptosis, and a typical-appearing facies.³²⁻³⁴ Undermasculinization of the genitalia including complete sex reversal can be seen in male fetuses.

Bradley and colleagues³⁵ summarized findings in 33 women who delivered infants with Smith-Lemli-Opitz syndrome. Twenty-four of 26 women who had second-trimester estriol values obtained had levels less than the 5th percentile (<0.5 MoM). The median level in this group was 0.23 MoM (below the first percentile). A risk assessment based on low maternal serum unconjugated estriol levels has been suggested but is not presently available.³⁶ Reliable and inexpensive prenatal testing for Smith-Lemli-Opitz syndrome based on amniotic fluid cholesterol or 7-dehydrocholesterol levels is available.³⁷

Placental steroid sulfatase deficiency is an X-linked recessive disorder resulting from deletion of Xp22.3. This enzyme deficiency prevents removal of the sulfate molecule from fetal estrogen precursors, preventing conversion to estriol. The fetal phenotype depends on the extent of the deletion, with greater than 90% of cases presenting as X-linked ichthyosis that can be treated with topical keratolytic agents. However, in about 5% of cases, there can be a deletion of contiguous genes causing mental retardation. The deletion can, on occasion, extend to cause Kallman syndrome or chondrodysplasia punctata. The lack of estrogen biosynthesis may result in delayed onset of labor, prolonged labor, or stillbirth.

Prenatal diagnosis for the deletion leading to placental sulfatase deficiency and congenital ichthyosis can be performed by identifying the gene deletion by karyotype or fluorescence in situ hybridization.³⁸⁻⁴⁰ Although very low estriol levels, usually below the level of detection, can identify males at risk for this disorder, testing in these cases is not routinely offered because the phenotype is usually mild. However, the rarer, more serious cases of extensive deletions will be missed.⁴¹

Second-Trimester Ultrasound Markers of Down Syndrome

The clinical suspicion of Down syndrome is suspected when an infant is found to have specific physical findings that occur frequently in Down syndrome infants but can also occur in normal individuals. These include a simian crease in the fetal hand, a short femur or humerus, clinodactyly, and excessive nuchal skin. Similarly, the in utero diagnosis of Down syndrome can be suspected when anomalies or physical features that occur more frequently in Down syndrome than in the general population are noted on an ultrasound examination. Certain of these congenital anomalies, such as atrioventricular canal or duodenal atresia, strongly suggest the possibility of Down syndrome and are independent indications to offer invasive testing. Although when these anomalies are present there is a high risk of trisomy 21, these anomalies have low sensitivity and thus are not useful in screening. For example, when duodenal atresia is identified, there is an approximate 40% risk of Down syndrome, yet it is seen in only 8% of affected fetuses. Physical characteristics that are not themselves anomalies but that occur more commonly in fetuses with Down syndrome are called *markers*. By comparing the prevalence of markers in Down syndrome fetuses to their prevalence in the normal population, a likelihood ratio can be calculated that can be used to modify the a priori age or serum screening risk. This is the basis for ultrasound screening for Down syndrome.

For a marker to be useful for Down syndrome screening, it should be sensitive (i.e., present in a high proportion of Down syndrome pregnancies), specific (i.e., rarely seen in normal fetuses), easily imaged in standard sonographic examination, and present early enough in the second trimester that subsequent diagnostic testing by amniocentesis can be performed so that results are available when pregnancy termination remains an option. A list of available markers and their likelihood ratios are seen in Tables 17-5 and 17-6, respectively.

Before considering each marker individually, it is important to remember that the predictive value of any test (e.g., a marker) depends on the prevalence in the population of the condition being tested for. In the case of sonographic markers for trisomy 21, the clinical importance of a marker, therefore, varies according to the a priori risk as determined by maternal age, the results of multiple serum markers, and the presence of any other sonographic markers detected at the same examination. It is wise, therefore, to defer discussion of the impact of markers until the ultrasound examination has been com-

TABLE 17-5 SECOND-TRIMESTER ULTRASOUND MARKERS ASSOCIATED WITH DOWN SYNDROME

Widened ischial spine angle
Foot length
Short or absent nasal bone

pleted and the results of serum screening have been reported. Markers commonly sought to assess the risk of Down syndrome include the following:

1. An increased nuchal fold (>6 mm) in the second trimester is the most distinctive marker. The fetal head is imaged in a transverse plane similar to that for measuring the biparietal diameter. The thalami and the upper portion of the cerebellum should be in the plane of the image. The distance between the external surface of the occipital bone and the external surface of the skin is then measured. About 35% of Down syndrome fetuses but only 0.7% of normal fetuses have a nuchal skin fold measurement greater than 5 mm. This ratio yields a likelihood ratio of 50 but includes fetuses with more than one marker. When an increased nuchal fold is an isolated finding, the likelihood ratio is still strong at 20-fold. This high likelihood ratio is obtained because of the rarity of an increased nuchal fold in an unaffected population (i.e., high specificity). For women with an a priori risk of less than 1:1600 (age-related risk for a 20-year-old), a 20-fold increase results in a risk estimate of at least 1:270. Thus, the presence of an increased nuchal fold alone is an indication to offer invasive testing.⁴²⁻⁴⁷
2. The fetal nasal bone has been demonstrated to be hypoplastic or absent in up to 60% of Down syndrome pregnancies imaged in the second trimester and only about 1% to 2% of unaffected pregnancies. Complete absence will occur in about 37% of affected cases with hypoplasia occurring in about half. In normal pregnancies, absence is seen in 0.9% of cases and hypoplasia in 2.4%. Nasal bone length can be converted to a likelihood ratio and used for Down syndrome risk assessment. When performed by experienced operators, nasal bone evaluation may be the best single ultrasound marker for second trimester risk assessment.⁴⁸
3. Down syndrome fetuses in the second trimester may have short proximal extremities (humerus and femur) relative to the expected length for their biparietal diameter. This can be used to identify at-risk pregnancies by calculating a ratio of observed to expected femur length based on the fetus's biparietal diameter. An observed-to-expected ratio of less than 0.91 or a biparietal diameter-to-femur ratio of more than 1.5 has a reported likelihood ratio of 1.5 to 2.7 when present as an isolated finding. A short humerus is more strongly related to Down syndrome, with reported likelihood ratios

TABLE 17-6 LIKELIHOOD RATIOS (LR) FOR ISOLATED MARKERS IN THREE STUDIES

Sonographic Marker	AAURA LR* (N = 1042)	Nyberg et al. LR (95% CI) [†] (N = 8830)	Smith-Bindman et al. LR (95% CI) [‡] (N = meta-analysis of >131,000)

ranging from 2.5 to 7.5. Bahado-Singh and coworkers⁴⁹ combined humerus length with nuchal skin fold to estimate Down syndrome risk and calculated the likelihood ratios for various measurements to adjust estimated Down syndrome risk for each patient.

- Echogenic intracardiac foci occur in up to 5% of normal pregnancies and in approximately 13% to 18% of Down syndrome gestations.⁵⁰ The likelihood ratio for Down syndrome when an echogenic focus is present as an isolated marker has ranged from 1.8 to 2.8. The risk does not seem to vary if the focus is in the right or left ventricle or if it is unilateral or bilateral.
- Increased echogenicity of the fetal bowel, when brighter than the surrounding bone, has a Down syndrome likelihood ratio of 5.5 to 6.7.⁵¹⁻⁵³ This finding can also be seen with fetal cystic fibrosis (CF), congenital cytomegalovirus infection, swallowed bloody amniotic fluid, and severe intrauterine growth restriction. Therefore, if amniocentesis is performed for this finding, testing for the other potential etiologies should be considered.
- Mild fetal pyelectasis (a renal pelvis anterior-posterior diameter greater than 4 mm) has been suggested as a potential marker for Down syndrome. As an isolated marker, the likelihood ratio ranges from 1.5 to 1.9 (see Table 17-6). This has been found by Snijders and coworkers⁵⁴ not to be significantly more frequent in Down syndrome pregnancies than in normal pregnancies (i.e., low specificity).
- Other markers described include a hypoplastic fifth middle phalanx of the hand,⁵⁵ short ears, a sandal gap between the first and second toes,^{56,57} an abnormal iliac wing angle,⁵⁸ and an altered foot-to-femur ratio.⁵⁹ These markers are inconsistently used because of the time and expertise required to obtain them.

Use of Second-Trimester Ultrasound to Estimate the Risk of Down Syndrome

As with other screening modalities, second-trimester ultrasound can be used to alter the a priori risk in either direction. A benign second-trimester scan having none of the known markers and no anomalies has been suggested to have a likelihood ratio of 0.4, assuming the image quality is satisfactory. Nyberg and coworkers⁶⁰ used this approach to

calculate an age-adjusted ultrasound risk assessment for Down syndrome in 8914 pregnancies (186 fetuses with Down syndrome, 8728 control subjects). Some type of sonographic finding (major abnormality, minor marker, or both) was observed in 68.8% of fetuses with trisomy 21 compared with 13.6% of control fetuses ($P < .001$). The observation that about one third of fetuses with Down syndrome have neither a marker nor an anomaly has been used to adjust the estimated risk of Down syndrome downward by approximately 60% to 65% (likelihood ratio, 0.4) when the "genetic ultrasound" is normal. This sensitivity was observed in a single experienced center. It is doubtful that the same sensitivity can be achieved in every center.⁶¹

A positive likelihood ratio can be used to estimate an increase in risk. The magnitude of the increase depends on the marker(s) or anomalies seen. Nyberg and colleagues reviewed their own data^{60,62} and the data of others⁶³ to estimate a likelihood ratio for each marker as an isolated finding (see Table 17-6). An isolated minor or "soft" marker was the only sonographic finding in 42 (22.6%) of 186 fetuses with trisomy 21, compared with 987 (11.3%) of 8728 control fetuses ($P < .001$). Nuchal thickening, nasal bone hypoplasia, and hyperechoic bowel showed the strongest association with trisomy 21 as isolated markers, followed by shortened humerus, echogenic intracardiac focus, shortened femur, and pyelectasis. Echogenic intracardiac focus was the single most common isolated marker in both affected fetuses (7.1%) and control fetuses (3.9%) but carried a low risk.

Combined Ultrasound and Second-Trimester Maternal Serum Marker Risk Assessment

Ultrasound markers can also be combined with serum markers if they are independent. Souter and coworkers⁶⁴ demonstrated a relatively small correlation that needs to be taken into consideration if a quantitative approach is used. Bahado-Singh and colleagues⁶⁵ combined ultrasound markers with maternal analytes, including urinary hyperglycosylated hCG and urinary α -core fragment of hCG. In a sample of 585 pregnancies, the sensitivity was 93.7%, with a false-positive rate of 5%.

Adapted from Snijders RJM, Nicolaides KH: *Ultrasound Markers for Fetal Chromosomal Defects*. New York, Parthenon, 1996.

Second-Trimester Ultrasound Screening for Other Chromosomal Abnormalities

Fetal aneuploidy other than Down syndrome can be suspected based on ultrasound findings (Table 17-7). Choroid plexus cysts occur in 1% of fetuses between 16 and 24 weeks' gestation and have been associated with trisomy 18. Thirty percent to 35% of fetuses with trisomy 18 have choroid plexus cysts. Among fetuses with a choroid plexus cyst, about 3% have trisomy 18, most (65% to 90%) of whom have other ultrasound findings (Table 17-8). Although an isolated choroid plexus cyst was estimated to yield a probability of trisomy 18 of 1 of 150 in one review, many of the series reviewed contained a high proportion of older women, which would overstate the risk. Snijders and coworkers⁶⁶ calculated that an isolated choroid plexus cyst has a likelihood ratio for trisomy 18 of 1.5 and can be used to calculate an individual's risk for trisomy 18. The size, location, or persistence of the cyst does not alter this risk.⁶⁷⁻⁷¹

Table 17-7 displays the magnitude of the associations between various ultrasound findings and aneuploid conditions as estimated from a referral population. The rates noted may overestimate the strength of the association when such findings are noted on a screening examination.

First-Trimester Ultrasound Screening for Aneuploidy

In his initial description of the syndrome that bears his name, Langdon Down described skin so deficient in elasticity that it appeared to be too large for the body. This was particularly noticeable in the neck area. The skin in the fetal neck can now be seen with ultrasound as early as 10 to 12 weeks of gestation and is known as a nuchal translucency (NT). The quantification of this additional "skin behind the neck" can be used for first-trimester Down syndrome screening.⁷²

The NT is a fluid-filled space in the posterior fetal nuchal area. NT is defined as a collection of fluid under the skin behind the neck in fetuses between 11 and 14 weeks' gestation. This can be successfully measured by transabdominal ultrasound examination in approximately 95% of cases.

Studies conducted in women with increased risk of aneuploidy demonstrated an association between increased NT and chromosomal defects.⁷³⁻⁹⁰ Subsequent studies demonstrated that an NT thickness above the 95th percentile was present in approximately 80% of trisomy 21 fetuses.⁸⁹ As with other serum and ultrasound markers, the significance of the NT thickness depends on the a priori risk for a chromosomal abnormality. NT thickness increases with gestational age or crown-rump length. Figure 17-2 illustrates the NT between 11 and 14

weeks' gestation. These observations suggested that NT could be used as a screening test for Down syndrome by converting the deviation from the expected mean to a likelihood ratio.

NT combined with the maternal and gestational age to assess the risk for Down syndrome was studied in more than 100,000 pregnancies.⁹¹ NT was greater than the 95th percentile in more than 70% of fetuses with trisomy 21. The risk of Down syndrome was calculated by the maternal age and gestational age prevalence multiplied by the likelihood ratio. A cutoff of 1:300 was used. The studied sample included 326 fetuses with trisomy 21. Eighty-two percent of trisomy 21 fetuses were identified, with a false-positive rate of 8.3%.⁹¹ When a screen-positive rate of 5% was selected, the sensitivity was 77% (95% confidence interval [CI], 72% to 82%). Subsequent studies have demonstrated similar Down syndrome detection rates, between 70% and 75% (Table 17-9).

The screening paradigm using an ultrasound measurement to determine a likelihood ratio is reliable only if NT is measured in a standard fashion. Standards for NT measurements include the following:

1. The minimal crown length should be 45 mm and the maximal, 84 mm. The success rate for accomplishing a measurement for these gestational ages is between 98% and 100%. The success rate falls to 90% at 14 weeks and onward.⁹²
2. Either transabdominal or transvaginal scanning can be used, with about 95% of cases able to be imaged by the transabdominal route.⁹³
3. A true sagittal section of the fetus as for measuring the fetal crown-rump length must be obtained.
4. The magnification must be such that the fetus occupies at least three fourths of the image. The magnification should be increased so that each increment in the distance between calipers should only be 0.1 mm. Studies have demonstrated that ultrasound measurements can be accurate to the nearest 0.1 to 0.2 mm.⁹⁴
5. Care must be taken to clearly distinguish between the fetal skin and the amnion. At this gestational age, both structures appear as thin membranes. This can be accomplished by either waiting for spontaneous fetal movement away from the amniotic membrane or by bouncing the fetus off the amnion by asking the mother to cough or tap on her abdomen (Fig. 17-3).
6. The maximal thickness of this subcutaneous translucency between the skin and the soft tissue overlying the cervical spine should be measured by placing the calipers on the lines as illustrated in Figure 17-4.

Adapted from Nicolaides KH, Sebire NJ, Snijders RJM: *The 11-14 Week Scan*. New York, Parthenon, 1999.

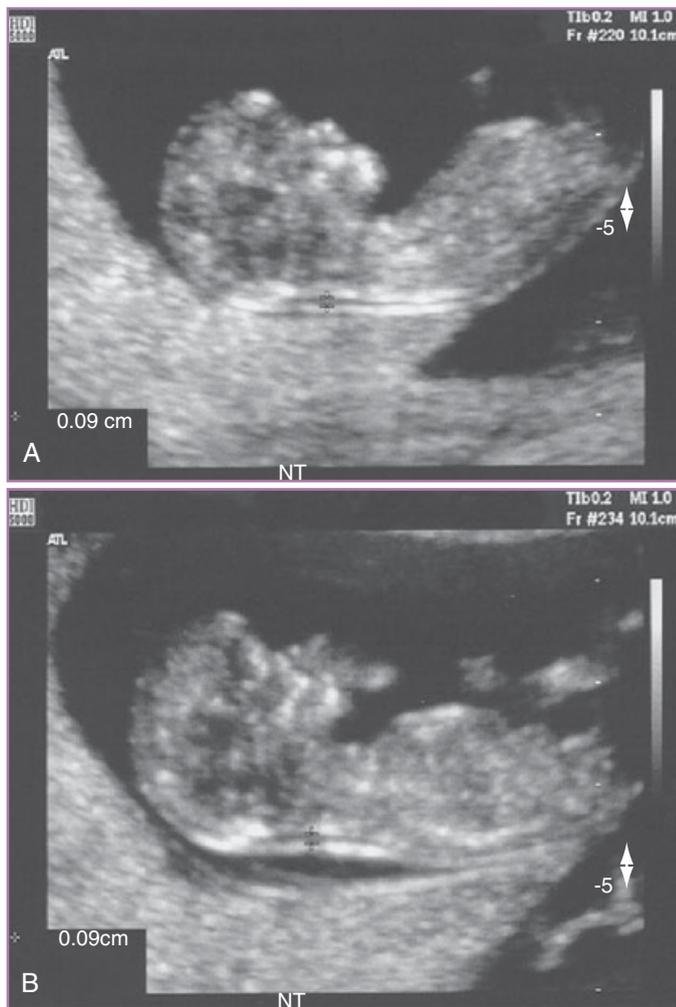

FIGURE 17-3 First-trimester nuchal translucency (NT) measurement. Clear distinction of the amnion as opposed to the skin edge is made by waiting for fetal movement. Measurement before the fetus moves (**A**) is less accurate than after fetal movement (**B**).

7. During the scan, these measurements should be taken and the maximum one recorded and used for Down syndrome risk calculation.
8. The NT should be measured with the fetal head in the neutral position. When the fetal neck is hyperextended, the measurement can be increased by 0.6 mm, and when the neck is flexed, the measurement can be decreased by 0.4 mm.⁹⁵
9. The umbilical cord may be found around the fetal neck in approximately 5% to 10% of cases, which may produce a falsely increased NT, adding about 0.8 mm to the measurement.⁹⁶ In such cases, the measurements of NT above and below the cord differ, and the smaller measurement is the most appropriate.

Even with these criteria, standardization of NT measurements remains difficult. Certification courses are available with continuous quality assessment to maintain proper technique. The ability to achieve a reliable measurement has been linked to the motivation of the sonographer. A study comparing the results obtained from hospitals where NT was clinically used compared with those where they were merely

FIGURE 17-4 Proper placement of the calipers for measuring the nuchal translucency. (From Nicolaides KH, Sebire NJ, Snijders RJM: *The 11-14 Week Scan*. New York, Parthenon, 1999.)

measured but were not acted on, reported that, in the interventional groups, successful measurement was achieved in 100% of cases, whereas the noninterventional centers were successful in only 85%.⁹⁷ In a recent prospective study,⁹⁸ the NT was measured by two to four operators in 200 pregnant women, demonstrating that after an initial measurement, a second one made by the same operator or another operator varied from the initial measurement by less than 0.5 and 0.6 mm, respectively, in 95% of cases. It is suggested that a large part of the variation between operators can be accounted for by placement of the calipers rather than generation of the appropriate image. Subsequent studies⁹⁹⁻¹⁰¹ have continued to report small interoperator differences.

Because NT values are incorporated into a standardized algorithm along with biochemical analytes, it is critical that these ultrasound measurements be performed and monitored appropriately. To accomplish this, certification and quality review programs have been developed to ensure that accurate and precise NT measurements are obtained. The Fetal Medicine Foundation of London was the first to offer formalized NT training and quality review. In the United States, the Nuchal Translucency Quality Review (NTQR) program was initiated in 2005. Both programs teach the mechanics of obtaining an NT measurement, have an image review process to ensure that the standard technique is used correctly, and perform ongoing epidemiologic monitoring of sonographer and sonologist performance. Two studies have evaluated the techniques used to ensure consistent NT results. Both confirmed that ongoing expert review of images is an inefficient and impractical approach. Epidemiologic monitoring in which individual operator's performance is compared with expected standards is preferable.^{101,102}

First-Trimester Biochemical Screening

Two serum analytes are useful for first-trimester screening. Pregnancy-associated plasma protein A has been demonstrated to have a mean value of 0.4 MoM in trisomy 21 pregnancies. The free β subunit of hCG is elevated in Down syndrome pregnancies, with a mean value of 1.8 MoM. Screening using pregnancy-associated plasma protein A (PAPP-A) alone identifies about 40% to 45% of trisomy 21 pregnancies, and free β -hCG identifies about 23%, both with a false-positive rate of 5%.¹⁰³⁻¹⁰⁵ Combining both free β -hCG and PAPP-A can identify 60% to 65% of trisomy 21 pregnancies, for a similar 5% false-positive rate.¹⁰⁶ This is a serum analyte detection rate similar to that seen with triple screening in the second trimester.

The total hCG molecule can also be used for first-trimester screening but has slightly less discrimination power than does the free β subunit,¹⁰⁷ especially at less than 11 weeks' gestation. Free β -hCG begins to increase in performance as a Down syndrome marker as early as 9 weeks' gestation, reaching values almost twice those in unaffected pregnancies by 13 weeks. Levels of total hCG begin to increase above those in unaffected gestations at 11 weeks.^{108,109} The impact of substituting total hCG for the free β subunit on overall Down syndrome screening remains uncertain. A recent meta-analysis showed that in younger patients (<35 years), detection of Down syndrome increased by 4, 5, 6, and 7 percentage points at 9, 10, 11, and 12 weeks, respectively, when free β was added to pregnancy-associated plasma protein A and nuchal translucency compared with 0, 0, 2, and 4 percentage points when intact human chorionic gonadotropin was added.¹¹⁰ In patients with advanced maternal age (>35), inclusion of free β -hCG reduced the false-positive rate by 2.5, 3.1, 3.8, and 4.4 percentage points compared with 0.1, 0.3, 1.0, and 2.2 percentage points for intact hCG at 9, 10, 11, and 12 weeks, respectively. Other authors have found less impact. Using samples from the FASTER study, Canick and coworkers¹¹¹ showed that at 12 weeks' gestation, the addition of free β -hCG to NT and PAPP-A added only 0.9% (–3.3 to 6.3) detection. However, at earlier gestational ages the impact of free β -hCG would be greater.

Combined First-Trimester Nuchal Translucency and Biochemistry Screening

Combining NT with serum analytes improves first-trimester Down syndrome detection rates. Table 17-10 summarizes the large international experience with first-trimester Down syndrome screening using free β -hCG, PAPP-A, and NT measurements. Overall, for a 5% false-positive rate, combined first-trimester risk assessment provides a Down syndrome detection rate of approximately 88% (95% CI, 84.0% to 89.4%). In women older than 35, 90% to 92% of trisomy 21 pregnancies can be identified with a 16% to 22% false-positive rate.^{20,112} First-trimester screening can also identify trisomy 18 pregnancies. Over 90% of such pregnancies are screen positive when combined biochemical and NT screening is used.¹¹²

When combining analytes, differences in gestational age-specific performance should be considered.¹¹³⁻¹¹⁵ At all gestational ages between 9 and 12 weeks, NT and PAPP-A are the most efficient markers. In combination, they are most efficient at 11 weeks, when free and total hCG are least efficient. In practice, screening is performed between 11 and 13 weeks of gestation.

Additional First-Trimester Markers of Down Syndrome

Biochemical Markers

ADAM 12 is the secreted form of a disintegrin and metalloprotease 12, a glycoprotein of the Meltrin family synthesized by the placenta and secreted throughout pregnancy. ADAM 12 has proteolytic function against insulin-like growth factor (IGF) binding proteins IGFBP-3 and IGFBP-5 and regulates the bioavailability and action of IGF-1 and -2.¹¹⁶ Studies have shown that first-trimester ADAM 12 levels are reduced in women carrying a Down syndrome pregnancy, and that the reduction is more pronounced in earlier gestation.¹¹⁷⁻¹¹⁹ Discrimination appears best at around 8 to 10 weeks, with an overall median MoM of 0.79 in Down syndrome pregnancies.¹¹⁹ Population modeling shows that a combination of ADAM 12 and PAPP-A measured at 8 to 9 weeks, combined with NT and free β -hCG measured at 12 weeks, could achieve a detection rate of 97% with a 5% false-positive rate, or 89% with a 1% false-positive rate.¹¹⁹

Ultrasound Markers

Nasal Bone. Similar to findings in the second trimester, investigators have suggested that assessment of the fetal nasal bone (NB) can be used in the first trimester to predict trisomy 21. This is based on the flat nasal bridge area, which is a well-described component of the Down syndrome phenotype, as well as on several histopathologic and radiographic studies demonstrating differences in the nasal bones of Down syndrome fetuses. Stempfle and colleagues¹²⁰ found that NB ossification was absent in one quarter of Down syndrome fetuses investigated between 15 and 40 weeks' gestation, compared with none of the controls. Similarly, Tuxen and colleagues¹²¹ evaluated Down syndrome fetuses between 14 and 25 weeks' gestational age by radiograph and pathologic study and found that the NB was absent in one third.

Sonek and colleagues⁴⁸ published the first large prospective trial of aneuploid risk evaluation using first-trimester ultrasound assessment of the fetal nasal bone. They determined that the fetal nasal bone could routinely be imaged and that its absence was associated with trisomy 21 (Fig. 17-5). The NB was absent in 73% of trisomy 21 fetuses compared with only 0.5% of euploid fetuses. They estimated that if NB assessment were combined with maternal age and NT measurement, 93% of Down syndrome cases would be detected at a false-positive rate of 5%, and 85% with a false-positive rate of 1%.

A recent review of the literature by Rosen and D'Alton¹²² evaluated 35,312 women having first-trimester ultrasound assessment for NB. In 33,314 cases (94.3%), the NB was successfully imaged. The sensitivity

TABLE 17-10 STUDIES OF DOWN SYNDROME DETECTION RATES IN FIRST-TRIMESTER SCREENING

Study (ref)	Pregnancies Screened	Down Syndrome Cases (Screen-Positive/Total)	Detection Rate
BUN (Wapner [112], 2003)	8,216	48/61	79%
FASTER (Malone [20], 2005)	38,033	100/117	86%
SURUSS (Wald [138], 2003)	47,053	84/101	83%
Nicolaides ([143], 2005)	75,821	321/325	93%
TOTAL	167,210	533/604	88.2%

Screening tests were for free β -subunit of human chorionic gonadotropin, pregnancy-associated plasma protein A, and nuchal translucency (with a 5% false-positive rate).

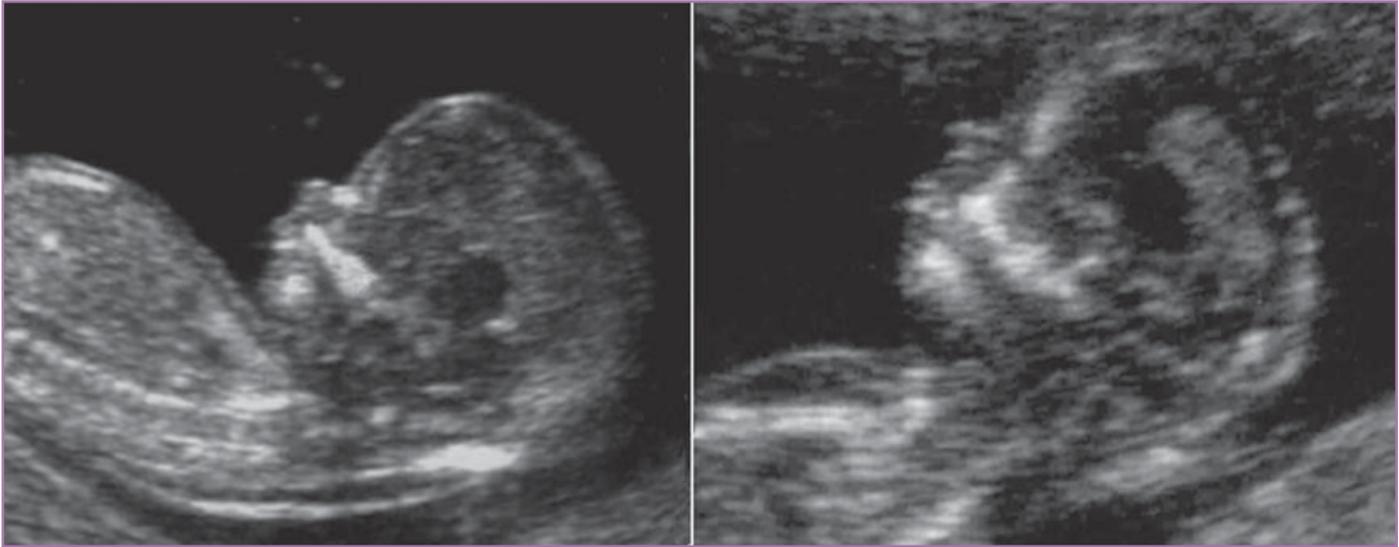

FIGURE 17-5 Ultrasound images of the fetal nasal bone (NB) in the first trimester. First-trimester ultrasound images of euploid (*left*) and trisomy 21 (*right*) fetuses demonstrate the presence of the nasal bone in the normal gestation and its absence in trisomy 21. Scanning techniques are those suggested by the Fetal-Medicine Foundation for assessing NB and include the following: (1) The image is magnified so that each movement of the calipers causes a 0.1-mm incremental change. (2) A midsagittal view of the fetal profile is obtained. (3) The angle between the ultrasound transducer and a line passing from the fetal forehead to the chin is 45 degrees. (4) When the NB is present, three echogenic lines should be visible. The NB and overlying skin look like an equal sign. In the same view, the skin over the nasal tip should be visible. If both the nasal tip and skin are present, and the NB echo cannot be visualized or is less echogenic than the skin, the NB is considered absent. (Fetal-Medicine Foundation, available at <http://www.fetalmedicinefoundation.com/nasal.htm>.)

of NB alone for detecting trisomy 21 was 65% with a false-positive rate of 0.8%. The positive predictive value of the screen was 54%, meaning that approximately 1 in 2 fetuses with an absent NB had trisomy 21. If the NB was absent, the likelihood that a fetus had trisomy 21 was increased 87-fold. The negative likelihood ratio with a normal NB was 0.35 (95% CI, 0.32 to 0.39).

As experience with NB has increased, relationships between absent NB, fetal crown-rump length (i.e., gestational age), NT, and ethnicity have been established. The current data demonstrate that in euploid pregnancies, NB absence occurs more frequently with increasing NT. In a series of 5851 high-risk patients containing 333 trisomy 21 fetuses, absence of the NB had a likelihood ratio of 37.1 when the NT was less than the 95th percentile, and this was reduced to 13.4 when the NT was 4 or greater.¹²³ The same study showed that the NB was more likely to be absent at earlier gestational ages. For example, in euploid fetuses with a crown-rump length between 45 and 54 mm, the NB was absent in 4.7% of cases. At a crown-rump length between 75 and 84 mm, the NB was absent in only 1.0% of cases. Prefumo and colleagues¹²⁴ found that NB hypoplasia was more common in the euploid fetuses of women of African descent when compared with either Asian or white populations (odds ratio, 2.3). Cicero and colleagues¹²⁵ also found an increased incidence of absent fetal NB in the first trimester in women of Afro-Caribbean and southern Asian descent. The NB was absent in 2.5%, 9.0%, and 5.0% of white, Afro-Caribbean, and southern Asian populations, respectively. Likelihood ratios for trisomy 21 with absent NB were 31.3, 8.8, and 14.2, respectively, in these three populations.

NB status is independent of serum biochemistry, allowing NB assessment to be combined with measurements of NT and maternal serum markers to increase first-trimester screening performance.¹²⁶ In a retrospective case-control study of a high-risk population with a median maternal age of more than 38 years assessed by NT, NB, and biochemistry, it was estimated that 97% of Down syndrome cases

would be detected at a false-positive rate of 5%.¹²⁷ For a false-positive rate of 0.5%, the detection rate would be 90.5%. Although these data are promising, detection rates using this combined screen would be expected to be significantly lower in an unselected population using a similar 5% false-positive rate. In addition, appropriate imaging of the NB appears to be technologically more difficult than measurement of the NT, making its use in a primary screening program less attractive.¹²⁸

Tricuspid Regurgitation. Another potential ultrasound marker is tricuspid regurgitation determined by pulsed wave Doppler ultrasonography.^{129,130} This finding is present in around 8% of normal fetuses and 65% of those with trisomy 21. Combining tricuspid regurgitation with NT and PAPP-A would be expected to achieve a detection rate of 95% with a 5% false-positive rate, or 90% with a 2% false-positive rate.¹³¹

Ductus Venosus Wave Form. A third potential marker is abnormal blood flow through the ductus venosus. Studies have shown that pulsation of the ductus venosus gives detection rates of 65% to 75% with a 4% to 5% false-positive rate,¹³² and the rate increased to 75% to 80% when NT was added. When serum biochemical markers measured at 10 weeks were also added, the modeled detection rate increased to 92% at a 5% false-positive rate, or 84% at a 1% false-positive rate.¹³³

Impact of Spontaneous Miscarriages on First-Trimester Screening

A potential disadvantage of earlier screening is that chromosomally abnormal pregnancies that are destined to miscarry will be identified. The impact of this can be evaluated because 69% of trisomy 21 fetuses living in the first trimester and 76% of those alive in the second trimester will be born alive.⁴ Using this information, Dunstan and Nix¹³⁴

calculated that a detection rate of 80% in the first trimester is approximately equivalent to a second-trimester sensitivity of 75%, suggesting that when early spontaneous losses of trisomy 21 pregnancies are considered, first-trimester screening is superior to that presently available in the second trimester.

First-trimester screening would be less desirable if screen-positive pregnancies or those with enlarged NTs were preferentially lost. In a study of 108 fetuses with trisomy 21 diagnosed in the first trimester because of increased NT, Hyett and colleagues found that six patients elected to continue the pregnancy.¹³⁵ In five of the six fetuses the translucency resolved, and at the second-trimester scan the nuchal fold thickness was normal. All six of these trisomy 21 fetuses were born alive. Wapner and colleagues¹¹² calculated that greater than 80% of screen-positive trisomy 21 pregnancies would be born alive.

Other Approaches to Down Syndrome Screening: Combining First- and Second-Trimester Screening Tests

Screening performance may be improved by combining analytes performed at different gestational ages.^{136,137} These approaches include the following.

Integrated Aneuploidy Screening (Noninformative Sequential). Wald and colleagues¹³⁷ described a protocol for screening based on tests performed during both the first (NT and PAPP-A) and second trimesters (quad screen). A single risk estimate is calculated in the second trimester using all six of the measured analytes. Integrated screening has a detection rate of approximately 95% with a 5% false-positive rate.^{20,137} Approximately 85% of affected pregnancies would be detected with a false-positive rate of only 0.9%.^{137,138} Although this screening approach is quite sensitive and specific, withholding the risk estimate until the second trimester precludes earlier prenatal diagnosis by chorionic villus sampling (CVS) and is not an acceptable approach for many women.¹³⁹

If NT scanning is not available, an integrated serum screen may be performed (PAPP-A in the first trimester and a quad screen in the second trimester). This approach has a detection rate of 86% to 90% at a 5% false-positive rate.^{20,137}

Sequential Testing. In an attempt to maximize screening performance by combining first- and second-trimester analytes yet retain the benefit of first-trimester diagnosis, various methods of sequential screening have been proposed. In these approaches, first-trimester risk results are calculated and used for clinical management, with second-trimester testing performed in selected cases.

Three approaches to sequential risk assessment are presently available. In independent sequential testing, a first-trimester combined risk is calculated with a 1:270 screen-positive cutoff. Decisions on invasive testing are made on the basis of these results. In the second trimester, a quad screen is performed and calculated independent of the first-trimester results. This approach provides detection rates greater than 95%,^{20,136} but it has an unacceptably high false-positive rate of greater than 10% because independent calculation of the quad screen risk does not take into consideration the reduced second-trimester prevalence of Down syndrome pregnancies after first-trimester prenatal diagnosis.

Stepwise sequential testing reduces the high false-positive rate of independent sequential testing and offers the highest risk patients the option of first trimester invasive testing by using a high first-trimester risk cutoff and calculating the second-trimester risk by integrating information from both trimesters.¹⁴⁰ For example, using a 1:65 cutoff in the first trimester identifies 70% of affected pregnancies with only

a 1% false-positive rate. If all screen-negative patients proceed to second-trimester screening, an overall detection rate of 95% can be obtained with a 5% false-positive rate. Although this approach has excellent performance, with a high proportion of affected pregnancies identified in the first trimester, it is logistically demanding.

Contingent sequential screening is similar to stepwise sequential screening, but patients with a very low first-trimester combined risk do not have second-trimester analysis performed. Using an approach in which patients with a first-trimester risk of 1:1300 or less complete screening in the first trimester, only 15% to 20% of patients have to return for second-trimester analysis.^{141,142} Contingent sequential screening has a detection rate of 92% to 94% for a 5% screen positive rate.¹⁴⁰

Nasal Bone Contingency Screening. Nasal bone assessment is technically more difficult to perform than NT, which may limit availability. To address this Nicolaides and colleagues¹⁴³ proposed a two-stage screen, reserving NB assessment for patients at intermediate risk after the combined first-trimester screen is complete. In this model, patients evaluated by NT and serum markers with a risk of 1 in 100 or greater would be offered CVS, and those with a risk of less than 1:1000 would be deemed to have such a low risk that no further testing is offered. Those with a risk between 1:101 and 1:1000 would have NB evaluation. In initial studies, performance of this two-stage approach was similar to using NB assessment as part of the initial screen. The two-stage approach would have a significant advantage because only about 15% of pregnancies would require NB evaluation, which could be performed in centers that have developed special expertise in this technique.

Can Maternal Age Be Eliminated as an Indication for Invasive Prenatal Diagnosis?

Maternal age of 35 or older has been a standard indication for invasive testing for more than 35 years. When it was initially suggested, approximately 5% of births were to women older than 35 years, as were 30% of trisomy 21 gestations. Presently, almost three times as many women giving birth are older than 35, and this group contains about 50% of trisomy 21 conceptions. For every invasive procedure done with maternal age as the only indication, the odds of being affected are approximately 1:100.²⁰ As screening has improved, the importance of maternal age as a single indication for testing has been reevaluated.

In women aged 35 years and older, 87% of Down syndrome pregnancies and 25% of unaffected pregnancies will be triple-screen positive at a cutoff of 1:250.¹⁸ The incidence of Down syndrome in this age group is approximately 1:100. Table 17-11 demonstrates that performing an amniocentesis on screen-negative women (risk <1:270) aged 35 years or older would lead to the loss of three normal pregnancies from procedure-induced complications for every Down syndrome pregnancy identified. First-trimester screening has greater than a 90% sensitivity with a 15% false-positive rate in women aged 35 years or older.¹¹² Using the approach illustrated in Table 17-1, it can be calculated that almost four normal pregnancies will be lost for each Down syndrome pregnancy identified.

Screening the entire population of pregnant women regardless of age provides the most effective use of resources. Presently, 14.2% of women older than 35 are offered invasive testing, as are about 5% of women under age 35 who are screen positive, making greater than 18% of pregnant women eligible for testing. If second-trimester screening were used for all patients regardless of age and only screen-positive patients were offered invasive testing, the number of procedures would

TABLE 17-11 COMPARISON OF SCREENING APPROACHES FOR WOMEN AGED 35 YEARS AND OLDER*

	Invasive Procedures for All Women ≥ 35 Years (<i>N</i> = 10,000)	First-Trimester Screening for All Women ≥ 35 Years (<i>N</i> = 10,000)	Second-Trimester Screening for All Women ≥ 35 Years (<i>N</i> = 10,000)
Down syndrome pregnancies	100	100.0	100
Down syndrome detected	100	90.0	87
Down syndrome missed	0	10.0	13
Invasive procedures performed	10,000	1500.0	2500
Pregnancies lost due to procedure	50	7.5	13
Pregnancies lost to diagnose one trisomy 21 pregnancy in screen-negative women	N/A	4.3	3

Based on population of 10,000 pregnant women ≥ 35 years old

*Assumes one procedure-related loss for every 200 invasive procedures performed. First-trimester screening: sensitivity, 90%; false-positive rate, 16%. Second-trimester screening: sensitivity, 87%; false-positive rate, 25%.

be reduced to only 6.4% of the pregnant population. If first-trimester screening is used, the number of eligible patients is only 3.8%.

Age-related autosomal and sex chromosome trisomies other than trisomy 21 would potentially be missed if invasive testing for age were abandoned. Presently, both second- and first-trimester screening for trisomy 18 are available and efficient. Wapner¹¹² showed a 100% detection rate using first-trimester combined screening in women aged 35 years and older. About 50% of the sex chromosome abnormalities will be screen positive in the second trimester in women aged 35 years and older.¹⁴⁴

The American College of Obstetricians and Gynecologists has recommended that maternal age of 35 years should no longer be used as a cutoff to determine who is offered screening and who is offered invasive testing.¹⁴⁵ This approach has to be preceded by explicit patient counseling to explain the risks and advantages of both options.

Maternal Serum α -Fetoprotein Screening for Neural Tube and Other Structural Defects

Physiology

Maternal serum screening for neural tube defects was the initial foray into pregnancy screening for congenital anomalies. Because 95% of neural tube defects occurred in families without a history of a previously affected offspring, prenatal detection of these defects was largely fortuitous before 1980. Screening is based on elevated levels of MSAFP, which occurs in anencephaly and spina bifida.

AFP is a fetal-specific globin similar to albumin in molecular weight and charge but with a different primary structure and distinct antigenic properties. The gene for AFP is located on chromosome 4q. AFP is synthesized early in gestation by the yolk sac and subsequently by the fetal gastrointestinal tract and liver. The level of fetal plasma AFP peaks between 10 and 13 weeks of gestation and declines exponentially from 14 to 32 weeks and then more sharply until term. The exponential fall in fetal plasma AFP is most likely the result of the dilution effect of increasing fetal blood volume, as well as of a decline in the amounts synthesized by the fetus, as fetal albumin is increasingly produced as the primary oncotic protein in fetal blood.

AFP enters the fetal urine and is excreted into the amniotic fluid. Peak levels of amniotic fluid AFP are reached between 12 and 14 weeks' gestation, declining between 10% and 15% per week during the second trimester, and levels are almost undetectable at term.

Maternal serum AFP levels rise above nonpregnant levels as early as the 7th week of gestation. MSAFP levels are significantly lower than AFAP levels but progressively increase during gestation until 28 and 32 weeks, when they peak. This paradoxical rise in MSAFP when amniotic fluid and serum levels are decreasing is believed to be accounted for by increasing placental mass and progressive permeability to fetal plasma proteins. Thus the amount of AFP detected in maternal serum is increased in the presence of multiple placentas (i.e., in multifetal gestation).

In normal pregnancies, transport of AFAP into maternal serum contributes little to the MSAFP compartment. The significant difference in fetal serum AFP compared with that in the amniotic fluid and maternal serum serves as the basis for using this fetal protein to screen for fetal lesions such as neural tube defects, which potentially leak high levels of AFP into the amniotic fluid and, hence, the maternal serum. The concentration gradient between fetal plasma and AFAP is about 150 to 200:1. The concentration differential between fetal and maternal serum is about 50,000:1. Thus, the presence of a small volume of fetal blood or serum in the amniotic fluid can raise the AFP level significantly.

Screening

MSAFP screening for neural tube defects is ideally performed between 16 and 18 weeks of pregnancy. Cutoffs between 2.0 and 2.5 MoM yield detection rates of almost 100% for anencephaly and 85% to 92% for open spina bifida, with a false-positive rate between 2% and 5%. As with all screening modalities, the positive predictive value for an individual patient depends on the population risk. Table 17-12 demonstrates the odds of an individual woman having a child with a neural tube defect, based on the degree of elevation of her serum AFP and on her a priori risk of having a child with a neural tube defect. Because MSAFP values rise between 16% and 18% per week during the second trimester, use of gestational age-corrected MSAFP MoM for comparison between laboratories is recommended. The median is preferred to the mean because it is less influenced by occasional outliers.

MSAFP is performed using an enzyme immunoassay. All laboratories performing this test should have their own normal ranges and a mechanism for continuous quality control assessment. The College of American Pathologists operates a nationwide external proficiency test

TABLE 17-12 ODDS OF HAVING A FETUS WITH OPEN SPINA BIFIDA BASED ON SERUM α -FETOPROTEIN (AFP) LEVEL AT 16 TO 18 WEEKS' GESTATION

Rights were not granted to include this table in electronic media. Please refer to the printed publication.

From Milunsky A (ed): *Genetic Disorders and the Fetus: Diagnosis, Prevention, and Treatment*, 3rd ed. Baltimore, Johns Hopkins University Press, 1992, p 656.

that is an essential element in population-based screening programs. Most laboratories presently use an upper-limit cutoff of 2.0 MoM. Some laboratories use a somewhat higher cutoff, up to 2.5 MoM. The choice of a specific cutoff is a balance between the anticipated detection rate and the false-positive rate. Because ultrasound screening for the evaluation of elevated numbers of neural tube defects has replaced the need for amniocentesis in many cases, a trend toward choosing a lower AFP threshold to gain a higher detection rate with slightly more false-positives has occurred.

Because of interlaboratory variation and interassay variation, many clinics repeat an MSAFP that initially falls between 2 and 3 MoM. If the repeat value is normal, no further evaluation is required. However, the variance of MSAFP by gestational week related to assay precision or individual fluctuation yields no practical value in performing a repeat MSAFP on either the same or a second sample taken up to 1 month later. Most centers thus choose to obtain an ultrasound after any elevated MSAFP level.

A number of factors influence the interpretation of an MSAFP value. The most important factor for efficient MSAFP screening is the accuracy of the gestational age determination. Because there is an exponential rise in MSAFP over the recommended screening period of 15 to 20 weeks, a variation of 2 weeks between the actual gestational age and that used for MSAFP interpretation can be misleading. A potential confounding factor is that fetuses with spina bifida may have biparietal diameters that are reduced by approximately 2 weeks. Consequently, femur length and biparietal diameter should be measured to confirm gestational age for AFP screening. A first-trimester ultrasound is the preferable means of documenting gestational age; results of this ultrasound can be submitted to the laboratory in place of the last menstrual period.

Maternal weight affects the MSAFP concentration. The heavier the woman, the lower the MSAFP value as a result of dilution in the larger blood volume. Adjusting MSAFP values for maternal weight increases the detection rate for open spina bifida. Dividing the observed MoM by the expected MoM for a given weight enables adjustment for differences in weight. Correction for weights greater than 250 pounds significantly increases the rate of elevated MSAFP results, suggesting overcorrection. Therefore, some laboratories recommend linear cor-

TABLE 17-13 FETAL ANOMALIES IDENTIFIED BY AN ELEVATED AMNIOTIC FLUID α -FETOPROTEIN, ENHANCED BY ACETYLCHOLINESTERASE (AChE)

Positive AChE	Negative AChE
Anencephaly	Aneuploidy
Open spina bifida	Intrauterine fetal demise
Encephalocele	Obstructive uropathy

Cloacal extrophy	
Epidermolysis bullosa	
Aplasia cutis congenita	
Normal gestation	

rection of MSAFP only up to a weight of 200 pounds. Presently, weight correction of MSAFP reports is routinely performed.

Maternal ethnicity may also alter the interpretation of an MSAFP level, because black women have a 10% to 15% higher MSAFP than nonblacks.¹⁴⁶ This is important because the incidence of neural tube defects in blacks is lower. Other ethnic groups also have slightly different MSAFP levels, but they do not vary sufficiently to warrant corrections. Pregnant women with insulin-dependent diabetes mellitus have MSAFP values that are significantly lower than nondiabetic women in the second trimester,^{147,148} which requires adjustments in the interpretation. This is critical because there is up to a 10-fold higher frequency of neural tube defects in the offspring of these patients. MSAFP also must be altered in multiple gestations, and this adjustment is discussed later.

There may be a genetic component to raised MSAFP. Women with an elevated MSAFP in one pregnancy appear to have an increased risk of elevated values in subsequent gestations. A false-positive AFP has been seen in multiple members of some families.^{149,150}

Evaluation

Once an elevated MSAFP has been detected, the next step is ultrasound evaluation to confirm the gestational age, rule out twin gestation, identify other causes of elevated MSAFP such as fetal demise and oligohydramnios, and identify other structural defects that can cause elevated MSAFP, such as omphalocele, gastroschisis, and duodenal atresia (Table 17-13). The most important aspect of this ultrasound is confirmation of gestational age. In up to 50% of cases, incorrect dating is identified, and adjustment of the initial value resolves the issue. If the elevated MSAFP remains unexplained, further testing by either amniocentesis or targeted ultrasound is required.

Until recently, the standard diagnostic test for an elevated MSAFP was amniocentesis with evaluation of AFAP and acetylcholinesterase (AChE) levels. AFAP determination has nearly a 100% detection rate for anencephaly and a 96% to 99% detection rate for open spina bifida, with a false-positive rate of 0.7% to 1.0%.¹⁴⁹ The accuracy of amniotic fluid determination is enhanced by the addition of AChE. As opposed to AFP, which is a fetal serum protein, AChE is predominantly neurologically derived, giving it additional specificity for nervous system lesions.

The most common assay for AChE is a polyacrylamide gel electrophoresis, in which AChE can be distinguished from nonspecific cholinesterases on the basis of mobility. A combined use of AFP and AChE together appears to be the most sensitive and specific in determining neural tube defects.

As with AFP, there are a number of potential confounders with AChE. When fetal blood is present in the amniotic fluid, interpretation of AChE might be complicated and inaccurate. In addition, false-positive AChE results have been clearly documented in normal pregnancies before 15 weeks' gestation and may be seen in up to one third of cases under 12 weeks' gestation.

In experienced hands, targeted ultrasound for elevated MSAFP has been found to be as sensitive and specific as amniotic fluid AFP and AChE levels.^{151,152} Although ultrasound as a primary screening tool for spina bifida may identify only 60% to 80% of neural tube defects, targeted sonographic evaluation in high-risk cases is remarkably accurate. Sensitivities have been reported between 97% and 100%, with 100% specificity.

Ultrasound diagnosis of meningocele is frequently based on the finding of a cystic mass protruding from the dorsal vertebral bodies without skin covering. This is ideally seen in the transverse plane as a wide separation of the lateral processes of the lamina. In the coronal plane, widening of the parallel lines of the normal spine can be seen. It should be cautioned that occasionally coronal and sagittal views can be misleading, and the present standard for spina bifida screening by ultrasound is an image of transverse planes of individual vertebrae. Some cases of meningocele do not have a cystic structure and are identified only by a subtle widening of the posterior processes.

Indirect sonographic signs of meningocele have been found to be as important as visualization of the spinal lesion and are somewhat easier to image. These include ventriculomegaly, microcephaly, frontal bone scalloping (lemon sign), and obliteration of the cisterna magna with either an "absent" cerebellum or abnormal anterior curvature of the cerebellar hemispheres (banana sign) (Fig. 17-6).¹⁵³ These findings are seen in more than 95% of cases of neural tube defects imaged in the middle of the second trimester. The banana sign and lemon sign may not be present after 22 to 24 weeks' gestation. Anencephaly should routinely be identified by ultrasound as early as 11 or 12 weeks' gestation but should be reconfirmed by a scan at around 13 weeks because ossification of the skull in some cases may not be completed until that time (see Chapter 18).

Presently, the best approach to evaluate an elevated MSAFP is a combination of ultrasound imaging and amniocentesis. When ultrasound expertise is available and optimal images can be obtained of both the spine and the central nervous system, amniocentesis can be avoided. If ultrasound expertise or high-resolution equipment is not available or fetal position or maternal body habitus prevents optimal fetal visualization, further evaluation by amniocentesis should be offered.

Other Fetal Causes of Elevated Maternal Serum α -Fetoprotein and Amniotic Fluid α -Fetoprotein

The greater the elevation in both MSAFP and AFAFP is, the greater the risk of fetal abnormalities. Crandall and Chua¹⁵⁴ analyzed 1086 amniotic fluid samples with elevated AFP levels and found abnormalities associated with AFAFP elevations of 2.0 to 4.9, 5.0 to 9.9, and more than 10.0 MoM in 25%, 88.1%, and 97.7% of pregnancies, respectively.

In addition to neural tube defects, other lesions leaking fetal serum into the amniotic fluid can cause elevations of both MSAFP and AFAFP. These include fetal abdominal wall defects such as omphalocele, gastroschisis, or extrophy of the bladder; weeping skin lesions such as epidermolysis bullosa or aplasia cutis; and some cases of sacrococcygeal teratoma and fetal urinary tract obstruction. Table 17-13 lists other fetal conditions associated with elevated MSAFP with and without elevations of AChE.

Because AFP is produced in the fetal gastrointestinal tract and liver, reduced intestinal AFP clearance with regurgitation of intestinal contents has been associated with elevated MSAFP and AFAFP. Reflux of lung fluid can also cause elevated levels. This occurs with duodenal atresia, annular pancreas, intestinal atresia, pharyngeal teratoma, and congenital cystic adenomatoid malformation of the lung.

Exceedingly high MSAFP and AFAFP levels are associated with the rare condition of congenital fetal nephrosis.¹⁵⁵⁻¹⁵⁷ The elevated AFP is a result of altered filtering capabilities of the fetal glomeruli. Congenital nephrosis is an autosomal recessive disorder, with the most common mutations mapping to chromosome 19q, the nephrin gene (*NPHS1*). In the Finnish population, 36 mutations have been located within the gene, with two, Finmajor and Finminor, accounting for 94% of cases.¹⁵⁸ Lenkkeri and colleagues¹⁵⁹ reported that 20% (7 of 35) of non-Finnish cases have no detectable mutation along the nephrin gene sequence. Therefore, non-Finnish cases may have mutations in other sequences or on other chromosomes.^{158,159}

The condition is lethal in infancy if untreated, with an average lifespan of 7 months.¹⁶⁰ More aggressive treatments have been attempted, including dialysis and bilateral nephrectomy with subsequent renal transplant, resulting in some survivors. Unfortunately, a transplant cannot be performed until 2 years of age, on average.¹⁶¹

In Finland, where the disorder occurs in 1 of 2600 to 8000 pregnancies, screening programs using mid-trimester MSAFP have been used successfully to identify this condition.¹⁵⁰⁻¹⁶² In other areas of the world, when markedly elevated AFP levels are found without ultrasound-detected anomalies, congenital nephrosis must be considered.

The diagnosis is strongly suggested with the finding of an elevated MSAFP (usually greater than 5 to 6 MoM) followed by an extremely elevated (frequently more than 10 MoM) level in the amniotic fluid. Although one case of congenital nephrosis with a low AFP level (<2.5) has been described,¹⁵⁰ this is extremely unusual and probably was related to too early testing because the degree of elevation of AFAFP increases with gestational age, proportionate to the contribution that fetal urine makes to the amniotic fluid. Consistent with this is a case report in which serial amniocenteses showed a rapid increase in AFP levels between 14 and 18 weeks.¹⁶³ Other amniotic fluid markers of congenital proteinuria such as transferrin and albumin have been examined to help make a more definitive diagnosis, but the sensitivity of these substances is not sufficient.^{164,165}

Confirming congenital nephrosis in utero is confounded by the lack of ultrasound findings. Although echogenic and slightly enlarged kidneys have been described, in most cases the kidneys appear normal, the amount of amniotic fluid is normal, and placentomegaly, which may occur, does not appear until late in gestation. If no ultrasound anomalies are seen, the karyotype is normal, and elevated AFAFP is confirmed, congenital nephrosis must be suspected, but a normal gestation (false-positive) is possible.¹⁵⁰ In these cases, in utero fetal kidney biopsy provides a means to examine the renal cortex, glomerular basement membrane structure, and podocyte morphology,¹⁶⁶ because the pathologic characteristics are present in the second trimester.¹⁶⁷ Electron microscopic evaluation of the biopsy sample is required to visualize altered podocyte morphology diagnostic of this condition.

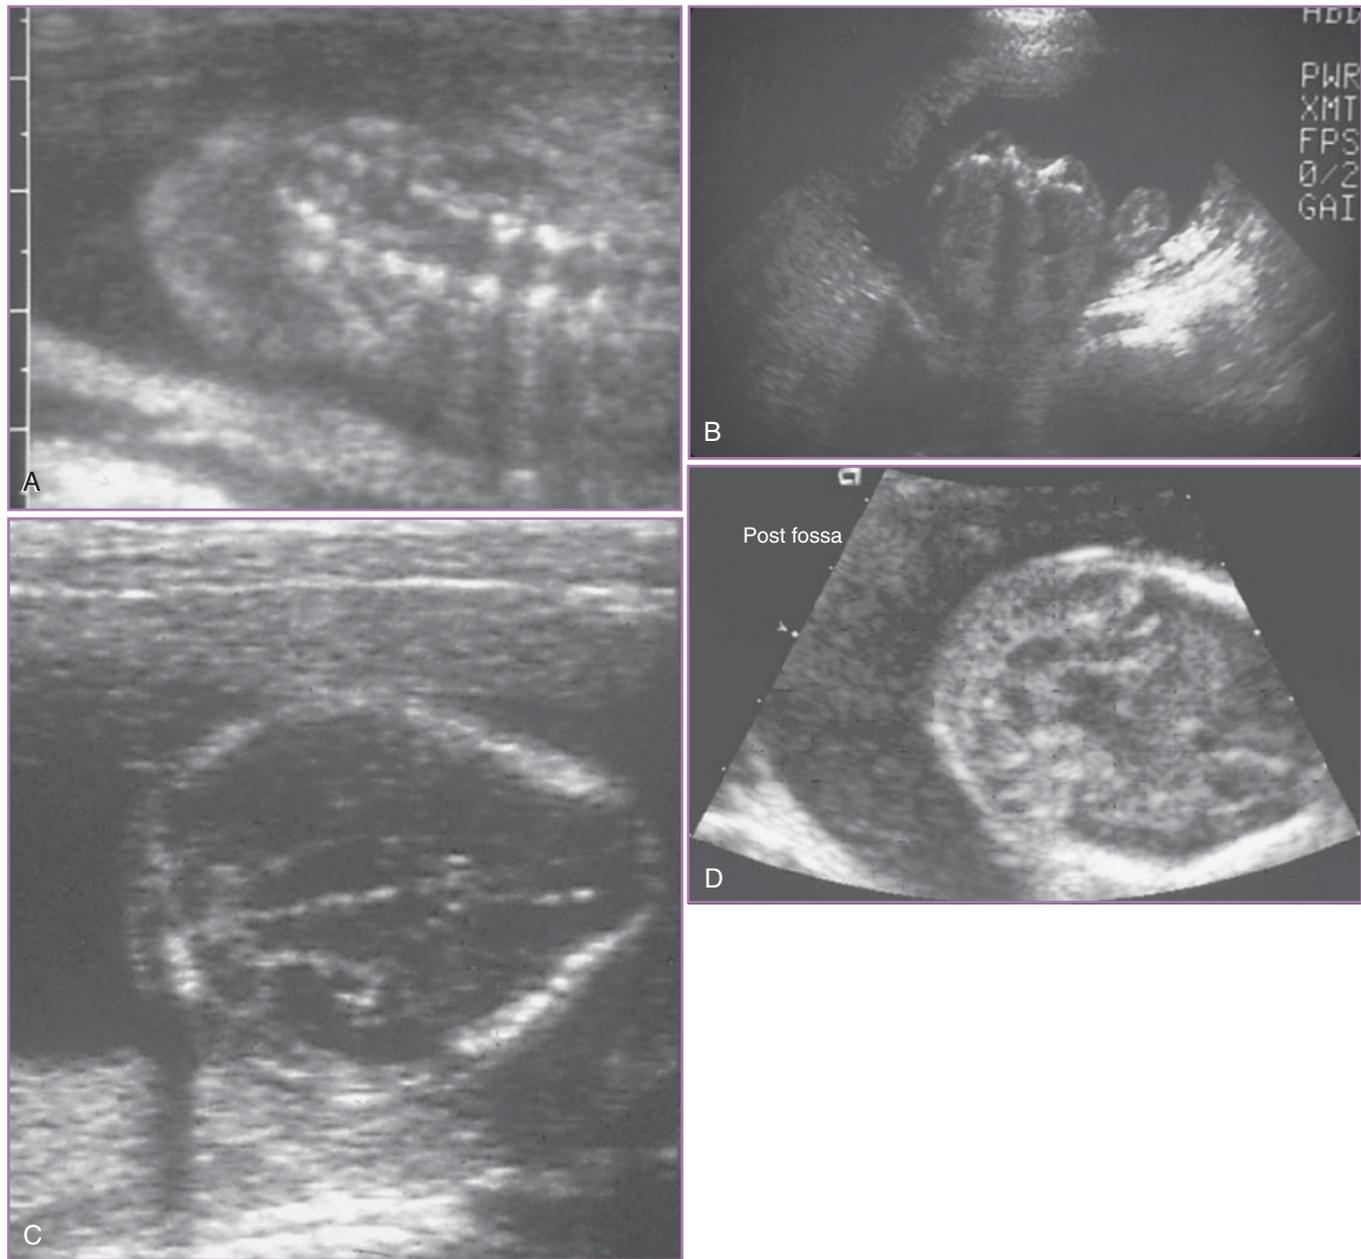

FIGURE 17-6 Ultrasound of a fetus with a neural tube defect. Sagittal (A) and transverse (B) views of the spine. Transverse view of the skull, with scalloping of the frontal bones, the lemon sign (C), and herniation of the cerebellum, the banana sign (D).

Ultrasound Screening for Fetal Congenital Anomalies

The value of routine second-trimester ultrasound as a screening test is unknown. The Routine Antenatal Diagnostic Imaging Ultrasound Study⁶¹ was a randomized controlled trial to test whether routine ultrasound during pregnancy would reduce perinatal morbidity and mortality. This study concluded that routine ultrasound did not alter perinatal outcomes and therefore should not be routinely performed on all women. Limitations to this study are numerous; for example,

nearly 70% of the control group received an ultrasound examination at some point in their pregnancy, more congenital anomalies were detected in the screened group, but the overall rate of detected anomalies was only 35%, and experienced referral centers demonstrated a 23% higher detection rate (35% versus 13%) than nontertiary centers.

At present, the American College of Obstetricians and Gynecologists does not recommend ultrasound as a routine part of prenatal care,¹⁶⁸ but other authors argue that denial of access to universal ultrasound with its current abilities may be unethical.¹⁶⁹ Whether routine or targeted, anatomic screening should be done by experienced centers to increase detection of anomalies and limit false-positive results.¹⁷⁰

Increased Nuchal Translucency and Normal Karyotype

An increased NT has been described with certain nonchromosomal fetal disorders.^{79,80,82-84,86,171-183} In some cases, this may be coincidental. However, in others, such as cardiac defects, diaphragmatic hernias, and fetal skeletal and neurologic abnormalities, a true relationship appears likely. Additionally, an association between increased NT and poor perinatal outcomes, including miscarriage and perinatal death, exists.¹⁸⁴ This information is important in counseling patients who have an elevated NT and a normal karyotype.

In approximately 90% of explored cases in which the NT is greater than the 99th percentile but below 4.5 mm, a healthy infant can be expected. With NTs between 4.5 and 6.4 mm, about 80% of births will result in a healthy newborn. Measurements greater than 6.5 mm have only a 45% incidence of normal results.¹⁸⁴

The association of increased NT with fetal cardiac and great vessel defects is significant (Table 17-14).¹⁸⁵⁻¹⁹⁴ A large series from the Fetal Medicine Foundation Project showed that the prevalence of major cardiovascular abnormalities increases with increasing NT.¹⁸⁴ With an NT measurement between the 95th percentile and 3.4 mm, the frequency of heart and great vessel anomalies was 4 per 1000. When the NT was between 3.5 and 4.5 mm, the incidence increased to 27 per 1000, and when the NT was greater than 6.5 mm, the frequency was 170 per 1000. In a similar, but retrospective, study of approximately 30,000 chromosomally normal singleton pregnancies, the prevalence of cardiac defects increased from 0.8 per 1000 in individuals with an NT below the 95th percentile, to almost 64 per 1000 when the NT was above the 99th percentile.¹⁹⁵ Alternatively, approximately 40% of all fetuses with cardiac defects will have an NT above the 99th percentile, and 66% will be above the 95th percentile.¹⁹⁵

This information strongly suggests that the presence of an NT above the 99th percentile, and perhaps above the 95th, should be followed with a fetal echocardiogram. In this group of individuals, the frequency of major cardiac defects would be anticipated to be about 2%, which is higher than the threshold risk for pregnancies presently receiving echocardiograms, such as those with a mother affected with diabetes mellitus or a family history of an affected offspring. If a cutoff at the 95th percentile is used and 5% of all pregnancies would be offered testing, resources to accomplish this may be insufficient. However, if a 99th percentile NT measurement is used, only about 1%

From Hyett J, Perdu M, Sharland G, et al: Using fetal nuchal translucency to screen for major congenital cardiac defects at 10-14 weeks of gestation: Population based cohort study. *BMJ* 318:81, 1999.

of patients would require echocardiograms, with an incidence of positive findings of approximately 6%. Recent improvements in the resolution of ultrasound and increasing experience with first-trimester cardiac scanning suggest that major cardiac defects could be identified by the end of the first trimester.^{186,196-199} This means that patients identified with an enlarged NT who presently have their echocardiograms performed at 20 weeks may not need to delay testing.

Fetal anomalies occur frequently enough after an elevated NT that follow-up scans in the second trimester are recommended. These anomalies include diaphragmatic hernias, severe skeletal defects, and omphaloceles.¹⁸⁴ Table 17-15 lists the anomalies with a possible relationship with an increased NT.

The most difficult counseling issue involves patients with an elevated NT, a normal karyotype, and a normal second-trimester ultrasound. In a certain percentage of these cases, genetic syndromes not identifiable by ultrasound may be present, including Noonan syndrome, as well as others listed in Table 17-15. Recently, there has also been some speculation of an increased frequency of unexplained developmental delay in some of these infants (E. Pergament, personal communication, 2002). Presently, there is insufficient information to counsel patients specifically; however, in most cases, patients can be reassured that this frequency appears to be less than 10%.²⁰⁰

*Depends on ethnic group: 70% for southern European descent, 90% for northern European descent. Hb, hemoglobin; MCV, mean corpuscular volume.

Screening for Gene Mutations That Lead to Fetal Disease

Certain populations have an increased frequency of specific, identifiable, disease-causing gene mutations. This may occur because the population has remained relatively isolated, because many individuals in the population are descended from a few common relatives having a specific mutation (founder effect), or because the carrier state has a beneficial effect on survival in a particular environment (sickle cell carrier state protection from malaria). It has become a part of routine obstetric care to identify these at-risk individuals. Presently, candidates for screening are identified because of their race or heritage. Table 17-16 lists the standard screening tests that should be offered to pregnant patients based on their ethnicity.

The goal of testing is to provide individuals with information that will permit them to make informed reproductive decisions. Such testing is of maximal benefit when it is part of a comprehensive screening program. Components of this program should include patient education, counseling, and a relationship with medical facilities capable of performing invasive diagnostic testing when needed. To be responsive to patient needs, information related to genetics, in general and specific to their individual risks, should be given. This should include basic inheritance patterns, the variable nature of disease expression, the risk of occurrence, and the diagnostic and therapeutic options available. Educating a couple can be accomplished by using direct counseling, printed materials, or interactive online systems.

Before carrier testing is performed, informed consent should be obtained. This should demonstrate that the individual has fully understood the multiple options that ensue from testing. It is equally important to ensure that those who decline testing do so knowledgeably, and this should be documented. Any testing performed must be voluntary, and patients must be assured that every effort will be made to ensure confidentiality. As molecular diagnostics has become more available, the complexity of gene-based diagnosis and screening has become clear. The vast number of mutations with their varying phenotypic

consequences frequently require sophisticated laboratory capabilities and subsequent counseling by individuals explicitly trained in this area.

Cystic Fibrosis Screening

Cystic fibrosis (CF) is a multisystem genetic disorder in which defective chloride transport across membranes causes dehydrated secretions, leading to tenacious mucus in the lungs, mucous plugs in the pancreas, and high sweat chloride levels. CF is an autosomal recessive disorder with the responsible gene on chromosome 7 coding for the CF transmembrane conductance regulator (CFTR). CF can have a highly variable presentation and course, which ranges from severe pulmonary and gastrointestinal disease in infancy to relatively mild disease when initial presentation is during young adulthood. Mutations of the CF gene can lead to otherwise normal men with congenital absence of the vas deferens or women with chronic sinusitis or bronchitis as their only morbidity.

CF is one of the most common genetic diseases in the white population, with an incidence of about 1 in 3300 individuals. The gene is also relatively common in Ashkenazi Jews and has a fairly high incidence among Hispanics (1 in 9550). The disease is rare in native Africans and Asians (<1 in 50,000) but somewhat higher in American populations of these ethnic groups (1 in 15,300 and 1 in 32,100, respectively). Table 17-17 demonstrates the incidence of CF and the carrier frequency in various ethnic groups.

The gene causing CF was first cloned in 1989 and provided the initial ability to screen individuals with no family history. More than 600 mutations and DNA sequence variations have since been identified. The $\Delta F508$ mutation, the most common, is a frame-shift mutation caused by a three-base pair deletion in exon 10 of the CF transmembrane conductance regulator that codes for phenylalanine at the 508th amino acid. Although present in almost all populations, its relative frequency varies among different geographies and ethnic groups. The highest frequency is observed in the white population, where it accounts for approximately 70% of CF mutations. Some 15 to 20 other "common" mutations account for 2% to 15% of CF alleles, depending on the ethnic composition of the patient group.

TABLE 17-17 CARRIER FREQUENCY DISTRIBUTION OF COMMON CYSTIC FIBROSIS ALLELES IN VARIOUS ETHNIC GROUPS

Group	Incidence	Carrier Frequency	Delta F508 (%)	Common White Alleles (%)	Group-Specific Alleles (%)	Approximate Mutation Detection Rate (%)
Whites in North America	1/3,300	1/29	70	14	—	80-85
Hispanics	1/8,900	1/46	46	11	—	57
Ashkenazi Jews	1/3,970	1/29	30	67	—	97

†5T in *cis* can modify R117H phenotype or alone can contribute to congenital bilateral absence of vas deferens (CBA VD); 5T analysis.

The sensitivity of CF screening using DNA mutation analysis depends on the frequency of common identifiable mutations in the screened population. Although greater than 90% carrier detection is presently possible in a number of ethnic groups, a standard panel of mutations has been developed to maximize overall screening efficiency that provides the greatest pan-ethnic detection and can be practically performed (Table 17-18). This panel was initially composed of 25 mutations but in 2004 the number was reduced to 23.²⁰¹ The panel contains all CF-causing mutations with an allele frequency of at least 0.1% in the general U.S. population. An understanding of the distribution of mutations in the CF transmembrane conductance regulator is continually advancing, and it is likely that this panel will continue to evolve. Panels with more mutations are available, as is complete gene sequencing, and may be useful in certain specific clinical situations.

There has been much discussion and debate over which ethnic and racial groups should be offered CF carrier testing. Some maintain that screening should be limited to the highest-risk populations, such as non-Jewish whites of European ancestry and Ashkenazi Jews, in which both the carrier frequency (1:25 to 1:30) and the mutation detection rate (25 mutations detect more than 80% of CF alleles) are sufficiently high to make screening cost-effective. This would exclude African Americans, with a detection rate of only about 75%. Hispanics would also be excluded, despite their relatively high incidence of the disease, because detectable alleles account for only 57% of their CF mutations. Screening would be even less effective in Asian Americans, who would have only 30% sensitivity. Others argue that the admixture of populations in the United States makes it difficult to exclude patients on the

basis of specific ethnic group and that even attempting to make such a determination in a busy clinical setting may place an undue burden on primary care physicians.

To resolve this debate, the National Institutes of Health issued a consensus statement in 1997 indicating that CF testing should be offered to adults with a positive family history of CF, to partners of people with CF, to all couples planning a pregnancy, and to couples seeking prenatal testing, particularly those in high-risk populations. It was believed that genetic testing should be offered in the prenatal setting to enhance the ability to make reproductive choices and to engage individuals when their interest and use of the information was maximal.

A second National Institutes of Health-sponsored conference focusing on implementation of the consensus recommendations was held in 1998. Shortly thereafter, the American Colleges of Medical Genetics and Obstetrics and Gynecology, in conjunction with the National Human Genome Research Institute, issued a joint opinion entitled "Preconception and Prenatal Carrier Screening for Cystic Fibrosis." This document recommended narrowing the population screened to non-Jewish whites and Ashkenazi Jews. Information about screening should be made available to other ethnic and racial groups through educational brochures or other efficient methods. These lower-risk groups should be informed of the availability of testing but should also be advised of the limitations encountered for their particular situation. For example, Asian Americans, African Americans, and Native Americans without significant white mixture should be informed of the rarity of the disease and the low yield of the test in

their respective populations.^{202,203} Pre-conception testing should be encouraged, but for practical purposes, most testing should continue to occur in the prenatal setting.

In appropriate populations, there are two possible approaches to screening. In sequential screening, one member of the couple (usually the woman) is tested first, and only if a positive result is obtained is the partner tested. Alternatively, couple-based screening analyzes specimens from both partners, with each informed of his or her specific results. Present recommendations are that either is appropriate, with the method depending on the target population, the nature of the clinical setting, and the judgment of the practitioner. Couple-based testing is recommended for white couples of northern European and Ashkenazi Jewish descent, particularly when concurrently testing for other common genetic disorders. Sequential screening is believed to be more useful for groups in which the carrier frequency is lower and when obtaining a simultaneous sample from the partner is impractical. In general, the individual provider or center should choose the method they believe is most practical in their setting.

All patients with negative screen results should be reminded that carrier screening is not 100% sensitive. This is particularly pertinent in couples when one partner is found to carry a mutation. The residual risk after a negative CF carrier test depends on the ethnic and racial group of the patient (Table 17-19). In northern and eastern European populations in which CF mutation screening detects up to 90% of mutant alleles and in which the carrier frequency is 1 in 25, a negative screen reduces the risk of being a carrier to 1 in 241. Screen-negative couples will then reduce their risk of having an affected child from 1 in 2500 ($1/4 \times 1/25 \times 1/25$) to 1 in 232,324 ($1/4 \times 1/241 \times 1/241$). If one parent has a mutation and the other is negative, the risk of an affected child is 1 in 964 ($1/4 \times 1 \times 1/241$). When both parents are found to have identifiable mutations, the risk of an affected child is 1 in 4. Prenatal diagnosis by either chorionic villus sampling or amniocentesis, along with genetic counseling, would be recommended.

For individuals with a family history of CF, medical records identifying the mutation should be obtained. If the mutation has not been identified, screening with an expanded panel of mutations, or in some cases complete sequencing, may be necessary. Individuals with a reproductive partner with either CF or congenital bilateral absence of the vas deferens may also benefit from either an expanded panel or gene sequencing.

In most cases, interpretation of the screening results is straightforward, but complicated situations may occur and frequently involve the 5T variant polymorphism. This is one of three poly(T) (thymidine) alleles (5T, 7T, and 9T) in intron 8 of the CF transmembrane conductance regulator gene. It occurs in about 5% of the population and decreases production of the CFTR protein. The 5T mutation can cause congenital bilateral absence of the vas deferens or atypical CF when present in a male in *trans* with a common CF allele. This arrangement has no clinical significance in females. Accordingly, identification of the 5T variant will produce complicated counseling issues, because it expands the risk ascertainment beyond classic CF. Because of this, most laboratories do not offer 5T analysis as part of routine screening. Testing for this variant is only appropriate as a reflex test when the R117H mutation is detected on the primary screen. This is required because classic CF occurs when 5T is in *cis* with R117H on one chromosome and a CFTR mutation is present on the other chromosome. Accordingly, patients positive for both R117H and 5T require further analysis to determine if the 5T is in *cis* or *trans* with the R117H allele. To accomplish this, the laboratory requests specimens from appropriate family members. Using this approach, the initial screening is for classic CF rather than fertility of the fetus.

Jewish Disease Testing

A number of recessive disorders occur more frequently in the Ashkenazi Jewish population. Carrier testing for two of these, Tay-Sachs disease and Canavan disease, is now considered standard of care.²⁰⁴

Tay-Sachs Disease. Tay-Sachs disease is an autosomal recessive lysosomal storage disorder caused by deficiency of the enzyme hexosaminidase A. This results in a group of neurodegenerative disorders caused by intralysosomal storage of the specific glycosphingolipid GM2 ganglioside. Classic Tay-Sachs disease is characterized by loss of motor skills beginning between 3 and 6 months of age, with progressive neurodegeneration, including seizures, blindness, and eventual total incapacitation and death usually before the age of 4. The juvenile (subacute), chronic, and adult-onset variants of the hexosaminidase A deficiencies have later onsets, slower progression, and more variable neurologic findings, including progressive dystonia, spinocerebellar degeneration, motor neuron disease, and, in some individuals with adult-onset disease, a bipolar form of psychosis.

TABLE 17-19 IMPACT OF A NEGATIVE CYSTIC FIBROSIS (CF) SCREENING PANEL (25 MUTATIONS) ON THE CARRIER RISK*

Ethnic Group	Detection Rate (%)	Estimated Carrier Risk	
		Before Test	After Negative Test
Ashkenazi Jews	97	1/29	Approx. 1 in 930

Carrier parent		1/2	Approx. 1 in 6
Carrier grandparent		1/4	Approx. 1 in 14

*Residual carrier risk after a negative test is modified by the presence of a positive family history.

†This is a pooled set of data and requires additional information to accurately predict risk for specific Hispanic populations.

The incidence of the Tay-Sachs carrier state is between 1:27 and 1:30 in the Ashkenazi Jewish population (i.e., from Central and Eastern Europe), resulting in a birth prevalence of 1 in 3600 infants. Among Sephardic Jews and all non-Jews, the disease frequency is approximately 100 times less, corresponding to a 10-fold lower carrier frequency (1 in 250 to 1 in 300). As the result of extensive genetic counseling of carriers and prenatal diagnosis, the incidence of Tay-Sachs disease in Ashkenazi Jews in North America has already been reduced by greater than 90%.^{205,206}

In addition to occurring in Ashkenazi Jews, Tay-Sachs disease can occur in children of any ethnic, racial, or religious group, but certain populations that are relatively isolated genetically, such as French Canadians of the eastern St. Lawrence River valley area of Quebec, Cajuns from Louisiana, and the Amish in Pennsylvania, have been found to carry hexosaminidase A mutations with frequencies comparable with, or even greater than, those observed in Ashkenazi Jews.

Population screening for the carrier state of Tay-Sachs disease uses serum or leukocyte determination of hexosaminidase A enzyme activity using synthetic substrate. Carriers have significantly reduced levels compared with noncarriers. Serum samples are used for testing all males and for nonpregnant women not on oral contraceptives. Pregnant women, those on oral contraceptives, and women who have a tissue destructive disorder such as diabetes mellitus, hepatitis, or rheumatoid arthritis should have a white blood cell determination of enzyme activity, because these conditions artificially lower the serum hexosaminidase A level, leading to a false diagnosis of the carrier state. When the enzymatic testing is abnormal or inconclusive, DNA analysis of the hexosaminidase A gene is performed to confirm the diagnosis, identify the specific mutation, and rule out the presence of a pseudodeficiency allele that is present in approximately 2% of the Ashkenazi Jewish population and approximately 35% of the non-Jewish population.²⁰⁷

Two pseudodeficiency alleles exist and can be tested for. Individuals heterozygous for the pseudodeficiency allele have an apparent deficiency of hexosaminidase A enzymatic activity with the synthetic substrate but not with the natural substrate, GM2 ganglioside. Their levels are similar to those of Tay-Sachs carriers, leading to a potential incorrect determination of a carrier. Homozygous pseudodeficient individuals have extremely low or absent hexosaminidase A levels similar to individuals affected with Tay-Sachs disease. Neither compound hetero-

zygotes having one Tay-Sachs allele and one pseudodeficient allele nor homozygotes for the pseudodeficient allele have any neurologic abnormality.

There are more than 90 disease-causing mutations in the hexosaminidase A gene, but routine mutation analysis tests for only the six most common mutations.²⁰⁸ Molecular analysis of the six-mutation hexosaminidase panel will identify between 92% and 98% of Jewish carriers but only between 23% and 46% of non-Jewish carriers (Table 17-20). Some laboratories use mutation analysis as their primary screening approach in the Ashkenazi population. However, this will identify only 92% to 94% of carriers, so some will be missed. Laboratories seeing a high proportion of French-Canadian patients may offer extended panels or test for selected mutations that are specific to that population. In Quebec, a 7.6-kb deletion is the most common allele associated with Tay-Sachs disease. Accordingly, when testing individuals from the French-Canadian population or other populations with founder mutations, care should be taken to identify a laboratory performing analysis for the appropriate mutations. It is not uncommon for a couple in which one partner is Jewish and the other is not to inquire about testing. It is presently recommended that such couples be offered carrier analysis by enzymatic testing, because DNA analysis with the routine six-mutation panel would fail to detect a significant proportion of the non-Jewish carriers. Also, individuals who have French-Canadian, Cajun, and Amish ancestry should be offered carrier testing. Individuals who are pursuing reproductive technologies that involve gamete donation and who are at increased risk of being heterozygous for hexosaminidase A because of their ethnic background should also be screened.

Prenatal diagnosis for Tay-Sachs disease is possible by enzymatic analysis of either amniocytes or chorionic villi. Hexosaminidase A deficiency can be identified by CVS within 30 minutes of retrieval or from uncultured amniotic fluid.²⁰⁹⁻²¹¹ However, very few laboratories use this approach, preferring to use mutation analysis if the disease-causing mutation has been identified in both parents. Prenatal testing may also be recommended when one parent is a known heterozygote and the other has inconclusive enzymatic activity without a disease-causing mutation found on DNA analysis. It also may be recommended when the mother is a known heterozygote and the father is either unknown or unavailable for testing. Both of these latter scenarios require intensive genetic counseling.

Canavan Disease. Screening of Ashkenazi Jewish patients or couples for Canavan disease is now part of routine obstetric care.²¹² This disorder is caused by a deficiency in aspartoacylase and is characterized by developmental delay by the age of 3 to 5 months, with severe hypotonia and failure to achieve independent sitting, ambulation, or speech.²¹³ Hypotonia eventually changes to spasticity, requiring assistance with feeding. Life expectancy is usually into the teens.²¹⁴ Because about 99% of disease-causing mutations in persons of Ashkenazi Jewish heritage is identified by only three alleles, carrier testing is done by DNA mutation analysis.^{215,216} Testing by biochemical analysis is not routinely available because it relies on a complex enzyme assay and cultured skin fibroblasts.²¹⁷ Fifty-five percent of disease-causing alleles in non-Jewish individuals are identified by analysis of these three alleles as well.²¹⁸ Prenatal testing for pregnancies that are at 25% risk can be performed by either amniocentesis or CVS using mutation analysis. For the unusual couple where one partner is known to be a carrier and a mutation or the carrier status of the other is uncertain or unknown, prenatal testing can be performed by measuring the level of *N*-acetyl aspartic acid in amniotic fluid at 16 to 18 weeks.^{219,220}

Other Diseases Increased in the Jewish Population. A number of other disorders have been found to occur more frequently among the Ashkenazi Jewish population (Table 17-21).²²¹ The gene frequency for these disorders varies compared with those for Tay-Sachs or Canavan disease.²²² In some of these disorders, such as Gaucher

disease type I, the phenotype in some individuals is relatively benign or treatable. Although this autosomal recessive lysosomal storage disease has a carrier frequency of 1 in 18 in Ashkenazi Jewish individuals, the clinical course is heterogeneous, ranging from early onset of severe disease, with major disability or death in childhood, to a mild disease compatible with a normal productive life. The phenotype in this disorder is well correlated with the genotype. Of the more than 200 mutations in the affected acid α -glucosidase gene, four mutations (N370S, 84GG, L444P, and IVS2) account for 95% of those in Ashkenazi Jews. Although an affected individual who carries two copies of any combination of the 84GG, L444P, and IVS2 mutations will have severe neurodegenerative disease, individuals homozygous for the most common N370S mutation have a non-neurologic disorder with an average age at onset of 30. Some individuals may never come to medical attention. Individuals having the N370S mutation with one of the other three common mutations will also have non-neurologic disease but of a somewhat more severe phenotype than in N370S homozygotes. This predominance of relatively mild non-neurologic disease in the Ashkenazi Jewish population has led some to question whether screening in this population is appropriate. In addition, effective treatment of type I Gaucher disease with enzyme replacement exists.

Presently, in some centers, the availability of these carrier tests is discussed with Jewish couples so they can make individualized decisions about whether to have them performed. Overall, if these nine

TABLE 17-21 POTENTIAL SCREENING AVAILABLE FOR AUTOSOMAL RECESSIVE DISORDERS IN THE ASHKENAZI JEWISH POPULATION

Disease	Status	Genetic Defect	Carrier Frequency in Ashkenazi Jews	Comments
Cystic fibrosis	S	Transmembrane conductance regulator (CFTR) mutation	1:26	97% detection rate with 97 mutation panel
Tay-Sachs	S	Hexosaminidase A deficiency	1:30	Screening done by enzyme analysis. Carrier screening during pregnancy, while on oral contraceptives, or with debilitating illness requires leukocyte analysis. Pseudodeficient allele exists. 97% to 98% detection with enzyme analysis and 92% to 94% with mutation analysis.
Canavan	S	Aspartoacylase (ASPA) deficiency	1:40	Three common mutations account for 99% of disease-causing alleles.
Niemann-Pick type A	A	Acid sphingomyelinase deficiency	1:90	Three mutations with 95% detection.
Gaucher disease type 1	A	Glucocerebrosidase deficiency	1:14	The type 1 Gaucher disease seen in this population is the mild variant with no CNS involvement. Some affected individuals with mild disease may be identified through screening.
Fanconi anemia	A	Chromosome breakage	1:89	Five mutations with 95% detection
Bloom syndrome	A	Chromosome breakage	1:100	One mutation with 99% detection
Congenital deafness	A	Connexin 26 mutation	1:21	One mutation with 97% detection
Glycogen storage disease type IA	A	Glucose 6 phosphatase	1:71	Wide variability in severity of disease
Maple syrup urine disease	A	Branched-chain alpha-ketoacid dehydrogenase (BCKAD) complex	1:81	Two mutations with 99% detection
Mucopolidosis type IV	A	<i>MCOLN1</i>	1:122	Four mutations with 99% detection
Familial dysautonomia	A	<i>IKBKAP</i> gene mutation	1:30	Two mutations with 96% detection
				Two mutations with 99% detection

diseases are screened for, one in six Ashkenazi Jews will be determined to be a carrier for at least one disorder. To avoid the anxiety that such a high carrier rate may engender, it is recommended that both members of a couple be screened simultaneously, so that genetic counseling need be provided only to carrier couples.²²³

Hemoglobinopathies

Sickle Cell Syndromes

Sickle cell diseases are a common group of inherited hemoglobin disorders characterized by chronic hemolytic anemia, heightened susceptibility to infection, end-organ damage, and intermittent attacks of vascular occlusion causing both acute and chronic pain. Approximately 70,000 Americans of different ethnic backgrounds have sickle cell disease. In the United States, sickle cell syndromes are most frequently present in African Americans and occur at a frequency of 1:400. The disease is also found in high frequency in individuals from certain areas of the Mediterranean basin, the Middle East, and India.²²⁴

Sickle cell syndromes include sickle cell anemia, variant hemoglobin sickle cell disease, and hemoglobin S- β -thalassemia. Normal hemoglobin consists of hemoglobin A (α , β), hemoglobin F (α , γ), and hemoglobin A₂ (α , δ). The protein sequences are coded on chromosome 11 for the β , δ , and γ chains, and the β variants such as hemoglobin S, hemoglobin C, and hemoglobin D all occur from a mutation of this gene. Sickle cell anemia is the most common variant and results when an individual inherits a substitution of valine for the normal glutamic acid in the sixth amino acid position of the β globin chain. This substitution alters the hemoglobin molecule so that it crystallizes and alters the red cell into a sickle shape when the hemoglobin loses oxygen. Hemoglobin C is caused by a substitution of lysine in the same location.

Screening for sickle cell disease should be offered to individuals of African and African-American descent and to those from the Mediterranean basin, the Middle East, and India. Approximately 1 in 12 African Americans has sickle cell trait. The definitive test to determine the carrier state of sickle cell disease is hemoglobin electrophoresis, which is based on the altered electrical charge of abnormal hemoglobins caused by the amino acid substitutions. A simple sickle cell preparation fails to identify individuals carrying β -thalassemia or certain sickle cell variants (hemoglobins C, D, and E) and is no longer acceptable for screening. In addition, routine cellulose acetate gel hemoglobin electrophoresis cannot delineate all hemoglobin variants. If routine electrophoresis is abnormal, further testing by high-performance liquid chromatography may be necessary.

HEMOGLOBIN VARIANTS

Hemoglobin C occurs in higher frequency in individuals with heritage from West Africa, Italy, Greece, Turkey, and the Middle East. Individuals who are hemoglobin C homozygotes have a mild hemolytic anemia, microcytosis, and target cell formation. They may very occasionally have episodes of joint and abdominal pain. Splenomegaly is common, and aplastic crisis and gallstones may occur. Compound-heterozygous patients with hemoglobin S and C have a sickle syndrome that is very similar to sickle cell anemia. Hemoglobin C carriers have no anemia but usually have target cells on blood smear and may have a slightly low mean corpuscular volume (MCV) with no other clinical problems. Individuals who are compound heterozygotes for hemoglobin C and β -thalassemia who inherit a β^0 mutation have a moderately severe anemia, splenomegaly, and may have bone changes. Individuals

who inherit a β^+ mutation with hemoglobin C have only a mild anemia, low MCV, and target cells on blood smear.

On occasion, hemoglobin E is seen by electrophoresis. This is a structurally abnormal hemoglobin caused by a substitution of lysine for glutamic acid at the 26th position of the β globin chain, which causes abnormal processing of pre-messenger RNA to functional messenger RNA, resulting in decreased synthesis of hemoglobin E. The hemoglobin E gene is very common in areas of Southeast Asia, India, and China. Heterozygotes for hemoglobin E and hemoglobin A have no anemia, a low MCV, and target cells on blood smear. Hemoglobin electrophoresis shows approximately 75% hemoglobin A and 25% hemoglobin E. Homozygotes for hemoglobin E may have normal hemoglobin levels or only a slight anemia. The MCV is low, and many target cells are present. There is a single band in the hemoglobin C or A position on cellulose acetate electrophoresis and increased hemoglobin F (10% to 15%). There are no clinically significant problems. Individuals who are compound heterozygotes for hemoglobin E and β^0 -thalassemia can have a severe disease with profound anemia, microcytosis, splenomegaly, jaundice, and expansion of marrow space. Hemoglobin electrophoresis in these individuals shows hemoglobin E and a significant increase in hemoglobin F (30% to 60%). Individuals who are compound heterozygote for hemoglobin E and β^+ -thalassemia have a moderate disease with anemia, microcytosis, splenomegaly, and jaundice. Hemoglobin electrophoresis shows hemoglobin E at approximately 40%, hemoglobin A at 1% to 30%, and a significant increase in hemoglobin F (at approximately 30% to 50%).

SICKLE THALASSEMIAS

Beta-thalassemias are caused by mutations that reduce or abolish the production of the β globin subunits of hemoglobin. Compound heterozygotes of β -thalassemia and hemoglobin S have very significant clinical problems. In hemoglobin S- β^0 -thalassemia, no normal hemoglobin A is made, so electrophoresis of hemoglobin shows only hemoglobin S, increased hemoglobin A₂, and increased hemoglobin F. In hemoglobin S- β^+ -thalassemia, hemoglobin A is reduced, so hemoglobin electrophoresis shows hemoglobin A (5% to 25%), hemoglobin F, hemoglobin S, and increased hemoglobin A₂. The severity of the clinical manifestations of sickle cell thalassemia can vary greatly between patients. Most individuals with the hemoglobin S- β^+ -thalassemia have preservation of spleen function and fewer problems with infections, fewer pain episodes, and less organ damage than those with sickle cell disease. Individuals with hemoglobin S- β^0 -thalassemia may have very severe disease identical to disease in those homozygous for sickle cell anemia.

Sickle cell anemias are inherited as autosomal recessive disorders. Therefore, when both parents carry the hemoglobin S gene, the couple has a 1:4 risk of having an affected child. Prenatal diagnosis using molecular DNA detection of the mutation is routine. When one parent has a hemoglobin S mutation and the other is a carrier of β -thalassemia, the couple has a 25% risk of having a child with sickle thalassemia. If the specific parental mutation responsible for thalassemia is known, the gene can be detected by molecular analysis of villi or amniocytes and an affected child identified. If the thalassemia mutation is not identifiable, fetal blood sampling for globin chain synthesis may be required.

Beta-Thalassemia

Beta-thalassemia is characterized by reduced hemoglobin β -chain production and results in microcytic, hypochromic anemia, and an abnormal peripheral blood smear with nucleated red cells. There are reduced (β^+) to absent (β^0) amounts of hemoglobin A on hemoglobin electro-

phoresis.²²⁵ Patients homozygous for a β -thalassemia mutation have thalassemia major with severe anemia and hepatosplenomegaly. They usually come to medical attention within the first 2 years of life, and without treatment affected children have severe failure to thrive and a shortened life expectancy. Treatment requires a program of regular transfusions and chelation therapy, which can result in normal growth and development.

β -Thalassemia is inherited in an autosomal recessive manner, with two carrier parents having a 25% chance of an affected child. Heterozygotes are clinically asymptomatic and may have only slight anemia. Carriers are referred to as having thalassemia minor.²²⁶ The β -thalassemias result from more than 200 different hemoglobin β chain mutations.²²⁷ Despite this marked molecular heterogeneity, the prevalent molecular defects are limited in each at-risk population—that is, each racial or ethnic population has only four to 10 mutations that account for the large majority of the disease-causing alleles in that population (Table 17-22). For example, in individuals of Mediterranean, Middle Eastern, Indian, Thai, or Chinese extraction, a limited number of population-specific mutations account for between 90% and 95% of the disease genes. In Africans and African Americans, common mutations account for approximately 75% to 80%. This phenomenon has significantly facilitated molecular genetic testing.

Screening for thalassemia should be offered to all individuals of Mediterranean, Middle Eastern, Transcaucasian, Central Asian, Indian, and Far Eastern groups. Because thalassemia is also common in individuals of African heritage, carrier testing should be offered to all African Americans. As with sickle cell disease, the distribution is probably related to selective pressure from malaria, because the disease distribution is similar to that of endemic *Plasmodium falciparum* malaria.²²⁶ However, because of population migration and, in limited part, the slave trade, β -thalassemia is now also commonly seen in northern Europe, North and South America, the Caribbean, and Australia.

Carriers are identified by evaluation of the red blood cell indices, quantitative hemoglobin analysis, and hemoglobin β chain mutation studies. Carriers are initially identified by their red blood cell indices

that show microcytosis (low MCV, <80) and a reduced content of hemoglobin per cell (low mean corpuscular hemoglobin). Next, a hemoglobin electrophoresis displays a hemoglobin A_2 of more than 3.5% (Table 17-23). On rare occasions, carrier identification using MCV can be misleading. For example, coinheritance of an α -thalassemia gene may normalize red blood cell indices. Also, coinheritance of the δ -thalassemia gene can reduce the normal increased hemoglobin A_2 levels typical of β -thalassemia. Likewise, screening using only a routine hemoglobin electrophoresis as the primary test is insufficient, because thalassemia carriers can easily be missed when hemoglobin levels are normal, and the subtle increases in hemoglobin A_2 and F on electrophoresis may be overlooked. Therefore, a complete blood count with MCV and red cell count should be obtained and a quantitative hemoglobin electrophoresis should be performed, because the MCV is almost always low in β -thalassemia and the red cell count is elevated. Quantitative hemoglobin electrophoresis for hemoglobin A_2 and F is diagnostic.²²⁵

When the initial hematologic analysis is abnormal and the couple is at risk for having a child with either homozygous β -thalassemia or thalassemia-sickle cell disease syndrome, DNA analysis of the hemoglobin β chain is indicated to identify the disease-causing mutation. This helps identify carriers of mild and silent mutations of β -thalassemia that result in attenuated forms of the disease. Knowledge of the specific mutations will also be required if subsequent prenatal diagnosis is performed. However, the sensitivity of molecular testing remains less than 100%, so for some individuals a specific mutation cannot be identified.

Prenatal diagnosis is offered to couples when both members are carriers of β -thalassemia and their gene mutations have been identified. In these cases, mutation analysis can be performed by DNA extracted from either CVS or amniocentesis. Prenatal testing is occasionally offered to families in which one parent is a definitive heterozygote and the other parent has a β -thalassemia-like hematologic picture but no mutation can be identified by sequence analysis. If the father of a pregnancy with a known heterozygote mother is unavailable for testing and belongs to a population at risk, prenatal diagnosis can be offered. In either of the latter two situations, if the known mutation

is identified by CVS or amniocentesis, globin chain synthesis analysis is available for definitive diagnosis.

Alpha-Thalassemia

Alpha-thalassemia is a hemoglobinopathy caused by the deficiency or absence of α globin chain synthesis. The α globin gene cluster is located on chromosome 16 and includes two adult genes ($\alpha 1$ and $\alpha 2$) so that normal individuals have four α globin genes ($\alpha 1\alpha 2/\alpha 1\alpha 2$). α -Thalassemia can be divided into two forms based on the number of functioning genes. A severe form called α^0 -thalassemia results in a typical thalassaemic blood picture in heterozygotes and a severe, perinatally lethal form in homozygotes. α^0 -Thalassemia results from 1 of 17 gene deletions, all of which delete both α globin genes on each chromosome. Alternatively, α^+ -thalassemia is milder and is almost completely silent in heterozygotes. This form is commonly caused by one of six deletions that remove one of the two α globin genes on chromosome 16.

The homozygous state of α^0 -thalassemia resulting from deletions of all four α globin genes (—/—) causes severe hydrops fetalis and the predominance of hemoglobin Barts ($\gamma 4$) and a small amount of hemoglobin Portland ($\zeta 2\gamma 2$) in the fetus. This is routinely lethal in utero or in the early neonatal period if untreated. Although cases of fetal survival after in utero transfusion have been described, this must be followed by repetitive transfusions of the infant and subsequent bone marrow transplant. This approach is not routinely recommended. Maternal risks of hemoglobin Barts hydrops fetalis syndrome include preeclampsia and postpartum hemorrhage.

Hemoglobin H disease results from the compound heterozygous state for α^0 and α^+ (—/— α)-thalassemia, leading to the deletion of three of the four α chain genes. These individuals have a moderately severe hypochromic microcytic anemia and produce large amounts of hemoglobin H (β^4) because of the excessive quantities of β chains in their reticulocytes. In the most common form, these individuals lead a relatively normal life but may have fatigue, general discomfort, and splenomegaly. They rarely require hospitalization. There is a rare, more severe form of hemoglobin H disease arising from a compound heterozygous state of α^0 -thalassemia and nondeletion α^+ -thalassemia involving the more dominant α^2 gene.

α^0 -Thalassemia gene deletions are found in high frequency in individuals from Southeast Asia, South China, the Philippine Islands, Thailand, and a few Mediterranean countries, such as Greece and Cyprus. Because these populations are at risk for the homozygous state leading to hemoglobin Barts disease, they should be screened for the presence of the gene. The α^+ -thalassemia genes are frequent in Africa, the Mediterranean area, the Middle East, the Indian subcontinent, Melanesia, Southeast Asia, and the Pacific area. Because this leads to a mild form of thalassemia, routine screening for α -thalassemia in these populations is not recommended.

The carrier state for α^0 -thalassemia is identified by performing a complete blood count with indices. Carriers (—/ $\alpha\alpha$) have a decreased MCV (<80 fL) and a mean corpuscular hemoglobin level (<27 pg), as seen with α -thalassemia, but the carriers are differentiated by having a normal hemoglobin A₂ level (<3.5%). The diagnosis is confirmed by DNA testing, which can identify the specific deletion. Prenatal diagnosis is available by CVS or amniocentesis and is based on the molecular determination of the gene status.

Fragile X Syndrome

Fragile X syndrome is characterized by relatively typical phenotypic characteristics and moderate mental retardation in affected males.

Affected females have somewhat milder mental retardation.²²⁸ Classic features become more prevalent with age, including long face, large ears, prominent jaw, and macrotestes. There is delayed attainment of motor milestones and speech. Abnormal temperament is frequently associated with hyperactivity, hand flapping, hand biting, and autism spectrum disorder. Behaviors in postpubertal males include tactile defensiveness, poor eye contact, and perseverative speech. Physical and behavioral features can be seen in female heterozygotes, but with a lower frequency and milder involvement. Adult manifestations of the fragile X premutation carrier state occur. The fragile X-associated tremor/ataxia syndrome (FXTAS) is characterized by late-onset, progressive cerebellar ataxia and intention tremor in males who have a premutation.²²⁹ Other neurologic findings include short-term memory loss, executive function deficits, cognitive decline, parkinsonism, peripheral neuropathy, lower-limb proximal muscle weakness, and autonomic dysfunction. Penetrance is age related; symptoms in men are seen in 17% aged 50 to 59 years, in 38% aged 60 to 69 years, in 47% aged 70 to 79 years, and in 75% aged 80 years and older. Some female premutation carriers may also develop tremor and ataxia. In girls and women, premature ovarian failure (POF), defined as cessation of menses before age 40 years, has been observed in carriers of premutation alleles.²³⁰ A review by Sherman²³¹ concluded that the risk for POF was 21% (estimates ranged from 15% to 27% in various studies) in premutation carriers compared with a 1% background risk. In this review, an odds ratio of 2.5 was estimated for intermediate repeat sizes of 41 to 58. Ovarian failure occurred at as early as 11 years of age. In contrast, carriers of full mutation alleles are not at increased risk for POF.

Prevalence estimates of the fragile X syndrome have been revised downward since the isolation of the gene in 1991. Despite this, the original estimates are still occasionally quoted in the fragile X literature. Most recent studies using molecular genetic testing have estimated a prevalence of 1 in 4000 males. The prevalence of affected females is presumed to be approximately one half of the male prevalence.

Fragile X syndrome is inherited in X-linked dominant fashion. The molecular mutations leading to this syndrome result from expansion of a trinucleotide repeat (CGG) causing aberrant methylation of the gene. This results in decreased or complete absence of the protein gene product termed *fragile X mental retardation 1 protein* (FMR-1 protein). This protein is found in the cytoplasm of many cells but is most abundant in neurons.²³² The function of the protein remains unknown, but its absence leads to developmental abnormalities.

FMR-1 alleles are categorized according to the repeat number, which is correlated with the likelihood of expansion during maternal meiosis and the clinical manifestations. However, the distinction between allele categories is not absolute and must be made by considering both family history and repeat instability. Normal alleles are approximately 5 to 40 repeats. Alleles of this size are stably transmitted without any increase or decrease in repeat number. In these stable normal alleles, the CGG region is interrupted by an AGG triplet after every nine or 10 CGG repeats. These AGG triplets are believed to maintain repeat integrity by preventing DNA strand slippage during replication. Mutable normal alleles or intermediate alleles (also termed gray zone) may be broadly defined as 41 to 58 repeats. The risk for instability of alleles with 41 to 49 repeats when transmitted from parent to child is minimal. Any changes in repeat number are typically very small (plus or minus one or two repeats). Historically, the largest repeat included in the intermediate range has been 54. In fact, the intermediate range may extend slightly higher, as no transmission of alleles with 58 or fewer repeats is known to have resulted in an affected

individual. Because most clinical testing laboratories state that repeat measurements are plus or minus two to three repeats, it may be wise to consider reported test results with 55 to 58 repeats as potential premutations.

Premutation alleles of approximately 59 to 200 repeats have an increased risk of expansion to a full mutation and of causing the clinical phenotype. Alleles of this size are not associated with mental retardation but do convey increased risk for FXTAS and POF. Because of potential repeat instability with transmission of premutation alleles through maternal meiosis, women with alleles in this range are considered to be at risk for having children affected with fragile X syndrome and should consider prenatal diagnosis. Full mutation alleles are those with more than 200 repeats, with several hundred to several thousand repeats being typical. Aberrant hypermethylation of the deoxycytidylate residues contained in the CGG repeats usually occurs once repeat expansion exceeds approximately 200, leading to complete absence of FMR-1. This results in the complete fragile X phenotype in males. The phenotype of full mutation females, although also dependent on the size of the mutation, can be modified by random inactivation of either the normal or mutated X chromosome in the brain.²³³ Approximately 50% of females who have a full fragile X mutation are mentally retarded but are usually less severely affected than males with the full mutation.²³⁴ Importantly, about 50% of females who are heterozygotes for the full mutation are intellectually normal.²³⁵

The probability of a carrier of a premutation having a child with a full mutation depends on both the size of the premutation and the sex of the carrier. When premutations are transmitted by the father, only small increases in the trinucleotide repeat number may occur, and they do not result in full mutations. All daughters of “transmitting males” are unaffected premutation carriers, with the potential of subsequent expansion in their offspring. Women who are premutation carriers have a 50% risk of transmitting the abnormal chromosome in each pregnancy.²³⁶ Their risk of having an offspring with a full mutation is based on their premutation size. Table 17-24 demonstrates the likelihood of expansion to a full mutation based on the maternal premutation size. In these cases, prenatal diagnosis should be offered.

The presence of normal transmitting males and the variable likelihood of full expansion by females carrying a premutation will lead to pedigrees with skipped generations or the seemingly spontaneous occurrence of the fragile X syndrome.²³⁷ Therefore, carrier testing should be offered to all individuals seeking reproductive counseling who have either a family history of fragile X syndrome or undiagnosed mental retardation in individuals of either sex.²²⁷

Some centers offer all women seeking prenatal diagnosis the opportunity to have fragile X testing performed as part of routine screening. This approach is based on evidence that the frequency of the premutation is relatively high in the general population. One study of a French-Canadian population found that 1 in 259 women had a premutation in the FMR-1 gene.²³⁸ A more recent study of 14,334 Israeli women of child-bearing age identified 127 carriers with greater than 54 repeats, including three asymptomatic women with full mutations, representing a prevalence of 1 in 113 (885 in 100,000).²³⁷ The benefits of such a screening strategy have not been demonstrated.

Methodologies for molecular testing vary from laboratory to laboratory. Most laboratories screen patient DNA samples by the polymerase chain reaction (PCR) specific for the trinucleotide repeat region of the FMR-1 gene.²³⁹ This technique has high sensitivity for FMR-1 repeats in the normal and lower premutation range but may rarely fail to detect FMR-1 alleles in the upper premutation range. It also can fail to detect full mutations with a high repeat number (espe-

TABLE 17-24 RISKS FOR EXPANSION FROM A MATERNAL PREMUTATION TO A FULL MUTATION WHEN TRANSMITTED TO OFFSPRING

Number of Maternal Premutation CGG Repeats	Total Maternal Transmissions	Expansions to Full Mutations (%)*
55-59	27	1 (3.7%)
60-69	113	6 (5.3%)
70-79	90	28 (31.1%)
80-89	140	81 (57.8%)
90-99	111	89 (80.1%)
100-109	70	70 (100%)
110-119	54	53 (98.1%)
120-129	36	35 (97.2%)
130-139	18	17 (94.4%)
140-200	19	19 (100%)

*Unlike in classic X-linked dominant disorders, in which all females with a mutation are affected, only about 50% of females with a full mutation are mentally retarded. This variability in phenotype is likely to be related to X-chromosome inactivation, a phenomenon independent of *FMR1* mutations.

Adapted from Nolin SL, Brown WT, Glicksman A, et al: Expansion of the fragile X CGG repeat in females with premutation or intermediate alleles. *Am J Hum Genet* 72:454-464, 2003.

cially when used for prenatal testing). Because of these limitations, many laboratories also perform Southern blot analysis, which will detect the presence of full mutations and large premutations. When PCR reveals a normal or premutation allele size in male patients or two alleles within the normal or premutation range in female patients, further testing by Southern blot is not necessary.^{240,241}

Prenatal testing for fetuses at increased risk for FMR-1 full mutations is performed using DNA extracted from either amniocytes or chorionic villi. The Southern blot patterns for DNA expansions derived from amniocytes are identical to those found in adult tissues. However, unreliable methylation patterns can occur in DNA from cells obtained by CVS because methylation of villus tissue may occur at varying gestational ages.²⁴² Because the methylation pattern is predictive of gene function, it is occasionally used to make the distinction between a large premutation and a small full mutation. As a result, on occasion, follow-up amniocentesis or testing using PCR to determine the size of the FMR-1 alleles may be required. Chromosome analysis for fragile X status using modified culture techniques to induce the fragile sites seen in the affected X chromosomes is no longer used for diagnosis because of low sensitivity and increased cost when compared with DNA testing. Because of the complexity of FMR-1 trinucleotide repeat expansion detection and the accompanying methylation issues, a laboratory with known competence for FMR-1 prenatal molecular testing is strongly suggested.^{239,241,243}

Diagnostic Tests

Indications for Invasive Testing

Indications for diagnostic testing are dominated by advanced maternal age (>35 years) and positive screening tests and have been discussed. A prior history of a fetus with a chromosomal abnormality is the next most frequent indication for cytogenetic testing. The recurrence risk

after the birth of one child with trisomy 21 varies in the literature, with most studies quoting an empiric risk of approximately 1% to 1.5% for any trisomy.²⁴⁴ Closer scrutiny suggests that the risk depends on the age of the mother at the birth of the initial trisomic child. Warburton and colleagues²⁴⁵ demonstrated that if the initial trisomic child is born when a mother is less than 30 years old, a future pregnancy born while the mother is still under 30 years old has an eightfold increased risk over maternal age risk. This usually results in a risk of just under 1%. If the initial trisomy 21 birth occurred when the mother was older than 30, the risk of another trisomic child is not statistically greater than her age-related risk at the time of the next pregnancy.

The risk of a liveborn trisomic child after a trisomy 21 conception that was either spontaneously or electively terminated is uncertain. The work of Warburton and colleagues²⁴⁶ suggests that the karyotype of a miscarried pregnancy may predict the karyotype of subsequent miscarriages, but the relevance of this to live births is uncertain. Presently, most authorities recommend the conservative approach of offering the same risks as for a liveborn conception, so prenatal diagnosis in subsequent pregnancies is recommended.

After the birth of two or more trisomy 21 pregnancies, the possibility that one of the parents is either a somatic or germ cell mosaic for Down syndrome must be considered, and peripheral blood chromosome studies of the parents should be offered. Uchida and Freeman²⁴⁷ reported parental mosaicism in 2.7% to 4.3% of peripheral karyotypes in such parents. Mothers appeared to have a higher risk than fathers. The risk of recurrence in these families may be as high as 10% to 20%, and prenatal testing is indicated.

About 3% to 5% of Down syndrome cases are secondary to either a *de novo* or an inherited Robertsonian translocation. If the translocation is *de novo*, risk of another affected child is minimal, although gonadal mosaicism leading to a recurrence has been suspected in some families. Prenatal diagnosis may be offered in these cases. If the balanced translocation is present in the mother, the overall risk of an unbalanced liveborn Down syndrome child is 10% to 15% but varies according to the specific translocation (Table 17-25). If the translocation is paternal, the risk of an unbalanced offspring is approximately 0.5%, but this also depends on the nature of the translocation. In all cases of parental translocation, prenatal diagnosis is indicated.

Some offspring with inherited balanced Robertsonian translocations have been found to have uniparental disomy (UPD). This can have phenotypic consequences if chromosome 14 or 15 is involved. When a balanced Robertsonian translocation involving one of these

acrocentric chromosomes is present in a pregnancy, additional testing for UPD is indicated.²⁴⁸

The recurrence risk after the birth of a child with a trisomy other than 21 is poorly quantified. In a recent collaborative study of 1076 Japanese women with a history of a previous trisomy in whom second-trimester amniocentesis was performed, none of the 170 women with previous trisomy 18 offspring and none of the 46 women with a previous trisomy 13 offspring had another such fetus.²⁴⁹ In general, an empiric risk of about 1% is appropriate, and prenatal diagnosis should be offered.

A previous 45X pregnancy does not significantly increase the risk of a recurrence, but cases of maternal 45X/46XX mosaicism leading to a second affected child have been described.²⁵⁰ The recurrence after a triploid pregnancy is exceedingly low but has been reported to occur.²⁰⁰

Other cytogenetic indications for invasive testing include a parental reciprocal translocation or inversion, a parent or previous child with a mosaic karyotype or marker chromosome, or a sex chromosome/autosome translocation. The risk of an unbalanced offspring in these cases depends on the mode of ascertainment and the specific rearrangement, and genetic counseling is recommended.

Prenatal invasive testing is also indicated to obtain material for biochemical or DNA studies. The molecular abnormalities responsible for many disorders are being identified at a rapid rate, and any listing of these is soon outdated. A list of the more common genetic conditions for which DNA-based prenatal diagnosis is available is given in Table 17-26. A more detailed list, and a list of the centers performing each test, can be found at www.genetests.org. Many of these conditions are rare and their diagnosis is complex, so consultation with a genetics unit is encouraged before performing an invasive test.

Ultrasound identification of fetal structural anomalies is increasing in frequency as an indication for invasive testing. In addition to major structural defects that have long been known to be associated with fetal aneuploidy, more subtle markers have been demonstrated to increase the risk.^{251,252} In addition, ultrasound markers for fetal infection, anemia, or other disorders frequently requires evaluation by amniocentesis.

Amniocentesis

Historical Perspective

Amniocentesis was first performed in the 1880s for decompression of polyhydramnios.^{253,254} It was during the 1950s that it became a significant diagnostic tool, when measurement of amniotic fluid bilirubin concentration began to be used in the monitoring of Rh isoimmunization.^{255,256} In that same decade, amniotic fluid investigation for fetal chromosome analysis was initiated, as laboratory techniques for cell culture and karyotyping were developed. The first reported applications were limited to fetal sex determination by Barr body analysis.²⁵⁷ The feasibility of culturing and karyotyping amniotic fluid cells was demonstrated in 1966,²⁵⁸ and the first prenatal diagnosis of an abnormal karyotype, a balanced translocation, was reported in 1967.²⁵⁹

Technique of Amniocentesis

Mid-trimester amniocentesis for genetic evaluation is most commonly performed between 15 and 18 weeks' gestation. At this age, the amount of fluid is adequate (approximately 150 mL), and the ratio of viable to nonviable cells is greatest. Before the procedure, an ultrasound scan is performed to determine the number of fetuses, confirm gestational age, ensure fetal viability, document anatomy, and locate the placenta

TABLE 17-25 PARENTAL CARRIER OF ROBERTSONIAN TRANSLOCATION: EMPIRIC RISK FOR DOWN SYNDROME LIVE BIRTH

Carrier	Risk for Down Syndrome Live Births
Mother: 13/21, 14/21, 15/21 translocation	10.0%-15%
Mother: 21/22 translocation	4.0%-15%
Father: 13/21, 14/21, 15/21 translocation	0.5%-5%
Father: 21/22 translocation	0.5%-2%
Either parent: 21/21	100%

TABLE 17-26 COMMON CONDITIONS FOR WHICH MOLECULAR PRENATAL DIAGNOSIS IS AVAILABLE

Disorder	Mode of Inheritance	Prenatal Diagnosis
α_1 -Antitrypsin deficiency	AR	Determine PiZZ allele. Not all homozygotes have liver involvement; pre-procedure genetic counseling critical.
α -Thalassemia	AR	α -Hemoglobin gene mutation (see text)
Adult polycystic kidney	AD	PKD1 and PKD2 gene mutations. In large families, linkage is possible in >90%. Gene mutation identifiable in ~50% of PKD1 and 75% of PKD2.
β -Thalassemia	AR	β -Hemoglobin gene mutation (see text)
Congenital adrenal hyperplasia	AR	<i>CYP21A2</i> gene mutations/deletions. Nine common mutations/deletions detect 90% to 95% of carriers. Sequencing available.
Cystic fibrosis	AR	CFTR gene mutation (see text)
Duchenne/Becker muscular dystrophy	XLR	Dystrophin gene mutation
Fragile X syndrome	XLR	CGG repeat number (see text)
Hemoglobinopathy (SS, SC)	AR	β -Chain gene mutation (see text)
Hemophilia A	XLR	Factor VIII gene inversion 45%, other gene mutations 45% (not available in all labs), linkage analysis in appropriate families.
Huntington disease	AD	CAG repeat length (PGD and non-informing PND possible to avoid disclosing presymptomatic parents' disease status).
Marfan syndrome	AD	Fibrillin (FBN-1) gene mutation. Linkage in large families. Approximately 70% have mutation identified (not always clinically available).
Myotonic dystrophy	AD	CTG expansion in the <i>DMPK</i> gene
Neurofibromatosis type 1	AD	NF1 gene mutation identifiable in >95% of cases but requires sequencing. Linkage in appropriate families.
Phenylketonuria	AR	4 to 15 common mutations, 40% to 50% detection. Further mutation analysis > 99%.
Spinal muscular atrophy	AR/AD	
Tay-Sachs disease	AR	Enzyme absence; gene mutation (see text)

AD, autosomal dominant; AR, autosomal recessive; PGD, preimplantation genetic diagnosis; PND, prenatal diagnosis; XLR, X-linked recessive.

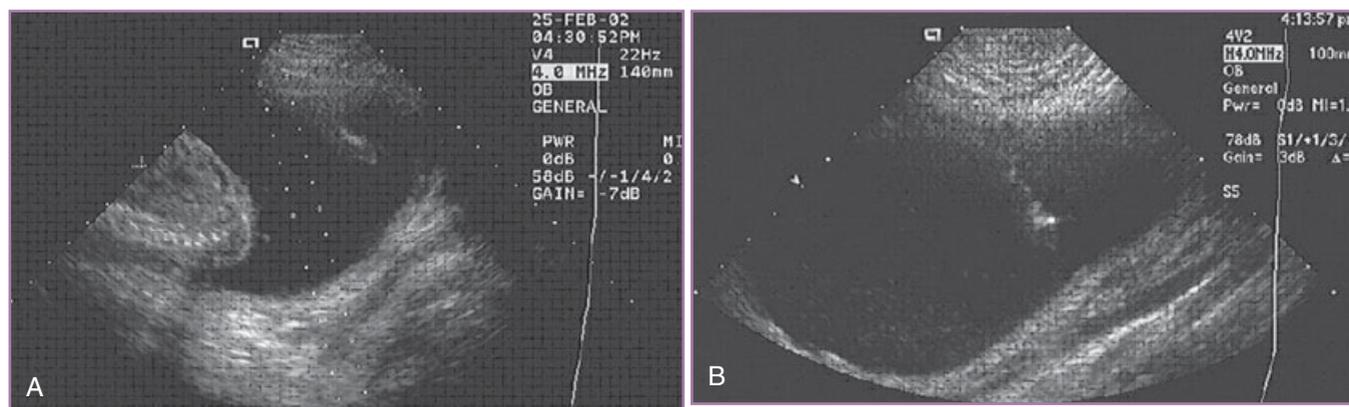

FIGURE 17-7 Ultrasound for amniocentesis procedure. Amniocentesis can be performed with a needle guide (A) or by free-hand technique (B). Either technique can be used, and the choice is usually by practitioner preference. Needle guides can be helpful when one member of the team (operator or sonographer) is less experienced or when dealing with oligohydramnios or morbid obesity.

and cord insertion. After an appropriate sampling path has been chosen, the maternal abdomen is washed with antiseptic solution. Continuously guided by ultrasound, a 20- to 22-gauge needle is introduced into a pocket of amniotic fluid free of fetal parts and umbilical cord (Fig. 17-7). The pocket should be large enough to allow advancement of the needle tip through the free-floating amniotic membrane that may occasionally obstruct the flow of fluid. The first 1 to 2 mL of aspirated amniotic fluid is discarded to prevent maternal cell contamination of the tissue culture, and then 20 to 30 mL of amniotic fluid is withdrawn. Fetal heart rate and activity are documented immediately after the procedure.

Transplacental passage of the needle should be avoided when possible, but if it is unavoidable, attempts should be made to traverse the thinnest portion, away from the placental edge and the umbilical cord insertion.²⁶⁰ If the placenta must be traversed, color Doppler is helpful to avoid any large fetal vessels at the sampling site. The area close to the placental cord insertion should be avoided, because it contains the largest vessels. Using this approach, transplacental amniocentesis does not increase fetal loss rates in the hands of experienced operators.^{261,262}

Amniocentesis should be performed using continuous ultrasound guidance. Guidance should be maintained throughout the procedure

to avoid inadvertent puncture of the fetus and to identify uterine contractions that occasionally retract the needle tip back into the myometrium. Romero and colleagues²⁶³ showed that continuous guidance decreases the number of insertions as well as of dry and bloody taps.

The procedure may be performed either freehand or with a needle guide.^{260,264} The freehand technique allows easier manipulation of the needle if the position of the target is abruptly altered by a uterine contraction or fetal movement. On the other hand, a needle guide allows more certain ascertainment of the needle entry point and a more precise pre-entry determination of the sampling path. The guide may allow easier sampling in certain situations, such as when oligohydramnios is present or for patients who are morbidly obese. A needle guide is especially helpful for relatively inexperienced operators or sonographers. Most guides now allow easy intraoperative removal of the needle from the guide and quick adaptation to freehand guidance once the uterus has been entered.²⁶⁵

If the initial attempt to obtain fluid is unsuccessful, a second attempt in another location should be performed after reevaluation of the fetal and placental positions. Amniotic membrane tenting and the development of needle-induced uterine wall contractions are most frequently the cause of initial failure. No more than two attempts should be made at any single session. If two attempts have been unsuccessful, the patient may be rescheduled in several days. Studies have demonstrated that fetal loss rate increases with the number of insertions. Marthin and coworkers²⁶² reported a postamniocentesis loss rate of 3.8% after three insertions, compared with 1.2% after a single pass. Loss rates do not increase with the number of separate procedures. In experienced centers, return visits are rarely required, occurring in less than 1% of cases.²⁶⁶

Laboratory Considerations for Amniocentesis

The cells within the amniotic fluid arise from the fetal skin, respiratory tract, urinary tract, gastrointestinal tract, and placenta. After retrieval, the cells are put into tissue culture, either in flasks or more often on coverslips. After 3 to 7 days of growth, sufficient mitoses are present for staining and karyotype analysis. Cells grown in flasks are harvested and analyzed together, whereas those grown on coverslips are analyzed in situ as individual colonies. Amniocyte culture is quite reliable, with failure occurring in less than 1% of cases.

MOSAIC RESULTS

Chromosomal mosaicism—the presence of two or more cell lines with different karyotypes in a single sample—occurs in approximately 0.1% to 0.3% of amniocentesis cases. This most frequently results from postzygotic nondisjunction,²⁶⁷ but it can also occur from meiotic errors with trisomic rescue (see Laboratory Aspects of Chorionic Villus Sampling, later). The most common etiology is pseudomosaicism,²⁶⁷ where the abnormality is evident in only one of several flasks or confined to a single colony on a coverslip. In this case, the abnormal cells have arisen in vitro, are not present in the fetus, and are not clinically important. Even the observation of multiple cell lines on more than one coverslip or in more than one flask in a sample does not necessarily mean that the fetus is mosaic, because the results are confirmed in only 70% of cases.²⁶⁸ Some mosaic results (e.g., trisomy 20) occur in the amniotic fluid relatively frequently but are rarely confirmed in the fetus.²⁶⁹

True fetal mosaicism is rare, occurring in 0.25% of amniocenteses, but can be clinically important, leading to phenotypic or developmental abnormalities.²⁶⁷ In many cases, the question of whether amniotic fluid mosaicism involves the fetus can be resolved by karyotyping fetal

lymphocytes obtained by percutaneous umbilical blood sampling (PUBS).²⁷⁰ However, this approach may not be valid in all cases, because the mosaic cell line may involve fetal tissues but be excluded from the fetal hematopoietic compartment and therefore not present in a fetal blood sample.²⁶⁹ Certain chromosomes, such as 22, are notorious for exclusion from fetal blood and may require testing of additional fetal tissues such as the skin.²⁷¹

Evaluation of mosaic results should include detailed ultrasound assessment to assess fetal growth and exclude structural anomalies. If both ultrasound and fetal sampling are normal, the parents can be reassured that, in most cases, the fetus is unaffected.²⁷⁰ However, a small chance of fetal involvement still exists because the presence of an undetectable but clinically significant abnormal cell line can never be absolutely excluded. Because of the complexity of interpreting mosaic amniotic fluid results, consultation with a cytogenetics laboratory and a clinical geneticist is recommended.

USE OF FLUORESCENCE IN SITU HYBRIDIZATION

Fluorescence in situ hybridization (FISH) probes are relatively short, fluorescence-labeled DNA sequences that are hybridized to a known location on a specific chromosome and allow the number and location of specific DNA sequences to be determined. Interphase cells are evaluated by counting the number of discrete fluorescent signals from each probe. A normal diploid cell queried with a probe for the centromere of chromosome 18 would have two signals, whereas a trisomy 18 cell would have three.

Prenatal interphase evaluation of uncultured amniotic fluid can detect aneuploidies caused by monosomies, free trisomies, trisomies associated with robertsonian translocations, triploidy, and other numerical chromosomal abnormalities. In standard practice, probes involving chromosomes 13, 18, 21, X, and Y are used. This technology does not routinely detect cytogenetic abnormalities such as mosaics, translocations, and rare aneuploidies.^{272,273}

Since 1993, the position of the American College of Medical Genetics has been that prenatal FISH is investigational. In 1997, the U.S. Food and Drug Administration cleared the specific FISH probes to enumerate chromosomes 13, 18, 21, X, and Y for prenatal diagnosis. Subsequent studies demonstrate an extremely high concordance rate between FISH and standard cytogenetics (99.8%) for the specific abnormalities that the assay is designed to detect.²⁷⁴⁻²⁷⁷ These performance characteristics support the use of FISH for prenatal testing when a diagnosis of aneuploidy of chromosome 13, 18, 21, X, or Y is highly suspected by virtue of maternal age, positive maternal serum biochemical screening, or abnormal ultrasound findings.²⁷⁸

Presently, it is suggested that FISH analysis not be used as a primary screening test on all genetic amniocenteses because of its inability to detect structural rearrangements, mosaicism, markers, and uncommon trisomies. Evans and coworkers²⁷⁹ surveyed the results of almost 73,000 prenatal cases from seven centers and reported that only 67% of abnormalities would have been detected by routine FISH. This interpretation may be misleading in that some of the missed abnormalities would not have had an impact on fetal development. Because all abnormalities would be detectable by tissue culture, FISH analysis is not cost-effective. Most laboratories use FISH to offer quick reassurance to patients with an unusually high degree of anxiety, or to test fetuses at the highest risk, such as those with ultrasound anomalies. It is also beneficial when rapid results are crucial to subsequent management, such as with advanced gestational age. FISH on metaphase chromosomes using probes for unique sequences has greatly expanded the resolution of conventional chromosome analysis. This has been dem-

onstrated in countless case reports by the diagnosis of structural changes at the submicroscopic level (e.g., microdeletion syndromes) or by the determination of the origin of marker chromosomes and complex structural changes.²⁰⁰

Complications of Amniocentesis

A common finding after amniocentesis is cramping that lasts for 1 to 2 hours. Lower abdominal discomfort may occur for up to 48 hours after the procedure but is usually not severe. Fortunately, serious maternal complications such as septic shock are rare. Amnionitis occurs in 0.1% of cases²⁸⁰ and can occur from contamination of the amniotic fluid with skin flora or from inadvertent puncture of the maternal bowel. It may also follow procedure-induced amnion rupture. Postamniocentesis chorioamnionitis can have an insidious onset and frequently appears with flulike symptoms and with few early localizing signs. This can evolve into a systemic infection with marked maternal morbidity unless early aggressive treatment is undertaken. Therefore, a high index of suspicion is necessary.

The development of rhesus isoimmunization occurs in approximately 1% of Rh-negative women undergoing amniocentesis,²⁸¹⁻²⁸³ but it can be avoided by prophylactic administration of anti-D immunoglobulin after the procedure.

Amniotic fluid leakage or vaginal bleeding is noted by 2% to 3% of patients after amniocentesis. Unlike spontaneous second-trimester amnion rupture, which has a dismal prognosis, fluid leakage after amniocentesis usually resolves after a few days of bed rest. Successful pregnancy outcome after such an event is common.²⁸⁴ Occasionally,

leakage of amniotic fluid persists throughout pregnancy,^{285,286} but if the amniotic fluid volume remains adequate, a good outcome can be anticipated.

Pregnancy Loss after Mid-Trimester Amniocentesis

The safety of mid-trimester amniocentesis was documented in the mid 1970s by three collaborative studies performed in the United Kingdom, the United States, and Canada.^{285,287,288} These studies, performed prior to the clinical use of ultrasound, were not randomized but rather included unsampled matched control groups. The U.S. and Canadian studies showed similar loss rates (spontaneous abortions, stillbirths, and neonatal deaths) between the two groups. A greater risk of loss occurred with needles of 19 gauge or larger and with more than two needle insertions per procedure. Both studies reported total postprocedure loss rates of 3% to 4%.

In contrast to these studies, the British Collaborative Study found an excess of fetal loss (1% to 1.5%) in the amniocentesis group compared with control subjects. This study has been criticized for a number of concerns, including a significant proportion of sampled patients with elevated MSAFP levels, an unusually low complication rate in the control group, and a change in the matching criteria during the study.

Seeds²⁸⁹ performed a contemporary review of more than 68,000 amniocenteses from centers reporting 1000 or more procedures and analyzed results from both controlled and noncontrolled studies (Table 17-27). From this analysis he concluded the following:

TABLE 17-27 STUDIES* DESCRIBING ULTRASOUND GUIDANCE TO VISUALIZE NEEDLE PLACEMENT

Study (ref)	Amniocentesis cases (N)	Losses at ≤28 Weeks' Gestation (n)	Control Type, No. of Losses (No. of Control Subjects)	Comment
Farahani et al (530), 1984	2100	19 (0.9%)	Unmatched, 11 (2200)	No fetal trauma detected
Leschot et al (531), 1985	2920	64 (2.19%)		
Dacus et al (293), 1985	1981	32 (1.6%)	Randomized, 8 (2270)	Risk increased with the number of passes, bloody fluid, or no ultrasound scan
Tabor et al (294), 1986	2242	29 (1.3%)		
Andreason and Kristoffersen (532), 1989	1289	28 (2.2%)	Unmatched, 2 (258)	More risk with transplacental
Bombard et al (261), 1995	1000	12 (1.3%)		
Marthin et al (262), 1997	2083	28 (1.3%)	Matched, 29 (2045)	No increase with transplacental
Canadian Early and Mid Trimester Amniocentesis Trial (266), 1999	2090	40 (1.9%)		
Eiben et al (533), 1997	1802	12 (0.8%)		
Tongsong et al (534), 1998	2045	36 (1.8%)		
Roper et al (535), 1999	2924	35 (1.2%)		
Reid et al (536), 1999	3774	29 (0.8%)	Unmatched, 80 (5324)	More risk, but not significant with transplacental
Antsaklis et al (291), 2000	3696	79 (2.1%)		
Horger et al (537), 2001	4198	35 (0.83%)	Unmatched, 80 (5324)	Losses only to 60 days after procedure
Totals	34,144	478 (1.4%)		

*Studies include those with at least 1000 cases, with or without control subjects.

From Seeds JW: Diagnostic mid trimester amniocentesis: How safe? *Am J Obstet Gynecol* 191:607-615, 2004.

1. Amniocentesis with concurrent ultrasound guidance is associated with a procedure-related rate of excess pregnancy loss of 0.33% (95% CI, 0.09 to 0.56) in a comparison of all studies. Among only controlled studies, the procedure-related rate of loss is 0.6% (95% CI, 0.31 to 0.90). When calculating the total postprocedure rate of loss (to 28 weeks' gestation), the procedure-induced losses should be added to the 1.08% rate of natural losses occurring in women not undergoing amniocentesis.
2. The use of concurrent ultrasound guidance appears to reduce the number of punctures and the incidence of bloody fluid. In a comparison of all studies, pregnancy loss is diminished with the use of concurrent ultrasound guidance; however, when only controlled studies are compared, this trend remains, but the advantage is not significant.
3. The reported experience does not support an increased rate of pregnancy loss after placental puncture. Transplacental amniocentesis is associated with an aggregate rate of reported loss of 1.4%, which is identical to the overall rate of loss among all amniocentesis patients and lower than that reported from controlled studies.

Certain clinical factors influence the risk of pregnancy loss, independent of the amniocentesis procedure. For example, spontaneous abortion is more common in older patients and may be more common among patients of any age with an abnormal serum screen result. A prior pregnancy loss is reported to increase the risk, as is previous vaginal bleeding. The number of needle placements, the observation of bloody fluid, and especially the observation of green or murky fluid are seen to be associated with a significantly increased risk of pregnancy loss after amniocentesis.²⁹⁰⁻²⁹⁵

The only prospective randomized controlled trial evaluating the safety of second-trimester amniocentesis is a Danish study, which reported on 4606 low-risk healthy women, 25 to 34 years old, who were randomly allocated to either amniocentesis or ultrasound examination.²⁹⁴ The total fetal loss rate in the amniocentesis group was 1.7% and in the control subjects, 0.7% ($P < .01$). The observed difference of 1% (95% CI, 0.3 to 1.5) gave a relative risk of 2.3. The conclusions of this study were initially criticized because the original report stated that a 17-gauge needle (which is associated with higher risks than smaller needles) was used. Tabor and colleagues²⁹⁵ subsequently reported that they had in fact used a 20-gauge needle for most of the procedures.

Both the U.K. and Danish studies^{290,294} found an increase in respiratory distress syndrome and pneumonia in neonates from the amniocentesis groups. Other studies have not found this association. The U.K. study also showed an increased incidence of talipes and dislocation of the hip in the amniocentesis group.²⁸⁸ This finding has not been confirmed.

In early experience with amniocentesis, needle puncture of the fetus was reported in 0.1% to 3.0% of cases^{285,296} and was associated with fetal exsanguination,²⁹⁷ intestinal atresia,^{298,299} ileocutaneous fistula,³⁰⁰ gangrene of a fetal limb,³⁰¹ unioocular blindness,³⁰² porencephalic cysts,³⁰³ patellar tendon disruption,³⁰⁴ skin dimples,³⁰⁵ and peripheral nerve damage.²⁹⁶ Continuous use of ultrasound to guide the needle minimizes needle puncture of the fetus, which, in experienced centers, is an exceedingly rare but still seen complication.²⁸⁹

No long-term adverse effects have been demonstrated in children undergoing amniocentesis. Baird and colleagues³⁰⁶ compared 1296 liveborn children whose mothers had a mid-trimester amniocentesis to unsampled control subjects. With the exception of hemolytic disease resulting from isoimmunization, the offspring of women who had amniocentesis were no more likely than control subjects to have a dis-

ability during childhood and adolescence. Finegan and colleagues³⁰⁷ reported an increased incidence of middle-ear abnormalities in children whose mothers had amniocentesis.

Amniocentesis Performed before 15 Weeks' Gestation (Early Amniocentesis)

The desire for a first-trimester diagnosis stimulated interest in the feasibility of performing amniocentesis at less than 15 weeks' gestation. The technique at this gestational age varies from conventional amniocentesis in that less fluid is available and incomplete fusion of the amnion and chorion frequently cause tenting of the membranes, resulting in failed procedures in 2% to 3% of cases.^{266,308}

Although initial experience with early amniocentesis was reassuring,³⁰⁹⁻³¹² subsequent studies have raised serious concerns about its safety. In 1994, Nicolaides and coworkers³¹³ reported on more than 1300 women undergoing first-trimester diagnoses. In this study, significantly higher rates of fetal loss (5.3% versus 2.3%) were seen in the early amniocentesis group. This finding was echoed by Vandebussche and coworkers,³¹⁴ who reported a 6.7% higher occurrence of pregnancy loss for early amniocentesis compared with CVS. Sundberg and colleagues,³¹⁵ in a prospective randomized comparison of CVS to early amniocentesis, also found a higher loss rate with early amniocentesis but had to terminate the study early because of an unanticipated increase in talipes equinovarus (clubfoot) in the early amniocentesis group. Higher loss rates have also been found when comparing early amniocentesis to second-trimester amniocentesis. The Canadian Early and Mid-Trimester Amniocentesis trial reported a 1.7% higher incidence of fetal loss in the early amniocentesis group compared with second-trimester sampling when taking all fetal losses into account (7.6% versus 5.9%).³⁰⁸ There is also an increased frequency of culture failure and ruptured membranes compared with later procedures.^{308,313,315}

Of most concern is that fetal talipes equinovarus occurs in 1% to 2% of cases sampled by early amniocentesis.^{308,313,315,316} This rate is 10-fold higher than the 1 per 1000 births seen in the U.S. population. The clubfoot deformities are believed to occur secondary to procedure-induced fluid leakage, because they occurred in 1% of cases in which no leakage occurred and in 15% of cases when leakage occurred.³⁰⁸ For these reasons, amniocentesis should rarely, if ever, be performed before the 13th week of gestation. The safety of amniocentesis in weeks 13 and 14 is uncertain. Until its safety can be ensured, it is best to delay routine sampling until week 15 or 16 of pregnancy.

Chorionic Villus Sampling

The major drawbacks of conventional second-trimester genetic amniocentesis are the delayed availability of the karyotype and the increased medical risks of a pregnancy termination late in pregnancy. Furthermore, delaying the procedure until after fetal movement is appreciated by the mother is believed to inflict a severe emotional burden on the patient. As a result of these concerns, attempts have been made to move prenatal diagnosis into the first trimester. CVS, which samples the developing placenta rather than penetrating the amniotic membrane, has been the most successful approach to date at accomplishing this.

History of Chorionic Villus Sampling

The ability to sample and analyze villus tissue was demonstrated more than 25 years ago by the Chinese, who, in an attempt to develop a technique for fetal sex determination, inserted a thin catheter into the

uterus guided only by tactile sensation.³¹⁷ When resistance from the gestational sac was felt, suction was applied and small pieces of villi were aspirated. Although this approach seems crude by today's standards of ultrasonically guided invasive procedures, their diagnostic accuracy and low miscarriage rate demonstrated the feasibility of first-trimester sampling.

Initial experiences in other parts of the world were not as promising. In 1968, Hahnemann and Mohr³¹⁸ attempted blind transcervical trophoblast biopsy in 12 patients using a 6-mm diameter instrument. Although successful tissue culture was possible, half of these subjects subsequently aborted. In 1973, Kullander and Sandahl³¹⁹ used a 5-mm-diameter fiberoptic endocervicoscope with biopsy forceps to perform transcervical CVS in patients requesting pregnancy termination. Although tissue culture was successful in approximately half of the cases, two subjects subsequently became septic.

In 1974, Hahnemann³²⁰ described further experience with first-trimester prenatal diagnosis using a 2.5-mm hysteroscope and a cylindrical biopsy knife. Once again, significant complications, including inadvertent rupture of the amniotic sac, were encountered. By this time, the safety of mid-trimester genetic amniocentesis had become well established, and further attempts at first-trimester prenatal diagnosis were temporarily abandoned in the Western Hemisphere.

Two technologic advances occurred in the early 1980s that allowed reintroduction of CVS. The first of these was the development of real-time sonography, making continuous guidance possible. At the same time, sampling instruments were miniaturized and refined. In 1982, Kazy and associates³²¹ reported the first transcervical CVS performed with real-time sonographic guidance. That same year, Old and colleagues³²² reported the first-trimester diagnosis of β -thalassemia major using DNA from chorionic villi obtained by sonographically guided transcervical aspiration with a 1.5-mm-diameter polyethylene catheter. Using a similar sampling technique, Brambati and Simoni³²³ diagnosed trisomy 21 at 11 weeks' gestation.

After these preliminary reports, several CVS programs were established both in Europe and the United States, with the outcomes informally reported to a World Health Organization (WHO)-sponsored registry maintained at Jefferson Medical College in Philadelphia. This registry, along with single-center reports, was used to estimate the safety of CVS until 1989, when two prospective multicenter studies, one from Canada³²⁴ and one from the United States,³²⁵ were published and confirmed the safety of the procedure.

Technique of Transcervical Chorionic Villus Sampling

Ultrasound examination immediately before the procedure confirms fetal heart activity, appropriate size, and placental location. The position of the uterus and cervix is determined, and a catheter path is mapped. If the uterus is anteverted, additional filling of the bladder can be used to straighten the uterine position. Although most procedures require a moderately filled bladder, an overfilled bladder is discouraged, because it lifts the uterus out of the pelvis, lengthening the sampling path, which can diminish the flexibility required for catheter manipulation. Occasionally, a uterine contraction interferes with passage of the catheter. Delaying the procedure until the contraction dissipates is suggested (Fig. 17-8).

When the uterine condition and location are favorable, the patient is placed in the lithotomy position, and the vulva and vagina are aseptically prepared with povidone-iodine solution. A speculum is inserted, and the cervix is similarly prepared. The distal 3 to 5 cm of the sampling catheter is molded into a slightly curved shape and the catheter gently passed under ultrasound guidance through the cervix until a loss of resistance is felt at the endocervix. The operator then waits until the sonographer visualizes the catheter tip. The catheter is then advanced parallel to the chorionic membranes to the distal edge of the placenta. The stylet is then removed and a 20-mL syringe containing nutrient medium is attached. Negative pressure is applied by means of the syringe and the catheter removed slowly.

The syringe is then visually inspected for villi. These can frequently be seen with the naked eye as white branching structures floating in the medium. On occasion, however, viewing the samples under a low-power dissecting microscope is necessary to confirm the presence of sufficient villi. Maternal decidua is frequently retrieved with the sample but is usually easily recognized by its amorphous appearance. If sufficient villi are not retrieved with the initial pass, a second insertion can be made with minimal impact on pregnancy loss rate.

Technique of Transabdominal Chorionic Villus Sampling

Continuous ultrasound is used to direct a 19- or 20-gauge spinal needle into the long axis of the placenta (Fig. 17-9). After removal of the stylet, villi are aspirated into a 20-mL syringe containing tissue culture media. Because the needle is somewhat smaller than

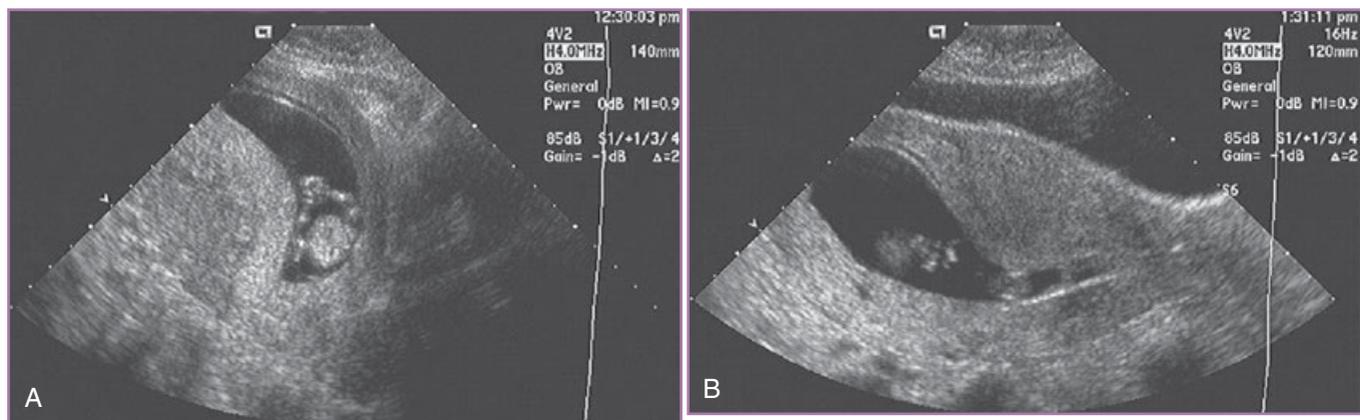

FIGURE 17-8 Ultrasound photos of a transcervical chorionic villus sampling. **A**, Typical uterine focal contraction characteristic of this gestational age involves the posterior wall of the uterus. **B**, The same patient 60 minutes later. The contraction has dissipated, the bladder has filled, and the operator is now able to pass the catheter into the posterior chorionic frondosum.

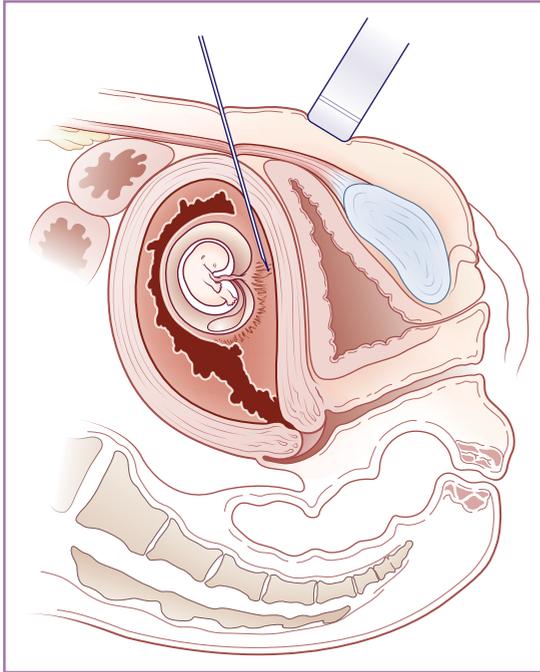

FIGURE 17-9 Transabdominal chorionic villus sampling.

Continuous ultrasound guidance is used to help guide the needle into the chorionic frondosum, remaining parallel to the plate. The sample is then obtained by back-and-forth movement of the needle while maintaining negative pressure. The needle tip is continuously kept in sight via ultrasound. (From Scioscia AL: Reproductive genetics. In Moore TR, Reiter RC, Rebar RW, et al [eds]: *Obstetrics and Gynecology: A Longitudinal Approach*. New York, Churchill Livingstone, 1993, p 72.)

the cervical sampling catheter, three or four to-and-fro passes of the needle tip through the body of the placenta are required to retrieve the villi. Unlike transcervical CVS, which is best performed before 14 weeks' gestation, the transabdominal procedure can be performed throughout pregnancy and therefore constitutes an alternative to amniocentesis or PUBS when a karyotype is needed. If oligohydramnios is present, transabdominal CVS may be the only approach available.

Comparison of Transcervical and Transabdominal Chorionic Villus Sampling

The transabdominal and transcervical approaches to villus sampling have been shown to be equally safe.^{326,327} In most cases, operator or patient choice determines the sampling route; however, in about 3% to 5% of cases, one approach is clearly preferred, so operators must be skilled in both. For example, a posterior placenta is sampled most easily by the transcervical route, whereas a fundal placenta is more simply approached transabdominally. Bowel in the sampling path may preclude transabdominal CVS in some cases, whereas necrotic cervical polyps or an active herpetic lesion should lead to transabdominal sampling.

More chorionic tissue is obtained by the transcervical method, but the proportion of cases in which less than 10 mg is obtained is similar in both groups. There are no differences in birth weight, gestational age at delivery, or congenital malformations with either method.

Laboratory Aspects of Chorionic Villus Sampling

Chorionic villi have three major components: an outer layer of hormonally active and invasive syncytiotrophoblast, a middle layer of cytotrophoblast from which syncytiotrophoblast cells are derived, and an inner mesodermal core containing blood capillaries.

The average sample from a transcervical aspiration contains 15 to 30 mg of villous material. The villi identified in the syringe are carefully and aseptically transferred for inspection and dissection under a microscope. The villi are cleaned of adherent decidua and then exposed to trypsin to digest and separate the cytotrophoblast from the underlying mesodermal core. The cytotrophoblast has a high mitotic index, with many spontaneous mitoses available for immediate chromosome analysis. The liquid suspension containing the cytotrophoblast is either dropped immediately onto a slide for analysis or may undergo a short incubation.^{328,329} This "direct" chromosome preparation can give preliminary results within 2 to 3 hours. However, most laboratories now use an overnight incubation to improve karyotype quality and thus report results within 2 to 4 days. The remaining villus core is placed in tissue culture and is typically ready for harvest and chromosome analysis within 1 week.³³⁰

The direct method has the advantage of providing a rapid result and minimizing the decidual contamination, whereas tissue culture is better for interpreting discrepancies between the cytotrophoblast and the actual fetal state. Ideally, both the direct and culture methods should be used, because they each evaluate slightly different tissue sources. Although the direct preparation is less likely to be representative of the fetus, its use minimizes the likelihood of maternal cell contamination, and, if culture fails, a nonmosaic normal direct preparation result can be considered conclusive, although rare cases of false-negative rates for trisomy 21 and 18 have been reported.^{331,332} Abnormalities in either may have clinical implications.

Most biochemical diagnoses that can be made from amniotic fluid or cultured amniocytes can usually be made from chorionic villi.³³³ In many cases, the results are available more rapidly and efficiently when villi are used, because sufficient enzyme is present to allow direct analysis rather than the products of tissue culture being required. However, for certain rare biochemical diagnoses, villi are not an appropriate or reliable diagnostic source.³³⁴ To ensure that appropriate testing is possible, the laboratory should be consulted before sampling.

Accuracy of Chorionic Villus Sampling: Cytogenetic Results

CVS is now considered a reliable method of prenatal diagnosis, but early in its development incorrect results were reported.^{329,335,336} The major sources of these errors included maternal cell contamination and misinterpretation of mosaicism confined to the placenta. Today, genetic evaluation of chorionic villi provides a high degree of success and accuracy, particularly in regard to the diagnosis of common trisomies.^{337,338} The U.S. collaborative study revealed a 99.7% rate of successful cytogenetic diagnosis, with only 1.1% of the patients requiring a second diagnostic test such as amniocentesis or fetal blood analysis to further interpret the results.³³⁸ In most cases, the additional testing was required to delineate the clinical significance of mosaic or other ambiguous results (76%), whereas laboratory failure (21%) and maternal cell contamination (3%) also required follow-up testing.

MATERNAL CELL CONTAMINATION

Chorionic villus samples typically contain a mixture of placental villi and maternally derived decidua. Although specimens are thor-

oughly washed and inspected under a microscope after collection, some maternal cells may remain and grow in the culture. As a result, two cell lines, one fetal and the other maternal, may be identified. In other cases, the maternal cell line may completely overgrow the culture, thereby leading to diagnostic errors, including incorrect sex determination,³³⁹⁻³⁴¹ and potentially to false-negative diagnoses, although there are no published reports of the latter. Direct preparations of chorionic villi are generally thought to prevent maternal cell contamination,^{328,339} whereas long-term culture has a rate varying from 1.8% to 4%.³⁴⁰ Because, in contrast to cytotrophoblast, maternal decidua has a low mitotic index, it is highly desirable for laboratories to offer a direct chromosome preparation as well as a long-term culture on all samples of chorionic villus. Even in culture, the contaminating cells are easily identified as maternal and should not lead to clinical errors. Interestingly, for reasons still uncertain, maternal cell contamination occurs more frequently in specimens retrieved by the transcervical route.³⁴⁰

Contamination of samples with significant amounts of maternal decidual tissue is almost always the result of small sample size, making selection of appropriate tissue difficult. In experienced centers in which adequate quantities of villi are available, this problem has disappeared. Choosing only whole, clearly typical villus material and discarding any atypical fragments, small pieces, or fragments with adherent decidua avoids confusion.³⁴² Therefore, if the initial aspiration is small, a second pass should be performed rather than risk inaccurate results. When proper care is taken and good cooperation and communication exist between the sampler and the laboratory, absence of even small amounts of contaminating maternal tissue can be accomplished.

CONFINED PLACENTAL MOSAICISM

The second major source of potential diagnostic error associated with CVS is mosaicism confined to the placenta. Although the fetus and placenta have a common ancestry, chorionic villus tissue does not always reflect fetal genotype.^{338,343} Although initially there was concern that this might invalidate CVS as a prenatal diagnostic tool, subsequent investigations have led to a clearer understanding of villus biology, so that accurate clinical interpretation is now possible. This understanding has also revealed new information about the etiology of pregnancy loss, discovered a new cause of intrauterine growth retardation, and clarified the basic mechanism of UPD.

Discrepancies between the cytogenetics of the placenta and the fetus occur because the cells contributing to the chorionic villi become separate and distinct from those forming the embryo in early development. Specifically, at approximately the 32- to 64-cell stage, only three to four cells become compartmentalized into the inner cell mass to form the embryo, whereas the remainder become precursors of the extraembryonic tissues.³⁴⁴ Mosaicism can then occur through two possible mechanisms.³⁴⁴ An initial meiotic error in one of the gametes can lead to a trisomic conceptus that would normally spontaneously abort. However, if during subsequent mitotic divisions one or more of the early aneuploid cells loses one of the trisomic chromosomes through anaphase lag, the embryo can be “rescued” by reduction of a portion of its cells to disomy. This results in a mosaic morula with the percentage of normal cells dependent on the cell division at which rescue occurred. More abnormal cells are present when correction is delayed to the second or a subsequent cell division. Because most cells in the morula proceed to the trophoblast cell lineage (processed by the direct preparation), it is highly probable that that lineage will continue to contain a significant number of trisomic cells. On the other hand, because only a small proportion of cells are incorporated into the inner cell mass, involvement of the fetus depends on the random distribution of the aneuploid progenitor cells. Involvement of the mesenchymal

core of the villus, which also evolves from the inner cell mass, is similarly dependent on this random cell distribution. Noninvolvement of the fetal cell lineage produces “confined placental mosaicism,” in which the trophoblast and perhaps the extraembryonic mesoderm will have aneuploid cells but the fetus will be euploid.

In the second mechanism, mitotic postzygotic errors produce mosaicism with the distribution and percent of aneuploid cells in the morula or blastocyst dependent on the timing of nondisjunction. If mitotic errors occur early in the development of the morula, they may segregate to the inner cell mass and have the same potential to produce an affected fetus as do meiotic errors. Mitotic errors occurring after primary cell differentiation and compartmentalization have been completed lead to cytogenetic abnormalities in only one lineage.

Meiotic rescue can lead to UPD. This occurs because the original trisomic cell contained two chromosomes from one parent and one from the other. After rescue, there is a theoretical one-in-three chance that the resulting pair of chromosomes came from the same parent, which is called UPD. UPD may have clinical consequences if the chromosomes involved carry imprinted genes in which expression is based on the parent of origin. For example, Prader-Willi syndrome may result from uniparental maternal disomy for chromosome 15. Therefore, a CVS diagnosis of confined placental mosaicism for trisomy 15 may be the initial clue that UPD could be present and lead to an affected child.^{345,346} Because of this, all cases in which trisomy 15 (either complete or mosaic) is confined to the placenta should be evaluated for UPD by amniotic fluid analysis. In addition to chromosome 15, chromosomes 7, 11, 14, and 22 are believed to be imprinted and require similar follow-up.³⁴⁷

Confined placental mosaicism (unassociated with UPD) can alter placental function and lead to fetal growth failure or perinatal death.^{344,348-353} The exact mechanism by which abnormal cells within the placenta alter function is unknown, but the effect is limited to specific chromosomes. For example, confined placental mosaicism for chromosome 16 leads to severe intrauterine growth restriction, prematurity, or perinatal death, with less than 30% of pregnancies resulting in normal, appropriate-for-gestational-age, full-term infants.^{15,29,349,354,355}

Mosaicism occurs in about 1% of all CVS samples^{337,340,354,356} but is confirmed in the fetus in only 10% to 40% of these cases. In most cases, if the mosaic results are confined to the placenta, fetal development will be normal. If the mosaic cell line involves the fetus, significant phenotypic consequences are possible. The probability of fetal involvement appears to be related to the tissue source in which the aneuploid cells were detected, with culture results more likely than direct preparation to reflect a true fetal mosaicism.

The specific chromosome involved also predicts the likelihood of fetal involvement.³⁴⁷ Phillips and coworkers¹⁵ demonstrated that autosomal mosaicism involving common trisomies (i.e., 21, 18, and 13) was confirmed in the fetus in 19% of cases, whereas uncommon trisomies involved the fetus in only 3%. When sex chromosome mosaicism was found in the placenta, the abnormal cell line was confirmed in the fetus in 16% of cases.

When placental mosaicism is discovered, amniocentesis can be performed to elucidate the extent of fetal involvement. When mosaicism is limited to the direct preparation, amniocentesis correlates perfectly with fetal genotype.¹⁵ When a mosaicism is observed in tissue culture, amniocentesis predicts the true fetal karyotype in approximately 94% of cases, with both false-positive and false-negative results seen.¹⁵ Three cases were reported of mosaic trisomy 21 on villus culture, and despite a normal amniotic fluid analysis, a fetus or newborn was born with mosaic aneuploidy.³³⁸

If mosaicism is found, follow-up amniocentesis should be offered in most cases. Under no circumstances should a decision to terminate a pregnancy be based entirely on a CVS mosaic result. For CVS mosaicism involving sex chromosome abnormalities, polyploidy, marker chromosomes, structural rearrangements, and most uncommon trisomies, the patient can be reassured if amniocentesis results are euploid and detailed ultrasonographic examination is normal. However, no guarantees should be made. As described previously, in certain cases testing for UPD is indicated. If common trisomies (21, 18, 13) are involved, amniocentesis should be offered, but the patient must be advised of the possibilities of a false-negative result. Follow-up may include detailed ultrasonography, fetal blood sampling, or fetal skin biopsy. At present, the predictive accuracy of these additional tests is uncertain.

Pregnancy Loss after Chorionic Villus Sampling

Although loss rates after CVS (calculated from the time of the procedure until 28 weeks' gestation) are approximately 1% greater than those after amniocentesis (2.5% versus 1.5%), this comparison fails to take into consideration that the background miscarriage rate at 11 to 13 weeks is about 1% greater than at 15 to 16 weeks. To appropriately compare the two procedures, studies must enroll all patients in the first trimester, assign them to either approach, and then calculate the frequency of all subsequent losses, including spontaneous and induced abortions. In 1989, the Canadian Collaborative CVS/Amniocentesis Clinical Trial Group³²⁴ reported such a prospective randomized trial and demonstrated equivalent safety of CVS and second-trimester amniocentesis. In more than 2650 patients assigned to either procedure, there was a 7.6% loss rate in the CVS group and a 7.0% loss rate in the amniocentesis group (relative risk [RR] = 1.10; 95% CI, 0.92 to 1.30). No significant differences were noted in the incidence of preterm birth, low birth weight, or rate of maternal complication.

A U.S. multicenter prospective nonrandomized study enrolled 2235 women in the first trimester who chose either transcervical CVS or second-trimester amniocentesis.³²⁵ An excess pregnancy loss rate of 0.8% in the CVS group over the amniocentesis group was calculated, which was not statistically significant. Repeated catheter insertions were significantly associated with pregnancy loss, with cases requiring three or more passes having a 10.8% spontaneous abortion rate, compared with 2.9% in cases that required only one pass.

Further information comes from a Danish randomized trial, which assigned 1068 patients to transcervical CVS, 1078 to transabdominal CVS, and 1158 to second-trimester amniocentesis. There was no difference in loss rates between transabdominal CVS and amniocentesis (RR = 0.9; 95% CI, 0.66 to 1.23). Overall, there was a slightly increased risk of pregnancy loss after CVS (RR = 1.30; 95% CI, 1.01 to 1.67) compared with amniocentesis, which was completely accounted for by an excess of losses in the group sampled transcervically (RR = 1.70; 95% CI, 1.30 to 2.22)—the technique with which this group of investigators had the least experience. Excess loss after transcervical CVS has not been replicated in four other direct comparisons.^{326,327,357,358}

A prospective, randomized, collaborative comparison of more than 3200 pregnancies, sponsored by the European Medical Research Council,³⁵⁹ reported that CVS had a 4.6% greater pregnancy loss rate than amniocentesis (RR = 1.51; 95% CI, 1.24 to 1.84). The present consensus is that operator inexperience with CVS accounts for the discrepancy between this trial and the other major studies. The U.S. trial consisted of seven experienced centers and the Canadian trial 11, whereas the Medical Research Council trial used 31. There were, on

average, 325 cases per center in the U.S. study, 106 in the Canadian study, and 52 in the European trial.

In conclusion, when appropriately compared, CVS and amniocentesis are equally safe, but the impact of operator experience cannot be underestimated. CVS, particularly the transcervical approach, has a relatively prolonged learning curve. Saura and colleagues³⁶⁰ suggested that more than 400 cases may be required before safety is maximized. The role of experience is further demonstrated by three sequential trials sponsored by the National Institute of Child Health and Human Development in which the majority of operators remained relatively constant. The postprocedure loss rate after CVS fell from 3.2% in the initial trial performed from 1985 to 1987,³²⁵ to 2.4% for the trial performed from 1987 to 1989,³²⁷ to only 1.3% in their most recent experience of 1997 to 2001.³¹⁶ Most recently, Caughey and coworkers³⁶¹ confirmed the continuing improvement seen with experience. When outcomes from their center were analyzed in 5-year time intervals, the overall postprocedure loss rate decreased from 4.4% in the interval from 1983 to 1987, to 1.9% from 1998 to 2003. When compared with their amniocentesis loss rates, no statistical or clinical difference between the two procedures was seen in the most recent interval.

Other Complications of Chorionic Villus Sampling

Postprocedure bleeding is the most common complaint after CVS. Most centers report postprocedure bleeding in 7% to 10% of patients sampled transcervically, whereas bleeding or spotting is relatively uncommon after transabdominal sampling, occurring in 1% or less of cases.³²⁵ Minimal spotting may occur in up to one third of women sampled by the transcervical route.³²⁵ On occasion, a small subchorionic hematoma may be seen after sampling.³⁶² This usually resolves spontaneously within a few weeks and is rarely associated with adverse outcome. Hematomas occur when the catheter is passed too deeply into the underlying vascular decidua basalis. Because passage into the decidua gives a "gritty" sensation, careful attention to the feel of the catheter can minimize this complication. Operators should also avoid sampling near or within large placental "lakes," which also leads to bleeding.³⁶³

Since the initial development of transcervical CVS, there has been concern that transvaginal passage of an instrument would introduce vaginal flora into the uterus. Although cultures of catheter tips have isolated bacteria in 30% of transcervical CVS cases,³⁶⁴⁻³⁶⁷ the incidence of chorioamnionitis is extremely low and occurs equally infrequently after either the transcervical or transabdominal procedure. In the U.S. collaborative trial, infection was suspected as a possible etiology of pregnancy loss in only 0.3% of cases.³²⁵

Early in the development of transcervical CVS, two life-threatening pelvic infections were reported.^{368,369} The practice of using a new sterile catheter for each insertion was subsequently universally adopted, and there have been no additional reports of serious infections. Infection after transabdominal CVS has been demonstrated and may result from inadvertent bowel puncture by the sampling needle.³²⁶

Acute rupture of membranes is exceedingly rare in experienced centers.³²⁵ Fluid leakage with oligohydramnios has been reported days to weeks after the procedure.^{370,371} In most cases, this is unrelated to the procedure but occasionally may be secondary to a procedure-induced hematoma.

An acute rise in MSAFP after CVS has consistently been reported, implying a detectable degree of fetomaternal bleeding.³⁷¹⁻³⁷⁴ The MSAFP elevation is not related to the technique used to retrieve villi but seems to depend on the quantity of tissue aspirated.³⁷⁴ Levels return to normal ranges by 16 to 18 weeks of gestation, thus allowing

MSAFP serum screening to proceed according to usual prenatal protocols. All Rh-negative nonsensitized women undergoing CVS should receive Rh-D immune globulin after the procedure. Exacerbation of preexisting Rh immunization after CVS has been described. Existing Rh sensitization, therefore, represents a contraindication to the procedure.³⁷⁵

Risk of Fetal Abnormality after Chorionic Villus Sampling

Firth and colleagues³⁷⁶ reported five occurrences of severe limb abnormalities out of 289 pregnancies sampled by CVS between 56 and 66 days. Four of these cases had the unusual but severe oromandibular-limb hypogenesis syndrome, which occurs in the general population at a rate of 1 per 175,000 births.³⁷⁶ Burton and coworkers³⁷⁷ then reported on 14 more post-CVS cases of limb reduction defects (LRD), ranging from mild to severe, only two of which occurred when sampling was performed beyond 9.5 weeks. After these two early reports, the WHO gathered additional data from its CVS registry, published reports,^{376,377} and case-controlled studies^{378,379} and concluded that “far greater data supporting CVS not being associated with LRD were available in various collaborative studies, in individual centers having the greatest experience, and in the WHO-initiated registry comprising 138,996 procedures.”³⁸⁰ They further concluded that CVS was not associated with LRD when performed after 8 completed weeks of pregnancy.³⁸¹ This infrequent occurrence of LRD after CVS was echoed by the American College of Obstetricians and Gynecologists, who stated that a risk for LRD of 1 in 3000 would be a prudent upper limit for counseling patients. Data on 216,381 procedures are now in the WHO CVS registry and have been reported.³⁸⁰ This report analyzed the frequency of limb anomalies, their pattern, and their associated gestational age at sampling and found no overall increased risk of LRD or any difference in the pattern of defects compared with the general population. To analyze a possible temporal relationship between CVS and LRD, a subset of 106,383 cases was stratified by the week at which the procedure was performed. The incidence of LRD was 11.7, 4.9, 3.8, 3.4, and 2.3 per 10,000 CVS procedures in weeks 8, 9, 10, 11, and more than 12, respectively. Only the rate at week 8 exceeded the background risk of 6.0 per 10,000 births. If cases from the cluster seen in the original report of Firth and coworkers³⁷⁶ are removed, the rate for week 8 procedures also falls below baseline. Brambati and colleagues,³⁸² in a small series of early CVS cases, had an LRD incidence of 1.6% for procedures performed in weeks 6 and 7, 0.1% in week 8, and (population frequency) 0.059% in week 9.

Present data confirm that performing CVS in the standard gestational window of 10 to 13 weeks does not increase the risk of LRD. Sampling before 10 weeks is not recommended, except in very unusual circumstances, such as when a patient’s religious beliefs may preclude a pregnancy termination beyond a specific gestational age.¹¹² These patients, however, must be informed that the incidence of severe LRD could be as high as 1% to 2%.

Prenatal Diagnosis and Multiple Gestation

Risk of Fetal Aneuploidy in Multiple Gestations

The overall probability that a given multiple gestation contains an aneuploid fetus depends on its zygosity. Because monozygotic twins originate from the same gamete, both fetuses possess the same karyotype, and the overall risk of aneuploidy is that of a singleton. Although this construct ignores the very small possibility of mitotic nondisjunc-

tion, such a possibility is such a rare occurrence that it should not change the overall risk calculation. In dizygotic twins, on the other hand, either one or both fetuses may be affected, with the chance for aneuploidy in either fetus being independent.

The risk of both dizygotic twin fetuses being affected is low (the singleton risk squared), whereas the risk of at least one affected fetus is approximately twice the singleton risk.³⁸³ These risks can be used to counsel patients if the zygosity is known.

If zygosity is unknown, the ratio of the risk of at least one fetus (in a twin pregnancy) being aneuploid to the risk of a singleton gestation being aneuploid can be approximated as 5:3. This approximation is based on the assumption that one third of all twin gestations are monozygotic twins. Despite the slight inaccuracy of this approach caused by the varying rates of monozygotic twins and dizygotic twinning with maternal age and ethnicity, this approximation is quite satisfactory for patient counseling. A more accurate determination taking these variations into account has been published by Meyers and colleagues.³⁸⁴ Based on these calculations, a 32-year-old woman with twins has nearly the same risk of having at least one aneuploid fetus as a 35-year-old woman with a singleton. Present recommendations are that invasive prenatal diagnosis be offered at this cutoff. Table 17-28 demonstrates the risk of fetal aneuploidy at different maternal ages in twin gestations using these calculations.

Higher-order multiple gestations resulting from assisted reproductive technology (ART) have a greater predilection for polyzygosity than naturally occurring multiples. The risk of at least one aneuploid fetus can be approximated as the singleton risk multiplied by the number of fetuses. Despite the fact that recent studies have shown that monozygotic twin pregnancies occur more frequently than anticipated after the use of ART,^{385,386} their frequency still remains low enough that this estimate is appropriate.

An even steeper increase in the risk of gene transmission for pregnancies at risk for mendelian disorders occurs with multiple gestations. For example, for a twin gestation at risk for an autosomal recessive disorder, there is a three-in-eight chance of at least one fetus being affected, and a one-in-eight chance that both will inherit the affected genes.

Screening Tests in Twins SECOND TRIMESTER

For singleton pregnancies, second-trimester biochemical screening is a routine practice. For twins, however, the value and accuracy of serum screening is much less certain because the contribution of an abnormal fetus will, on average, be brought closer to the normal mean

TABLE 17-28 CALCULATED RISK, AT TERM, OF DOWN SYNDROME IN AT LEAST ONE FETUS IN TWIN GESTATIONS

by an unaffected co-twin. This tends to decrease the overall screening sensitivity. Screening, however, can be useful nonetheless.

The mean and median values of MSAFP, unconjugated estriol, and hCG in twins have been studied and are presented in Table 17-29. Dividing the measured result by the twin median can be used to estimate a twin MoM for each analyte. These MoM values can then be used in singleton algorithms to estimate a risk of aneuploidy. Neveux and coworkers³⁸⁷ evaluated this approach and, based on a calculated model, predicted that 73% of monozygotic twin and 43% of dizygotic twin cases with a Down syndrome fetus would be detected with a 5% false-positive rate. In their clinical sample of 274 twin pregnancies, 5.5% screened positive. They had no cases of Down syndrome, making evaluation of the sensitivity difficult. Presently, the use of biochemical markers for aneuploidy screening in multiple gestations is extremely limited and is not recommended for general practice.

For the detection of neural tube defects, the levels of maternal AFP are again affected by the presence of a co-fetus. The mean MSAFP level in twin pregnancies ranges from 2.0 to 2.5 MoM. This is not surprising, considering double production. In singleton gestations, an MSAFP upper cutoff of 2.5 MoM will identify 75% of fetuses with a neural tube defect and has a false-positive rate between 2% and 3.3%. A similar cutoff in twin gestations would identify 99% of anencephalic fetuses and 89% of open neural tube defects,³⁸⁸ but this would be associated with an unacceptably high false-positive rate of 30%. A twin false-positive rate similar to that for singletons can be calculated by doubling the singleton cutoff level; for example, choosing an MSAFP cutoff value of 5.0 MoM for twins would have the same false-positive rate as a 2.5 MoM cutoff in singletons. The detection rate will be lower, however, because, when only one fetus has a neural tube defect, the normal coexisting fetus will contribute an AFP level near the singleton median. Maintaining the 75% sensitivity accomplished with singleton screening would require an MSAFP elevation of approximately 3.5 MoM, which would have a false-positive rate of 15%.

Presently, there is no standard agreement on the MSAFP elevation that warrants further evaluation in twins. Some centers use a cutoff of 4.0 MoM, which would identify approximately 60% of fetuses with open spina bifida but has approximately an 8% incidence of false-positive results. Other centers use a cutoff of 4.5 MoM, which has a sensitivity of approximately 50%.

FIRST TRIMESTER

First-trimester combined screening (NT, PAPP-A, hCG) for Down syndrome can be performed in twin gestations and may be preferable to second-trimester screening, as a fetus-specific risk rather than a pregnancy-specific risk can be obtained.^{115,389} The analyte levels are adjusted for twins as done for second-trimester screening (see Table 17-29). In dichorionic gestations, the NT of individual fetuses is measured, and then a fetus-specific risk is obtained using maternal age and

analyte levels. In monochorionic gestations in which the fetal karyotypes are identical, the NT measurements are averaged and a single likelihood ratio is calculated. This is combined with maternal age and serum analyte levels, resulting in a pregnancy-specific risk.

Overall, first-trimester combined Down syndrome screening in twins has a 72% detection rate with a 5% false-positive rate.³⁸⁹ Using NT alone is less efficient, with a 69% detection rate. The performance of this approach is better for monochorionic gestations, as both fetuses will be affected and the analyte values from each will trend in the same direction. In dichorionic pregnancies, which are more likely to be dizygotic and have discordant karyotypes, the abnormal biochemical analytes from an affected gestation may be diluted by those from the normal fetus. Theoretical modeling suggests that combined screening has an 84% detection rate with a 5% false-positive rate in monochorionic gestations, compared with 70% in dichorionic twins. Performance in these subgroups is better when biochemical analytes are added to NT measurements.

Amniocentesis in Multifetal Gestations

Amniocentesis in multifetal pregnancy involves puncture of the first sac, withdrawal of amniotic fluid, injection of dye to mark the sampled sac, and then a new needle insertion to puncture the second sac.³⁹⁰ If the fluid aspirated after the second puncture is clear, this is confirmation that the first sac was not resampled. If color-tinged fluid is retrieved, the needle should be removed and another attempt at sampling the second sac should be made.

History has shown the possible toxic effects of dye instillation. Methylene blue is associated with small bowel atresia^{391,392} and an increased risk of fetal death.³⁹³ Its use is now contraindicated. Use of indigo carmine (the dye of choice) has been reviewed in large series by both Cragan and coworkers³⁹⁴ and Pruggmayer and coworkers,³⁹⁵ and no increased risk for small bowel atresia or any other congenital anomaly has been found. However, because of the theoretical risk of intra-amniotic dye, instillation-free techniques have evolved.^{264,396}

A single-puncture method has been described in which the site of needle insertion is determined by the position of the dividing membrane.²⁶⁴ After entry into the first sac and aspiration of amniotic fluid, the same needle is advanced through the dividing membrane into the second sac. To avoid contamination of the second sample with fluid from the first, the first 1 mL of fluid from the second sample is discarded. This method may cause iatrogenic rupture of the dividing membrane, with creation of a monoamniotic sac and its attendant risk of cord entanglement.³⁹⁷ This appears to occur almost exclusively in monochorionic gestations.

Bahado-Singh and colleagues³⁹⁸ described a technique of twin amniocentesis that entails identifying the separating membranes with a curvilinear or linear transducer. The first needle is inserted, fluid retrieved, and the needle left in place while a second needle is inserted

into the coexisting sac. Visualization of the two needle tips on alternate sides of the membrane confirms sampling of both fetuses. Patient tolerance of this technique may be a problem, as well as the potential requirement of two operators when sampling.

Complications of Amniocentesis in Multiple Gestation. A comparison of the relative safety of any invasive procedure in multiple gestations must take into consideration that, at any gestational age, loss rates for multiples are significantly higher than for singletons. Evaluation of the safety of invasive procedures, therefore, needs to be kept in context. Most series report postprocedure loss rates between 2% and 5% (Table 17-30). Literature evaluating the risk of pregnancy loss before 28 weeks in unsampled twins with a normal second-trimester ultrasound demonstrates rates of 4.5%,³⁹⁹ 5.8%,⁴⁰⁰ and 7.2%,⁴⁰¹ which helps to put the increase in postprocedure rates into perspective. However, the ideal way to evaluate procedure-induced loss rates is to compare similar cohorts of sampled and unsampled twins. Ghidini and colleagues⁴⁰² evaluated the risk of amniocentesis in twins by comparing 101 sampled pregnancies with an unsampled control group scanned at a matching gestational age. No significant difference in total loss rate was detected. A recent report attributed a 2% higher loss rate with amniocentesis (2.7% versus 0.6%) as compared with singletons or nonsampled twin gestations, with 13 losses in 476 pregnancies (95% CI, 1.5 to 4.6).⁴⁰³ The makeup of the sampled group was 47% with maternal age of at least 35 years, 21% with abnormal MSAFP, and 11% with abnormal ultrasound, which could have affected loss rates. No study in the current literature has the power to definitively quantify the procedure-induced loss rate in twins. Empirically, the procedure-related loss rate is 1% to 1.5%.

Patients with twins must also be counseled about the risk of finding a karyotypically abnormal child, which, because of the presence of two fetuses, is approximately twice that after a singleton procedure.³⁸³ Amniocentesis in twins does raise some very painful questions. Families need to consider the possibility of a test showing that one of the twins is normal and the other has an abnormality. Selective termination of the affected fetus is now a routine procedure and can be accomplished in 100% of cases with a postprocedure loss rate of 5% to 10% in experienced centers.²⁷⁹ However, this approach is also associated with an increased risk of preterm birth, especially when performed after 20 weeks' gestation or if the presenting fetus is terminated.⁴⁰⁴

Chorionic Villus Sampling in Multiple Gestations

Twin, as well as higher-order multiple, gestations have been sampled successfully using CVS.⁴⁰⁵⁻⁴⁰⁸ Each distinct placental site must be identified and sampled individually. Because no dye marker is available to ensure retrieval from a gestation, if there is any suspicion that two

*Loss before 22 weeks.

separate samples have not been obtained, a backup amniocentesis should be offered if the fetal sexes are concordant.⁴⁰⁵ However, this is rarely required if meticulous intraoperative ultrasound placement of the needle or catheter is performed. Another difficulty is the possible cross-contamination of samples when both placentas are on the same uterine wall (i.e., both anterior or both posterior). In these cases, sampling the lower sac transcervically and the upper transabdominally minimizes the chance of contamination. When a biochemical diagnosis is required, the potential for misinterpretation is even greater because a small amount of normal tissue could significantly alter the test result. These cases should only be sampled in experienced centers.

Complications of Chorionic Villus Sampling in Multiple Gestations. Studies assessing procedure-related loss rates after CVS sampling of twins are shown in Table 17-31. In experienced centers, no increased procedure-related loss risks are seen compared with second-trimester amniocentesis.

Which Procedure to Perform?

Whether to perform a first- or second-trimester procedure depends on a number of factors, including local availability of the procedures described. If both CVS and amniocentesis are available, the relative risks and the advantages of an earlier diagnosis need to be considered. Second-trimester amniocentesis is more readily available and technically easier to perform, but CVS provides the information more than 1 month sooner, thus giving earlier reassurance. When discordant results are encountered, if selective termination is chosen, its complications and loss rates are markedly decreased if performed at less than 16 weeks' gestation.²⁷⁹

Only one study to date has analyzed outcomes for twins after CVS compared with after second-trimester amniocentesis.⁴⁰⁷ In this work,

81 women had amniocentesis and 161 had CVS. Loss of the entire pregnancy before the 28th week followed amniocentesis in 2.9% of the cases and CVS in 3.2%. The fetal loss rate, which included loss of one fetus, was 9.3% for amniocentesis and 4.9% for CVS.

Percutaneous Umbilical Blood Sampling

In 1983, Daffos and coworkers⁴⁰⁹ described a method of obtaining fetal blood using ultrasound guidance of a 20- to 22-gauge spinal needle through the maternal abdomen into the umbilical cord. This technique (variously called PUBS, fetal blood sampling, cordocentesis, or funipuncture) offered considerable advantage in both efficacy and safety over the fetoscopic methods previously used to obtain fetal blood.

Until recently, a common reason for PUBS was the need for rapid karyotype. With the advent of rapid and safer cytogenetic diagnosis by either FISH of amniocytes or the rapid analysis of chorionic villi obtained by placental biopsy, the diagnostic indications for PUBS have changed. Currently, the primary genetic indication is evaluation of mosaic results found on amniocentesis or CVS. Most mendelian disorders that previously required fetal blood for diagnosis are now made using molecular DNA analysis of amniocytes or chorionic villi. PUBS is necessary only for the rare cases in which the specific mutation is not known. The most frequent nongenetic indications are assessment for fetal anemia, infection, and thrombocytopenia. These indications are described in detail in Chapters 24, 26, 27, and 38.

The main complication of PUBS is fetal loss, which is estimated to be approximately 2% higher than background risk.^{374,410} This exact risk is difficult to quantify because many of the fetuses studied had severe congenital malformations.

Best estimates for procedure-related risk are from the North American PUBS registry, which collected data from 16 centers in the United States and Canada. Information on 7462 diagnostic procedures performed on 6023 patients is available.⁴¹¹ Fetal loss is defined as intrauterine fetal death within 14 days of the procedure. The fetal loss rate in these cases is calculated to be 1.1% per procedure and 1.3% per patient.

The major causes for fetal loss were chorioamnionitis, rupture of membranes, puncture site bleeding, severe bradycardia, and thrombosis. The range of losses for participating centers varied from 1% to 6.7%, which reflects operator experience and differences in patient selection. These figures are subjective, relying on the operator's impression that a pregnancy loss was directly related to the procedure and not to the underlying fetal condition.

Technique of Percutaneous Umbilical Blood Sampling

Fetal vessels can be accessed within either the cord or the fetus itself. The cord is most reliably entered at the placental insertion site where it is anchored. Color Doppler imaging enhances visualization of the insertion site and is especially useful when oligohydramnios is present. Entering the cord near the umbilical insertion site or into a free loop is possible but can be more difficult. The hepatic vein is the most accessible and safe intrafetal location.⁴¹²

It is essential to verify that the blood sample is fetal in origin. The most definitive way to establish this is to compare the MCV of the retrieved red cells with a sample of maternal blood. This comparison is easily performed on small aliquots of blood by a standard channeling instrument. Fetal red blood cells are considerably larger than those of an adult, but the value is gestational-age dependent. The mean MCV

decreases from 145 fL at 16 weeks to 113 fL at 36 weeks of gestation.⁴¹³ Alternatively, one can visually confirm appropriate location of the needle by injecting a small amount of sterile saline. If the needle is in the umbilical vein, microbubbles can be seen moving toward the fetus.

Forestier and colleagues⁴¹⁴ recommended performing biochemical studies on the aspirated blood that include a complete blood count with differential analysis and determination of anti-I and anti-i cold agglutinin, β -hCG, factors IX and VIIIc, and AFP levels. It is not general practice to perform all these studies.

Other Invasive Diagnostic Procedures

On infrequent occasions, analysis of other fetal tissues may be required. Fetal skin biopsy is performed to diagnose fetal genetic skin disorders when molecular testing is not available, and it can also be helpful in the workup of fetal mosaicism for chromosomes (such as 22) known not to be manifested in fetal blood.²⁷¹ Fetal muscle biopsy for dystrophin analysis is used to diagnose muscular dystrophy in a male fetus if DNA testing is not informative.⁴¹⁵ Fetal kidney biopsy has diagnosed congenital nephrosis in utero,¹⁶⁴ and aspiration and analysis of fetal urine is imperative in the pre-shunt evaluation of fetal renal function.⁴¹⁶ Each of these procedures is performed under ultrasound guidance. Because they are only rarely required, their use is usually confined to only a few regional referral centers in hopes of limiting procedural risk.

Preimplantation Genetic Screening

Over the past two decades, methods of in vitro fertilization and embryo culture and transfer have developed into routine clinical practice. Simultaneously, the introduction of increasingly sophisticated genetic diagnostic procedures now allows prenatal diagnoses to be performed by testing one or two cells of a developing preimplantation embryo. This technique was developed initially to benefit patients at high risk for a fetal genetic disorder and for whom termination of an affected fetus was not an option. Most of these diagnoses were for relatively rare mendelian disorders. However, as the technology has progressed and the ability to perform cytogenetic analysis by FISH on single cells has improved, preimplantation genetic screening (PGS) has been used to improve outcomes for in vitro fertilization (IVF), patients with repetitive miscarriages, and women of advanced maternal age. As characterized by the European Society of Human Reproduction and Embryology, PGS is now divided into two general categories. High-risk PGS refers to analysis carried out for patients at risk of transmitting a genetic or chromosomal abnormality to their offspring. This includes single-gene defects as well as translocations and structural aberrations. Low-risk PGS (also referred to as PGS aneuploidy screening [PGD-AS]) is reserved for infertility patients undergoing in vitro fertilization, with the goal of increasing pregnancy rates by screening for aneuploidy.⁴¹⁷

The techniques available to retrieve preimplantation cells include polar body biopsy of prefertilized oocytes, biopsy of one or two cells (called blastomeres) from the six- to eight-cell early cleavage stage embryo on day 3, or removal of five to 12 cells from the trophoctoderm of the 5- to 7-day blastocyst.⁴¹⁸ In all cases, removal of the cells is well tolerated, with continued development of the embryo and no increased risk of congenital anomalies.⁴¹⁹

PGS for Karyotype Analysis

In 2003, more than 100,000 IVF cycles with PGS were reported in the United States, resulting in the birth of 48,000 babies.⁴²⁰ The most common indication was chromosomal evaluation for aneuploidy, including evaluation for both structural rearrangements and numerical abnormalities. Reciprocal translocation is the most common structural anomaly for which PGS is used. Analysis of chromosome number using FISH for chromosomes 21, 13, 18, X, and Y is performed for the indications of maternal age, a previous child with aneuploidy, repeated IVF failures, recurrent spontaneous abortions, or a combination of these.

As techniques have improved, cytogenetic results can be obtained in almost 90% of cases.^{421,422} However, clinical interpretive errors have occurred, probably because early-stage embryos are frequently mosaic, with mosaicism rates of 42% to 50%.^{421,423} Abnormal-appearing zygotes have the highest rates of mosaicism,^{421,424} but those appearing normal still carry a risk of approximately 20%.⁴²¹ Rates of mosaicism within the inner cell mass are similar to those in trophoblast precursors,⁴²⁵ showing that there is not a selection bias against aneuploid cells from integrating into the fetal precursor cells. Accordingly, the rate of misdiagnosis with one biopsied blastomere is at least 5.4%. Because of this potential for error, invasive prenatal diagnosis by CVS or amniocentesis is recommended for appropriate indications even when PGS has been performed. In contrast to blastomere biopsy, no misdiagnosis of aneuploidy has been reported with polar body biopsy to date.

Aneuploid screening and preselection of normal embryos is now used to improve in vitro fertilization implantation and pregnancy rates even if no genetic indication for testing is present. When this is performed, about 40% of embryos are suitable for transfer. The success of this approach has led to its being extended to other indications, such as repetitive aborters with normal parental karyotypes and multiple in vitro fertilization failures.

PGS for Monogenetic Disorders

PGS for monogenetic disorders requires the ability to evaluate the DNA of a single cell. To accomplish this, the DNA content of a single blastomere is amplified by PCR and then analyzed. The most common monogenetic disorders evaluated by PGS are CF, thalassemia, and spinal muscular atrophy among the autosomal recessive disorders; myotonic dystrophy, Huntington disease, and Charcot-Marie-Tooth disease among the dominant disorders; and fragile X, Duchenne/Becker muscular dystrophy, and hemophilia among the X-linked disorders. PGS is especially valuable for adult-onset autosomal disorders such as Huntington disease, when the parents want to avoid the birth of an affected child but do not wish to have their own diagnosis confirmed. Using PGS, only unaffected zygotes can be implanted without informing the parents of whether the gene was present. However, to maintain parental nondisclosure, this approach must be performed on all subsequent pregnancies, even if no evidence of the gene is seen in prior cycles.

Although the molecular diagnosis is considered to be quite accurate, errors have occurred. For example, an error may occur as a result of the failure of a primer to anneal to a relevant sequence, a phenomenon called allele dropout (ADO). This may lead to an incorrect diagnosis, especially when there is a compound heterozygote. Real-time PCR has become the optimal choice for high-risk PGS because of the limited quantity of DNA in a sample, and because of the need to provide a genotype result within a specified and limited amount of

time. The sensitivity of real-time PCR maximizes the detection of amplified DNA copies even when present in low amounts, which in turn reduces rates of amplification failure and ADO.⁴²⁶ Recent improvements in this technology have made errors exceedingly uncommon, with some centers now reporting 100% accuracy. Despite this, invasive prenatal diagnosis should still be performed to confirm the PGS result.

Perinatal Risks of IVF and PGS

Assisted reproductive technologies, including IVF, are a significant contributor to preterm delivery, predominantly through an increased rate of multiple gestations. Over 30% of ART pregnancies are twins or higher-order multiple gestations (triplets or greater), and more than half of all ART neonates are the products of multiple gestations.^{427,428} Furthermore, the frequency of monozygotic gestations and their additional perinatal risks is increased; especially with blastocyst transfers.⁴²⁸⁻⁴³²

Only recently have sufficiently sized and appropriately performed studies and meta-analyses been available to explore the perinatal effects of IVF in singleton gestations.^{427,433-438} Although the majority of pregnancies are uncomplicated, there are higher rates of adverse pregnancy outcomes. These include an increased frequency of preterm and term low birth weight, preterm deliveries, and perinatal mortality. Two well-performed meta-analyses have recently been reported. One meta-analysis of 15 studies comprising 12,283 IVF singleton offspring and 1.9 million spontaneously conceived infants demonstrated approximately a 1.6- to 2.7-fold increased risk for these outcomes.⁴³⁸ The second meta-analysis of 25 studies showed similar results, with a 1.7- to 3.0-fold increased risk in these same outcomes.⁴³⁴ Although evidence of the effect is convincing, questions remain about whether this is secondary to a treatment effect or to the underlying infertility.

Women with IVF-conceived singletons are at increased risk of preeclampsia, gestational diabetes, placenta previa, and stillbirth.⁴³⁹ They are also at a significantly higher risk of having induction of labor and both emergent and elective cesarean deliveries. Thus, some of the adverse outcomes, including low birth weight, very low birth weight, and preterm delivery, may be attributable, in part, to iatrogenic intervention. An increased incidence of abnormal placentation, including a 2.4-fold increased risk of placental abruption and a 6.0-fold increased risk of placenta previa, have been noted in IVF pregnancies compared with controls.

One of the most frequently evaluated effects of IVF is the occurrence of birth defects.^{436,437-446} Despite numerous studies, the results remain uncertain because of concerns including small sample size for specific anomalies, incomplete ascertainment of birth defects, confounding effects such as the cause of the infertility, and the potential of a parental genetic contribution. Two recent population-based studies with sufficient data to evaluate potential confounders demonstrate an increased risk for birth defects among ART infants.^{440,441} One registry-based study⁴⁴² stands out because of its large sample size, including 4555 IVF children, 4467 other ART children, and 27,078 controls from the Finnish Registry of Congenital Malformations. The adjusted odds ratio for major malformations was 1.3 (95% CI, 1.1 to 1.6). The major malformation increased was hypospadias (rate of 76/10,000 births compared with 29/10,000 in controls). Other strongly associated malformations include other genitourinary anomalies, neural tube defects, gastrointestinal defects, musculoskeletal defects, and cardiovascular defects. A meta-analysis of the prevalence of birth defects in infants after IVF or intracytoplasmic sperm injection (ICSI) compared with spontaneously conceived infants revealed a pooled odds ratio of 1.29

for 19 studies (95% CI, 1.01 to 1.67). Thus, the effect of IVF and other ART modifications on birth defects appears real but small.

Chromosomal abnormalities also appear to be slightly increased, especially after ICSI for male factor disorders.⁴⁴⁷ In one study of 8319 liveborn ICSI children, there was a slight but significant increase in sex chromosomal aneuploidy (0.6% versus 0.2%) and de novo chromosomal abnormalities (0.4% versus 0.07%). For all of these anomalies, it is not presently possible to distinguish the treatment effect from the effect of the etiology of the infertility because infertile males have a higher frequency of chromosomal abnormalities including microdeletions and translocations. Similarly, female partners of couples undergoing ART have an increased risk of chromosomal abnormalities.⁴⁴⁸ Although this risk is not high enough to routinely offer invasive testing to all women undergoing IVF, those having invasive testing to confirm PGS results should have a full karyotype analysis.

Noninvasive Prenatal Diagnosis

Many studies have demonstrated that both intact fetal cells and cell-free nucleic acids circulate freely in maternal blood. Because invasive prenatal diagnosis techniques such as CVS and amniocentesis can be expensive and associated with small risks to the mother and fetus, alternative noninvasive methods, such as searching for fetal cells and nucleic acids from maternal blood samples, are being explored. This is particularly relevant because as of January 2007, the American College of Obstetricians and Gynecologists recommended that all women who present for prenatal care before 20 weeks of gestation be offered screening and invasive testing for aneuploidy, irrespective of age, and be counseled about the differences between screening and invasive diagnostic testing.¹⁴⁵ Screening tests such as nuchal translucency and the quadruple maternal serum screen are noninvasive, but invasive procedures are required for diagnosis. Isolating fetal DNA from the maternal circulation in a reliable and reproducible manner has the potential to eradicate the small, albeit present, risks of invasive testing.

Prenatal Diagnosis Using Fetal Cells in the Maternal Circulation

Cytogenetic evaluation of fetal cells retrieved from the maternal peripheral circulation for analysis has demonstrated potential to become a noninvasive diagnostic test.⁴⁴⁹ The most promising results have been with the retrieval of fetal nucleated red blood cells. This cell line appears to be the most appropriate target, because they have specific antigens that can be used to enhance isolation⁴⁵⁰ and contaminating maternal nucleated red cells are rare. The staggeringly small number of fetal cells (0 to 20 cells in 20 mL of maternal blood) and their low concentration (one fetal cell per 100,000 to 10 million maternal cells) have hampered consistent retrieval. Over the years, laboratory techniques such as diffusion gradients, fluorescent cell sorting, and magnetic cell separation have been used to improve the yield and concentration of the fetal cells.⁴⁵¹ These approaches can increase the concentration of fetal nucleated red cells to approximately 1 in 3000 or greater. Once enriched, the cells can be analyzed using FISH probes for specific aneuploidies.

There have been a number of reports of successful retrieval of aneuploid cells from the maternal circulation of women carrying affected pregnancies.⁴⁵²⁻⁴⁵⁵ Most studies have shown sufficient enrichment for clinical analysis in approximately 50% of cases. The National

Institute of Child Health and Human Development Fetal Cell Isolation Study (NIFTY) concluded that the fetal sex detection rate was 41.4%.⁴⁵⁶ However, aneuploid pregnancies may have higher rates of fetal-maternal cell trafficking than euploid gestations, facilitating the diagnosis of abnormal pregnancies.⁴⁵³

Although fetal cell retrieval remains an intriguing option for noninvasive prenatal diagnosis, it is likely that routine feasibility will require the development of newer technologies. Work is underway on a number of possibilities. Many of these are using microfluidics to better separate the cells, and improved approaches to antibody-based isolation. In another approach, computer scanning technology is being used to rapidly survey the large number of cells on a slide and selectively identify those that are fetal. This technique requires the development of markers that are uniquely fetal, such as stains for early embryonic fetal hemoglobin. Once these rare cells are identified, there still remains the task of analyzing their genetic content. Although FISH for specific chromosomes has been used, fetal cell isolation and detection techniques cause cell injury, making FISH interpretation difficult and at times unreliable. The development of techniques to remove single cells from a slide and individually evaluate them using molecular technology is underway. Single-cell PCR may also allow the diagnosis of single-gene disorders.⁴⁵⁷

Free fetal DNA has also been detected in maternal plasma and has been explored as a potential approach to fetal diagnosis. This has certain technical advantages. It is less labor intensive because the amount of free fetal DNA is greater than the number of fetal cells and may account for greater than 3% of the total DNA in a maternal sample.⁴⁵⁸

Noninvasive Prenatal Diagnosis using Free Fetal DNA in the Maternal Circulation

Following the discovery of large amounts of cell-free tumor DNA in the plasma of patients with cancer, it was extrapolated that a rapidly growing fetus and placenta also possess tumor-like qualities. The presence of male fetal DNA sequences was demonstrated in maternal serum using standard PCR amplification of Y-specific DNA sequences to detect fetal DNA in the plasma of women carrying male fetuses.⁴⁵⁹ This prompted a new area of research as it was established that perhaps 25 times more fetal DNA is present in a pregnant woman's serum than can be extracted from the cellular fraction of maternal blood.⁴⁶⁰ There is an increase in fetal DNA concentration as gestation advances; in early pregnancy, the mean fractional concentration in maternal plasma is 3.4%, whereas in later pregnancy that value is 6.2%.⁴⁵⁸ Maternal plasma or serum analysis of fetal DNA has the advantage of being reliable, rapid, and reproducible, and it can be performed for a large number of samples. The main limitation is the availability of uniquely fetal gene sequences that identify the presence of fetal DNA in both male and female fetuses.⁴⁶¹

Identifying fetal DNA in the maternal circulation also prompted insights into physiology. Turnover of circulating fetal DNA in the maternal circulation was studied and it was determined that levels were undetectable by about 2 postpartum hours.⁴⁶² The mean half-life was estimated to be 16 minutes. This led to speculation that fetal DNA is continuously liberated into the maternal circulation. There is also indirect evidence to support that circulating fetal DNA fragments are small (less than 450 base pairs) and that it is protected within apoptotic bodies or within nucleosomes.⁴⁶³

Circulating fetal DNA has been hypothesized to arise from three sources: fetal hematopoietic cells, the placenta, and direct transfer of

DNA molecules. Data from studies on fetal cellular and nucleic acid trafficking in specific complications of pregnancy and preterm labor have demonstrated that fetal erythroblasts are not the exclusive source of fetal DNA.⁴⁶⁴⁻⁴⁶⁶ Because of its size and abundant cellular activity, the placenta is probably the primary source for circulating fetal DNA. This conclusion is based primarily on the direct relationship between the amount of cell-free fetal DNA and advancing gestation.^{458,467,468} Furthermore, Guibert and associates⁴⁶⁹ demonstrated fetal SRY gene sequences as early as 18 days after embryo transfer, whereas the definitive fetoplacental circulation is not established until 28 days after conception. These data advocate the theory that the source of fetal DNA is the trophoblast and not fetal hematopoietic cells.

Prenatal diagnostic techniques using free fetal DNA are limited because of the presence of contaminating maternal DNA, requiring that the fetal sequence of interest be distinguished from that of the mother. For example, in attempting to diagnose a fetal autosomal recessive disorder, mutations in the DNA of a carrier mother could not be differentiated from those of the fetus. However, if the father carries a mutation different from that of the mother, lack of the paternal allele in the maternal circulation would preclude the need for invasive testing. To diagnose an autosomal dominant disorder, the mutation would have to be *de novo* or of paternal origin. This approach is still investigational, and false-positive and false-negative results occur.

Clinical Implications of Fetal DNA in the Maternal Circulation

GENDER DETECTION

One clinically valuable application of fetal DNA analysis is the determination of fetal sex. Positive signals for Y chromosome DNA sequences indicate a male fetus, whereas absence indicates a female fetus.^{459,470} With the advent of real-time PCR, cell-free fetal DNA in the maternal plasma can be analyzed to determine fetal sex at as early as 5 to 7 weeks of gestation with a documented 100% sensitivity and specificity.^{456,467,471}

Early, noninvasive fetal sex determination has a number of valid clinical indications. For pregnancies at risk for an X-linked disorder, determination of the fetal sex helps determine whether invasive testing should be performed for diagnostic purposes. Another use is in the management of congenital adrenal hyperplasia, in which prenatal treatment of a female fetus with maternal dexamethasone to prevent masculinization of the genitalia must be initiated before 9 weeks' gestation. Using fetal DNA analysis, fetal sex can be determined earlier and unnecessary treatment of male fetuses can be avoided.⁴⁷²

FETAL RED BLOOD CELL GENOTYPE DETERMINATION

Antigens of the Rh blood group system are encoded by two genes, RhD and RhCE. These genes, which are 93.8% homologous, are organized into 10 exons in a tail-to-tail configuration (5'-RhD-3'-3'-RhCE-5').⁴⁷³ RhD-negative individuals are lacking the RhD gene locus located on chromosome 1p36.2-p34. Exceptions to this rule occur when the gene is present but not translated or not expressed, or when the epitopes of the antigen are composed of weak D (epitopes weakly expressed) or partial D (epitopes are absent) phenotypes.⁴⁷⁴ In whites, the majority of RhD-negative individuals are the result of a gene deletion. In Africans, however, the Rh-negative phenotype is most frequently the result of genes that contain RhD sequences but do not produce D antigen; these are the RhD-pseudogene and RhD-CE-Ds. The distribution of these genes differs between black Africans, African Americans, and black South Africans. False-negative results occur

because of undetected or absent fetal DNA in the maternal sample, early gestational age, or insensitive methods. To address this, techniques that separate fetal DNA from maternal DNA are being actively sought.⁴⁷⁵

Detection of the RhD sequence in plasma or serum from an RhD-negative pregnant woman would indicate an Rh-positive fetus, and its absence an Rh-negative pregnancy. In 1998, it was demonstrated that this could be accomplished with high sensitivity and specificity.^{476,477} Accuracy of fetal Rh genotyping has been reported to be approximately 95%, and many centers report 100% accurate results.^{478,479} False-positive and false-negative results occur because of gene variation, presence of atypical mutations, or gene deletions. For example, false positives can occur because of the presence of RhD variants.⁴⁷⁹ In the presence of a pseudogene, prenatal determination of fetal Rh type from maternal blood will reveal an RhD-positive type in a mother tested as Rh-negative by serology because of the abundant maternal D gene sequences that are not expressed but are amplified. Accordingly, primers for multiplex PCR amplification of RhD have to be selected carefully and designed around the RhD gene variants that are common in the studied population.

Prenatal determination of fetal red blood cell phenotype has two important clinical uses. First, in Rh-negative sensitized pregnancies for which the father is known to be heterozygous for the D allele, identification of an Rh-negative fetus prevents unnecessary surveillance or intervention. Secondly, a Rh-negative unsensitized woman carrying Rh-negative fetuses will not require antenatal RhoGAM administration.

Fetal blood typing has become a routine prenatal practice in Europe, specifically in the United Kingdom, France, and The Netherlands.^{480,481} Despite the wide availability of similar technology in the United States, it has not yet been widely adapted. Major obstacles include lack of standardized protocols, cost, reproducibility, and quality control.

Noninvasive Diagnosis of Fetal Aneuploidy

Aneuploid pregnancies appear to have altered levels of free and cellular fetal DNA compared with euploid gestations. Bianchi and coworkers⁴⁵³ have demonstrated elevations in DNA from intact fetal cells in trisomy 21 pregnancies. This has also been observed for free fetal DNA in maternal plasma. The median concentration of circulating fetal DNA in the second trimester has been found to be twice as high in women carrying fetuses with trisomy 21.⁴⁸² Fetal DNA levels have been found to be significantly elevated in trisomy 13 pregnancies but not in trisomy 18.⁴⁸³ Although the differences between normal and aneuploid pregnancies are not diagnostic, some authors have suggested that they may be useful as part of a screening algorithm.

Single Gene Disorders

Specific single-gene disorders identified using analysis of fetal DNA in the maternal circulation include myotonic dystrophy, achondroplasia, cystic fibrosis, β -thalassemia, and congenital adrenal hyperplasia.⁴⁸⁴⁻⁴⁸⁶ As discussed earlier, this is possible only if the mutation of interest is not present in the mother.

Nucleic Acids in Other Body Fluids

Fetal nucleic acids have been reported in other maternal fluid compartments, including cerebrospinal fluid,⁴⁸⁷ peritoneal cavity fluid,⁴⁸⁸ and maternal urine.⁴⁸⁹ However, these alternative sources have proved to be unreliable in terms of yield, sensitivity, and specificity. Advancements in reverse transcription PCR will enable more specific and sensitive

detection of nucleic acids, particularly in maternal urine, which could allow for the truest form of noninvasive prenatal diagnosis.

Cell-free fetal DNA has been amplified and analyzed from amniotic fluid samples using quantitative PCR and used for the rapid identification of specific fetal chromosome abnormalities, including aneuploidies of chromosomes 21, 18, 13, X, and Y.⁴⁹⁰ Using comparative genomic hybridization, on commercially available microarrays that encompass genetic sequences from all 24 human chromosomes, whole-chromosome and segmental aneuploidies can be determined. This suggests that cell-free fetal DNA in amniotic fluid samples may enhance the clinical application of the traditional metaphase karyotype (molecular karyotype), which could provide information not only about the presence or absence of whole-chromosome aneuploidy but also about subtle deletions or unbalanced rearrangements.⁴⁹¹

Fetal Cell-Free RNA in the Maternal Circulation

The mother and fetus share approximately half of their genomic DNA sequences, which can be viewed as being a major limitation to using DNA in maternal blood for prenatal testing. RNA analysis has therefore become a candidate for an independent fetal marker. Fetal mRNA sequences can be detected in the maternal plasma of women in early and in late pregnancy.⁴⁹² This mRNA is stable in peripheral blood, probably protected in the circulation by its association with particles.⁴⁹³

Genetic Evaluation of Stillbirth

A considerable proportion of stillbirths may occur from genetic causes. Six percent to 12% result from karyotype abnormalities,^{494,495} but in many cases, tissue cultures are unsuccessful, which contributes to a significant underestimation.⁴⁹⁶ The use of molecular-cytogenetic approaches that do not require culturing should be considered in these cases. Even in the presence of a normal karyotype, genetic abnormalities are present in 25% to 35% of perinatal autopsies.⁴⁹⁷ The American College of Obstetrics and Gynecology issued a committee opinion in 2001 suggesting that autopsy findings supplemented by genetic studies are invaluable in determining the potential etiology of fetal death.⁴⁹⁸ Evaluation should include a perinatal and family history, as well as physical examination of the fetus, photographs, autopsy, and placental examination. Cytogenetic, molecular, biochemical, and infectious disease studies should be considered when appropriate.

The most useful examination is the gross autopsy, which will reveal a change in diagnosis or additional findings in 22% to 76% of cases.⁴⁹⁹⁻⁵⁰² Alternatives to autopsy have been explored (e.g., magnetic resonance imaging [MRI]), as there may be cultural or social restrictions limiting autopsy evaluation. However, a review of 100 fetal autopsies in which MRI was also used concluded that postmortem examination was better.⁵⁰³ Fetal skeletal radiographs have not been found to be useful in fetuses without an abnormality on ultrasound.⁵⁰⁴

Chapter 18

Imaging in the Diagnosis of Fetal Anomalies

Frank A. Manning, MD, MSc

Congenital Anomalies: Definition and Population Frequency

Human development is a complex process by which the fusion of two haploid cells progresses by genetically signaled repeated cell division and exquisitely timed biochemical and biophysical differentiation so as to evolve through embryonic, fetal, and postnatal life expressing the unique characteristics of the individual's genome but sharing a commonality of structure and function with all humans. Phenotypic structural and functional variation occurs across the life span including the prenatal period. In embryonic/fetal life, most of these macroscopic phenotypic variations are insignificant, and they are not recognized nor do they have any impact on survival or the quality of postnatal life.

In contrast, some phenotypic variations result in either death or serious disability, and these phenotypic variations are termed *major congenital anomalies*. There are approximately 275 discrete macroscopic anomalies that have been described and hundreds of combinations of anomalies compiled as syndromes. In about 50% of cases, no cause for the anomaly is recognized, and in about 40% of cases there is either a chromosomal abnormality or a proven or suspect gene alteration. Teratogens (3%), uterine factors (2.5%), and multiple gestation (0.5%) are the remaining causes.¹

The measurement of the incidence of major congenital anomalies remains imprecise. Determination of the incidence of major anomalies at birth underestimates the true rate, because fetal deaths of anomalous fetuses are excluded and some anomalies are inapparent in the neonate. Estimates of the frequency of major anomalies derived from antepartum ultrasound assessment are inaccurate because of the limitations of the imaging methods. Nevertheless, the overall incidence of major anomalies is considered to be in the range of 2% to 3% of all pregnancies.²⁻⁵ The incidence of major anomalies can be expected to vary according to specifics of the study population, including ethnic heterogeneity, environmental conditions and exposures, maternal (but not paternal) age at conception,^{6,7} and the presence of comorbidities such as diabetes⁸ and obesity.⁹

Antenatal Recognition of Congenital Anomalies: Methods and Limitations

Whereas antenatal maternal serum *screening* for structural and chromosomal congenital anomalies is based on analysis of specific marker analytes in the maternal circulation (e.g., elevated serum α -fetoprotein in fetuses with neural tube defects,¹⁰ abnormal serum analyte pattern in aneuploid pregnancies¹¹) or on recognition of a marker (e.g., nuchal lucency) discrete from the specific anomaly,^{12,13} the *diagnosis* of an anomaly depends on direct visualization of the malformed or absent organ or organ systems, often coupled with evidence of dysfunctional sequelae. Over the years, a variety of methods have been introduced to visualize the fetus, including radiography, direct visualization through either the transparent membranes (transvaginal embryoscopy) or the amniotic fluid (fetoscopy), ultrasound, and magnetic resonance imaging. Each modality has advantages and limitations. In contemporary fetal medicine *dynamic ultrasound* is the primary method for detection of fetal structural defects, and the other modalities are reserved specific for confirmatory circumstances.

Currently, two-dimensional dynamic ultrasound imaging is the most commonly used method although three- and four-dimensional ultrasound techniques are becoming increasingly available and appear to offer improved recognition of some anomalies (e.g., facial clefts¹⁴) (Fig. 18-1). The sensitivity of ultrasound for detection of major anomalies is variable but in general surprisingly low. One important study² compared the major anomaly detection rate in a general population with scheduled ultrasound evaluations at 15 to 20 weeks and at 31 to 35 weeks to the anomaly detection rate in a population in whom ultrasound was done only for clinical indications. The incidence of fetal anomaly in this combined population of 15,281 women was 2.3%, but the anomaly *detection* rate in the scheduled ultrasound population was 35% as compared to 11% in the control group. These differences, although statistically significant, created controversy, because the prevailing belief was that the ultrasound detection rate was actually much higher. Subsequent reports for the most part have confirmed these data, with reported detection rates ranging from 22% to 55%.^{3,5,15,16} A secondary analysis of these data revealed no evident improvement in

FIGURE 18-1 The frontal view of the face of a near-term fetus produced by three-dimensional ultrasound imaging. Note the striking clarity of detail of the lips, philtrum, and nose. (Courtesy of Professor Delores Pretorius, Department of Radiology, University of California, San Diego.)

maternal and perinatal outcome between the screened and control population.¹⁷

The following factors influence the ultrasound detection rate of fetal anomalies:

- **Fetal anomaly type.** The detection rate by ultrasound varies widely according to the specific anomaly. The best detection rates are seen for major central nervous system (CNS) anomalies such as anencephaly (94% to 100%^{18,19}), with major fetal cardiac defects in the mid range (25% to 60%²⁰) and facial clefts tending to be lowest.^{21,22} The ultrasound detection rate is significantly increased when multiple anomalies are present,¹⁸ which underscores a clinical axiom: If you find one anomaly, look for more. The detection rate further increases as more scans are done: when patients are subjected to sequenced serial ultrasound anatomic surveys in the first and second trimesters, the detection rate nearly doubles.²³
 - **Gestational age.** Although the genesis of most fetal structural anomalies occurs during the embryonic period, detection by ultrasound is possible for most lesions in later gestational ages. Large anomalies such as anencephaly or limb-body wall defects can be recognized almost as soon as failure of normal development occurs. Other anomalies of embryonic origin are too small to be seen with early ultrasound and do not become manifest until functional abnormality occurs (e.g., aqueductal stenosis is not recognized until the mid to late second trimester and then only because of progressive obstructive fetal ventriculomegaly). Anomalies such as renal agenesis may not be suspected until there is severe oligohydramnios. Some anomalies are the result of failure of completion of a normal developmental process and are identified only at the conclusion of an adjacent normal event. For example, although omphalocele appears to be a result of failure of fusion of the lateral ecto-mesodermic folds to fuse in the midline, an event normally completed by about 28 days of embryonic life,²⁴ this anomaly cannot be recognized before the normal retraction of the midgut into the abdominal cavity from the umbilical cord at approximately 10 to 11 weeks.
 - **Risk factors.** The detection rate for a specific anomaly improves substantially when risk factors are present. For example, a history of a previous anomalous fetus raises the risk by about 50% in autosomal dominant conditions, by about 25% in autosomal recessive conditions, and by about 5% to 10% in multifactorial inheritance conditions. Risk is also increased three- to six-fold with a family history of anomaly, exposure to environmental toxins, or concurrent maternal disease such as pregestational diabetes²⁵ and obesity.^{26,27} Risk is increased in the presence of abnormal maternal serum analytes²⁸ or of nonspecific fetal markers such as nuchal lucency, oligohydramnios, and polyhydramnios.³ Thus when risk factors are present, targeting ultrasound imaging to specific areas of concern improves anomaly detection.
 - **Imaging method and image quality.** The advances in ultrasound imaging methods over the past 2 decades have been remarkable. They have evolved from single-line, to static B-mode, to gray-scale, to real-time (dynamic) B-mode, and now to real-time three-dimensional B-mode (four-dimensional) ultrasound. Concurrently, the introduction of new multifrequency transducers, a wider ultrasound frequency range, higher-speed computing, and real-time duplex and color Doppler have improved image quality and diagnostic precision. As a result, the detection rate for some anomalies (e.g., neural tube defects) has risen to almost 100% in skilled hands.
- Nevertheless, limitations remain in the ability of ultrasound to produce fetal images of adequate resolution to ensure that every possible anomaly can be detected. Ultrasound resolution is a function of sound frequency, target density, and distance and variation from adjacent tissues. Resolution is best at the interface between high- and low-density tissues (e.g., skin and amniotic fluid) and worst between tissues of similar tissue density (e.g., liver and gut, kidney and adrenal). Resolution also depends on the incidence angle of the ultrasound beam. Because bone attenuates the ultrasound signal, fetal position can have a profound impact on image quality; for example, fetal cardiac imaging is virtually impossible when the fetal spine lies between the ultrasound beam and the fetal heart. Similarly, maternal body fat attenuates the ultrasound signal, leading to poor image quality in up to 36% of obese patients,²⁹ and this limitation persists despite repeated examinations.³⁰ In obese patients, transvaginal scanning can produce improved image quality, as can application of a high-frequency vaginal transducer to the maternal umbilicus, but this is limited to early pregnancy and target distances of less than 10 cm.³¹ Thus it is important for medico-legal reasons to ensure that maternal weight is recorded in patients referred for ultrasound and to note in the report whether image quality was compromised by maternal body habitus.

TABLE 18-1 INTRAUTERINE FETAL INVASIVE TREATMENT: METHODS AND RELATIVE SURVIVALS

Fetal Anomaly (ref)	Treatment Method and Survival	Survival of Concurrently Untreated Fetus	Comment
Hydrocephalus (187)	Ventriculoamniotic shunt 83% (34/44) survival	—	10% operative mortality 33% intact survival
Myelomeningocele (68, 69)	Open or fetoscopic repair 90% (56/60) survival	—	44% (87/175) shunt dependent No obvious improvement in limb paresis Randomized trial underway
Congenital diaphragmatic hernia	Open repair ¹²³ 61% (32/53) survival	55% (11/20) survival	No advantage to open in utero repair
	Fetoscopic tracheal occlusion ¹²⁴ 73% (8/11) survival	77% (10/13) survival	Randomized trial stopped because of no benefit
Pleural effusion or congenital cystic adenomatoid malformation (188)	Thoracoamniotic shunt 67% (13/19) survival	—	
Aortic/pulmonary valve stenosis (189)	Balloon valvuloplasty 15% (3/20) clinical success	—	20% operative mortality Only 70% of attempts successful
Lower urinary tract obstruction (190)	Vesicoamniotic shunt 68% (74/109) survival	40% (23/58) survival	Significant survival improvement only in severe cases Postnatal renal failure, 33%

The Management of Fetal Structural Anomalies

The clinical management of the pregnancy complicated by a fetal anomaly depends on integration of fetal, obstetric, and maternal factors. The ultimate decision regarding management rests with the parents, but the health care team has the responsibility to acquire all available information to assist parents with their decision (Table 18-1). The following four factors affect fetal management.

Prognosis

Some anomalies (e.g., thanatophoric dwarfism, renal agenesis, anencephaly) are always *lethal*, with death occurring either in utero or in the early neonatal period. When the fetal prognosis is hopeless, clinical management is directed to preventing maternal morbidity. In early gestation, pregnancy termination is the usual management. In late pregnancy, management is generally to induce labor when the cervix is favorable and to avoid cesarean section for fetal distress.

Some fetuses have anomalies that are compatible with limited survival but associated with certain and very severe neurologic disabilities (e.g., hydrancephaly, trisomy 18). Management of these fetuses generally follows that for fetuses with lethal anomalies.

At the opposite extreme are fetal anomalies with recognizable anatomic manifestations but with lesions that in postnatal life can be repaired, limiting or eliminating debilitating functional sequelae (e.g., cleft lip). In such circumstances, educating the parents about the anomaly can be beneficial, allowing time for adjustment, acceptance, and arranging postnatal care.

Unfortunately, most anomalies fall into a category in which the prognosis is generally good but cannot be assigned with any degree of certainty (e.g., mild cerebral ventriculomegaly), with a spectrum of outcomes ranging from severe physical limitation but usually intact

mental faculties (e.g., spinal bifida) to intact physical faculties but uncertain mental faculties (e.g., agenesis of the corpus callosum).

Gestational Age at Diagnosis

Gestational age at the time of diagnosis of an anomaly has a powerful impact on management decisions. As a general rule, the earlier the gestational age is at the time of diagnosis, the more severe the defect and the worse the prognosis. This association exists in part because the younger the fetus is, the larger the defect must be to be recognized, and the larger the defect is, the greater the likelihood of damaging or disrupting both adjacent and remote tissues. In the mature fetus, delivery and postnatal evaluation may be the most appropriate management. In the immature fetus, termination of pregnancy is often selected, especially when the anomaly is associated with either a hopeless or very poor prognosis.

Progression

The management of an anomaly varies according to whether the lesion is stable and lacking downstream consequences, or whether it is progressive and apt to cause damage to other organs. Many anomalies, such as some cardiac lesions, are nonprogressive, have few functional effects in fetal life, and become manifest as causes of morbidity or mortality only in the neonate (e.g., a small VSD), whereas some anomalies cause a progressive deterioration in function and structure of the local and remote tissues (e.g., renal agenesis). For example, myelomeningocele is usually nonprogressive at the spine, but the tethering of the spinal cord can produce herniation of the cerebellar tonsils into the foramen magnum, resulting in progressive obstructive hydrocephalus. Management of the fetus with anomalies of a progressive, deteriorating character depends on balancing the risks associated with progression with the risks of preterm delivery.

Rarely, anomalous conditions spontaneously resolve in utero. Spontaneous resolution of obstructive hydrocephalus, obstructive uropathy, nonimmune hydrops, and some cardiac arrhythmias is

TABLE 18-2 RELATIVE AND ABSOLUTE INCIDENCE OF MAJOR CONGENITAL HEART LESIONS AND THEIR RECURRENCE RATES

Lesion*	Percentage of All CHD 25% to 75% (Median)	Per Million Live-Born Children 25% to 75% (Median)	% Recurrence	
			Siblings	Offspring
Ventricular septal defect	27.1-42.0 (32.4)	1667-3142 (2267)	4-6	2-22
Atrial septal defect	6.8-11.7 (7.5)	403-910 (563)	3	2-14
Patent ductus arteriosus [†]	5.3-11.0 (7.1)	350-774 (471)	2.5-3	2-11
Pulmonic stenosis	5.0-8.6 (7.0)	280-641 (404)	3	3-18
Coarctation of the aorta	3.8-5.8 (5.0)	289-419 (332)	2-7	2-8

known to occur. Management of the fetus with a resolved anomaly is usually conservative with the expectation of a good outcome.

Availability of Fetal or Neonatal Treatment

The availability of methods to correct or ameliorate fetal structural defects has a significant impact on management. Most truly effective treatments are applied in the neonatal period. The usual goal of managing a fetus with a nonlethal anomaly for which there is a reasonable prospect of minimal postnatal disability is to delay delivery until the fetus is mature (Table 18-2). Prenatal consultation with the neonatal team greatly facilitates care coordination and reduces mortality and morbidity.

In a few, very select cases, in utero intervention may be the treatment of choice. However, the initial optimism that accompanied the introduction of in utero treatment of the anomalous fetus has waned significantly as better-constructed studies have demonstrated that the treatment is often ineffective and associated with increased fetal and maternal morbidity.

Cardiovascular Anomalies: Incidence, Causes, Embryologic Development

Approximately 1% of all liveborn children have a structural cardiac anomaly. This rate is even higher when abortuses and stillbirths are included. The distribution of congenital heart anomalies is not equal

TABLE 18-3 CONGENITAL HEART DISEASE: RISK OF RECURRENCE

Defect	Recurrence Risks (%)		
	One Sibling Affected	Father Affected	Mother Affected
Aortic stenosis	2	3	13-18
Atrial septal defect	2.5	1.5	4-4.5
Atrioventricular canal	2	1	14
Coarctation	2	2	4
Patent ductus arteriosus	3	2.5	3.5-4
Pulmonary stenosis	2	2	4-6.5
Tetralogy of Fallot	2.5	1.5	2.5
Ventricular septal defect	3	2	6-10

Modified from Nora JJ, Nora AH: The evolution of specific genetic and environmental counseling in congenital heart diseases. *Circulation* 57:205-213, 1978.

among the various structural defects, and ventriculoseptal defects (VSDs) are by far the most common lesion (Table 18-3). In most instances, the precise cause of the maldevelopment of the fetal heart is unknown. Approximately 8% of cardiac anomalies are associated with recognizable genetic disease, including 5% that are associated with major aneuploidies (trisomy 21, monosomy X, trisomy 18, trisomy 13) and 3% that are associated with a single gene mutation, including Noonan syndrome (pulmonary stenosis and hypertrophic cardiomyopathy as the most common cardiac structural abnormalities), Apert syndrome (VSD, coarctation of aorta), Holt-Oram syndrome (atrio-septal defect [ASD]/VSD), and Ellis-van Creveld syndrome (single atrium).

Most cardiac malformations are inherited in multifactorial fashion, giving a 1% to 2% risk with no family history. However, the risk is increased when there is a *family history*: 4% to 6% with a single affected sibling, 8% to 12% with two first-degree relatives, and 5% to 10% if the mother has congenital heart disease. Fetal structural cardiac defects may also occur after *teratogen* exposure in utero. Lithium ingestion is associated with valvular defects (Ebstein anomaly). Retinoic acid can cause a variety of severe cardiac defects. *Fetal viral infections* are a recognized cause of fetal cardiac defects, rubella virus can cause pulmonary stenosis, mumps virus may cause endocardial fibroelastosis, and Cocksackie B virus is suspected to cause a variety of cardiac defects.

The fetal heart begins development as a simple contractile tube with four segments: from cranial to caudad they are the sinoatrial segment (the origin of the atria), the primitive ventricle (the origin of the left ventricle), the bulbus cordis (the origin of the right ventricle), and the conotruncus (the origin of the pulmonary artery and aorta). By about the 26th day, the contracting of the evolving heart can be visualized by ultrasound. The cardiac tube divides into two parallel tracts, each with an atrium, a ventricle, and an outflow tract, and concurrently the primitive tube moves ventrally and to the right so that the bulbus cordis (the origin of the right ventricle) moves to the right and anterior and the primitive ventricle (the origin of the left ventricle) moves to the left. The completion of this movement (termed cardiac looping) results in the normal configuration of the right ventricle anterior and to the right, and the left ventricle posterior and to the left.

The atria develop by division of the sinoatrial segment by the septum primum and secundum and the migration of mesenchyme to form the four discrete atrioventricular cushions and subsequently the tricuspid and mitral valves and the proximal portion of the ventricular septum. The atrioventricular canal rotates to the right and the ventricular septum posterior to the left, bringing the right atrium over the right ventricle and the left atrium over the left ventricle. The bulboarteriosus divides into two tracts and undergoes spiral rotation, bringing the pulmonary artery over the right ventricle and the aorta over the left ventricle. This complex process of division, differential growth, and rotation is completed by about the 7th week of fetal life. Thereafter, the heart grows in size but the structure remains essentially the same. Errors in migration result in univentricle, double-outlet right ventricle, and ventricle inversus. Failed cardiac looping results in transposition of the great vessels. Failure of division of the conotruncus results in truncus arteriosus.

For detailed information about specific cardiac malformations, diagnosis, and management, see Chapter 19.

Central Nervous System Anomalies

Embryologic Development

Developmentally, the CNS begins as a midline fold in the ectodermal neural plate that progresses to form an open-ended tube. As a result of differential growth, the tube folds cranially, initially to form the midbrain and then the hindbrain and forebrain; the caudal end remains unfolded and forms the spinal cord. These events occur very early in embryonic life, and by 4 weeks the CNS is fully differentiated into these four regions. By week 5, the forebrain (prosencephalon) divides into the cerebral primordial and the diencephalons, the midbrain (mesencephalon) remains unchanged and the hindbrain (rhomben-

cephalon) divides into the cerebellum and pons and the medulla oblongata.

The initial ectodermic tube remains hollow, and the epencephalon cavity forms the lateral ventricles and third ventricle and the rhombencephalon forms the fourth ventricle. The choroid plexus develops from pia mater and blood vessels invaginated into the inner walls of the developing ventricles, and by the 6th week they are producing cerebral spinal fluid (CSF). The caudal end of the ectodermic tube (neuropore) closes first, followed later by closure of the rostral (distal) neuropore. Closure of the neuropore depends on normal folate in the fetus. The vessels of the brain arise from mesenchyme migration. Anomalies of the CNS generally occur very early in embryogenesis, arising from abnormally programmed proliferation of the ectodermal segmental folds. Most CNS anomalies are contained within a particular ectodermal developmental region, and CNS anomalies in adjacent regions are usually the result of pressure distortions.

Hydrocephalus (Ventriculomegaly)

Diagnosis. Hydrocephalus, or more precisely ventriculomegaly, is a condition characterized by abnormal enlargement of the lateral ventricles with or without dilation of the third and fourth ventricle. Isolated third or fourth ventriculomegaly does not occur. Because the lateral ventricles are filled with CSF, visualization by ultrasound is easy and reliable. In contrast, because the third and fourth ventricles function more as CSF conduits, these structures are not normally visualized by prenatal ultrasound. The lateral ventricles are shaped like curved elongated ovals, and planar measurement is difficult. By convention, the size of the lateral ventricle is determined by the span measured at the midportion of the ventricle (Fig. 18-2), and nomograms for normal ventricle size and growth either as absolute values or as a ratio of hemisphere widths are available.³²

Obstruction to CSF flow is the most common cause of ventriculomegaly. Given the relatively large amount of CSF produced in the lateral ventricle by the choroid plexus and the lack of rigidity of the ventricular wall and surrounding cerebrum, in the presence of obstruction the ventricle dilates quickly and dramatically and thus ultrasound recognition is usually easy and reliable (Figs. 18-3 and 18-4). Typically, as the ventricle enlarges, the space between the choroid plexus on the

FIGURE 18-2 Fetus with mild ventriculomegaly. In this 20-week fetus, the ratio of lateral ventricular width to hemisphere width (LWV:HW ratio) was 1.23 (>95th percentile).

FIGURE 18-3 Mild to moderate ventriculomegaly. Note the choroid plexus, which seems to “dangle” into the lateral ventricle.

inner ventricle wall and the lateral wall widens, giving the impression of a “dangling” choroid.

Ventriculomegaly can arise from stenosis of either the third or fourth ventricle or of both. Third-ventricle stenosis occurs most commonly at the connection between the third and fourth ventricles (the aqueduct of Sylvius). *Aqueduct stenosis* results in pressure ventriculomegaly of the third and lateral ventricles and is usually a result of either restrictive gliotic reaction to infectious inflammation (50% of cases), genetic-origin developmental narrowing (25% of cases), sporadic idiopathic stenosis (20% of cases), or obstruction secondary to tumors (5% of cases). Inflammatory obstructive gliosis can be related to infection caused by *Toxoplasma*,³³ cytomegalic inclusion virus,³⁴ herpes simplex,³⁵ varicella, herpes zoster,³⁶ enterovirus,³⁷ lymphocytic choriomeningitis virus,³⁸ or parvovirus B19.³⁹

Genetic-origin aqueductal stenosis is most commonly related to X-linked recessive inheritance,⁴⁰ and in about half of these cases there are abduction anomalies of the thumbs. Autosomal recessive inheritance has also been observed in some cases,⁴¹ as well as uncertain inheritance.⁴² Tumors that obstruct the aqueduct include papilla, teratoma,⁴³ hamartoma,⁴⁴ cavum velum cyst,⁴⁵ primary neoplasms, and metastatic neoplasia, including that from the mother.⁴⁶ Associated anomalies generally occur only with aqueductal stenosis of genetic origin. These anomalies include other CNS anomalies such as agenesis of the corpus callosum, vascular abnormalities, and arachnoid cysts.⁴⁷

Prognosis. The prognosis of ventriculomegaly from aqueductal stenosis varies according to the cause, degree, and permanence of the obstruction. X-linked and autosomal recessive aqueductal stenosis have a very poor prognosis with high mortality (90%) and serious neurodevelopmental anomalies among the few survivors. For inflammatory aqueduct stenosis, the prognosis generally depends on the degree of ventriculomegaly, defined by the transverse diameter of the atrium.⁴⁸ Severe ventriculomegaly (i.e., transverse diameter >15 mm) is associated with severe neurodevelopmental delay in 90% of cases.⁴⁸ In contrast, isolated mild ventriculomegaly (transverse diameter of the atrium between 10 and 15 mm) has a very high postnatal survival, and normal development is observed in 80% of cases, mild disability in about 10%, and severe disability in about 10%.⁴⁹

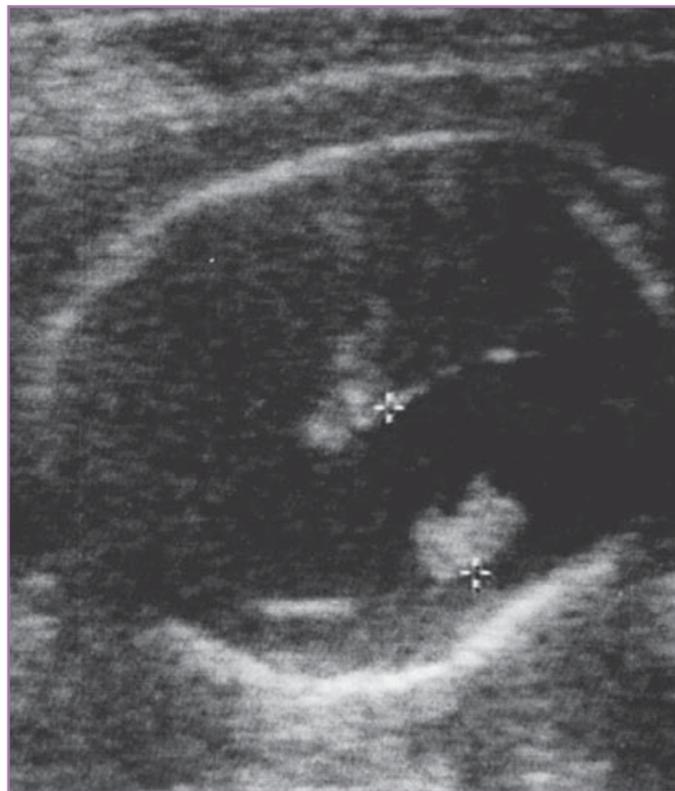

FIGURE 18-4 Cerebral ventriculomegaly. Fetal ventriculomegaly at 21 weeks' gestation secondary to aqueductal stenosis. The fetal head is normal in shape and size. The calipers measure the maximal width of the lateral ventricle. The key diagnostic features are the increase in ventricle size, as evidenced by an abnormal ventricle-to-hemisphere ratio (0.8125 in this case) and a prominent lateral shift of the choroid plexus. The midline structures were stable, and the cortical mantle was seen. Disease was rapidly progressive; the fetus was delivered at 24 weeks and died.

In utero fetal decompression of ventriculomegaly has been proposed as a means to halt or reverse progression of disease, relieve cortical compression, and prevent neurodevelopmental damage. Percutaneous ventriculoamniotic shunt placement, although technically feasible, did not benefit postnatal outcome, as 50% of treated survivors had severe disability.⁵⁰ Based on these poor results, the Fetal Medicine and Surgery Society recommended this therapy be abandoned. More recently, Bruner and colleagues⁵¹ used an open surgical approach (hysterotomy) to place ventriculoamniotic shunts in four fetuses with severe ventriculomegaly due to isolated aqueduct stenosis. The results were dismal, with one perinatal death related to chorioamnionitis and the three survivors having serious neurologic handicap. Clearly, at present, there is no role for in utero treatment of ventriculomegaly.

Dandy-Walker Malformation

Diagnosis. Dandy-Walker complex is characterized by a posterior fossa cyst that allows communication of the cyst with the fourth ventricle, resulting in obstructive ventriculomegaly of the third and lateral ventricles, often of a major degree. The ultrasound diagnosis of Dandy-Walker syndrome is relatively straightforward. In the transcerebellar axial plane, enlargement of the posterior fossa, overt splaying of the cerebellar hemispheres, a connection between the foramen magnum

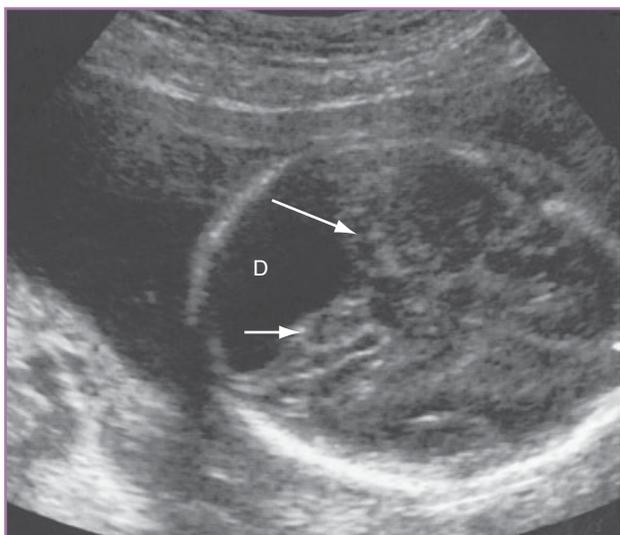

FIGURE 18-5 Dandy-Walker cyst. A small dysplastic cerebellar configuration (arrows) adjacent to the Dandy-Walker cyst (D). (From Sanders R, Blackmon L, Hogge W, et al: *Structural Fetal Abnormalities*, 2nd ed. Philadelphia, Mosby, 2002.

and the fourth ventricle (Fig. 18-5), and lateral ventriculomegaly are evident. The anomaly can be diagnosed by ultrasound in the first trimester.⁵²

A variant of the Dandy-Walker malformation with partial agenesis of the vermis and mild expansion of the foramen magnum can occur. It is critical to confirm the vermis abnormality, as simple enlargement of the foramen magnum (>10 mm) is a minor anomaly and associated with an excellent outcome. Dandy-Walker variant malformation is commonly (50% to 70%) associated with other anomalies, including other CNS anomalies (agenesis of the corpus callosum, holoprosencephaly), other organ system anomalies (polycystic kidney, facial clefting), and chromosomal anomalies including a 5p deletion⁵³ and a 13q deletion.⁵⁴

Prognosis. The prognosis for Dandy-Walker syndrome is very poor. In a recent study of 47 fetuses diagnosed with Dandy-Walker malformation or Dandy-Walker variant, 41 (82%) had associated anomalies, 44 died (mortality rate 94%), and all three survivors had serious neurodevelopmental handicap.⁵⁵

Neural Tube Defects

Failure of closure of the cranial end of the ectodermal neurotube results in anencephaly, and failure of closure of the caudal end results in defects in the dorsum of the vertebrae that may result in herniation of either the meninges (meningocele) or the meninges and spinal cord (myelomeningocele). In the United States, neural tube defects occur at a frequency of about 2 per 1000 live births. However, the frequency of this condition is decreasing because prevention by prenatal administration of folate,⁵⁶ implementation of universal maternal serum α -fetoprotein screening,¹⁰ and highly reliable ultrasound diagnosis.⁵⁷

Diagnosis. The ultrasound diagnosis of anencephaly is usually obvious: the calvarium and neocortex are absent (Fig. 18-6). Anencephaly is one of the few CNS anomalies that can be routinely diagnosed in the first trimester,⁵⁸ and in the second trimester a diagnostic rate of 100% is expected. The perinatal prognosis is hopeless.

Encephalocele

Diagnosis. Encephaloceles (posterior or anterior) are variants of neural tube defects. These conditions can also be diagnosed in early pregnancy and by the second trimester should be recognizable in most instances. The salient ultrasound feature is an echolucent bulge, most commonly in the posterior occipital region (Fig. 18-7).

Prognosis. The prognosis of encephalocele is completely dependent on whether there is associated herniation of brain tissue into the meningeal sac. When brain tissue herniation occurs, the mortality is high and intact survival rate very poor.⁵⁹ In contrast, when there is meningeal herniation only, rates of both survival and intact postnatal development are excellent.⁶⁰

Spina Bifida

Diagnosis. The ultrasound diagnosis of spina bifida in the second trimester is highly reliable with a skilled operator and in many studies superior to maternal serum alpha-protein screening.^{57,61} The most reliable ultrasound markers are intracranial and occur as a tethering of the spinal cord such that continued fetal growth results in herniation of the cerebellar tonsils into the foramen magnum (the Arnold-Chiari malformation). As a result of the downward migration of the brainstem, the frontal lobes retract and the anterior calvarium collapses to form a “lemon sign” (Fig. 18-8), which is present to varying degrees in almost every case.^{62,63} Normal cranial shape (i.e., a negative lemon sign) is an extremely accurate indication of the absence of spinal bifida. The hindbrain herniation with spina bifida causes flattening of the cerebellar hemispheres against the posterior calvarium, producing a characteristic “banana sign.” This sign is slightly less reliable than the lemon sign, and it never occurs as a sole finding with spina bifida. Ventriculomegaly to varying degrees is always present with spina bifida and characteristically worsens as pregnancy advances.

The defect in the spine occurs in the low lumbar area in 60% of cases, in the high lumbar, low thoracic area in 35%, and in the sacral area in 5%. The key ultrasound features of the spine are the absence of the dorsal aspect of the vertebrae and a protuberant cystic mass, which usually contains elements of spinal cord (meningomyelocele) (Fig. 18-9) but may be composed of meninges only (meningocele). Abnormal angulation of the spine may also be present (kyphosis or gibbus).

Recognized causal associations with neural tube defects are multifactorial inheritance patterns (the recurrence rate in subsequent pregnancies is 5% or higher), single gene defects (e.g., Meckel syndrome, Robert syndrome, Jarcho-Levin syndrome), chromosome abnormalities (especially trisomy 13 and 18), poorly controlled maternal diabetes, and teratogenic drugs such as valproic acid and retinoid A. Neural tube defects do not have a major impact on the fetus in utero, although occasionally anencephaly may result in swallowing disorders, causing hydramnios. With spina bifida, limb movements are usually normal and bladder filling and emptying may be observed.

Prognosis. The postnatal prognosis of spina bifida depends on the size and location of the lesion: in general, the lower and smaller the lesion, the better the outcome.⁶⁴ Pregnancy termination is common. Postnatal mortality is reported to be at least 15% in the first year of life, usually related to respiratory compromise caused by hindbrain herniation.⁶⁵ Lower limb paresis is very common. Bladder denervation is common, and renal failure is a significant cause of late infant death. Progressive obstructive hydrocephaly is very common, and at least 85% of infants born with spina bifida will require ventricular shunts.⁶⁶ In utero repair of myelomeningocele is possible.⁶⁷ Despite the lack of a randomized trial, more than 250 fetuses from four major academic centers have undergone prenatal surgical repair of

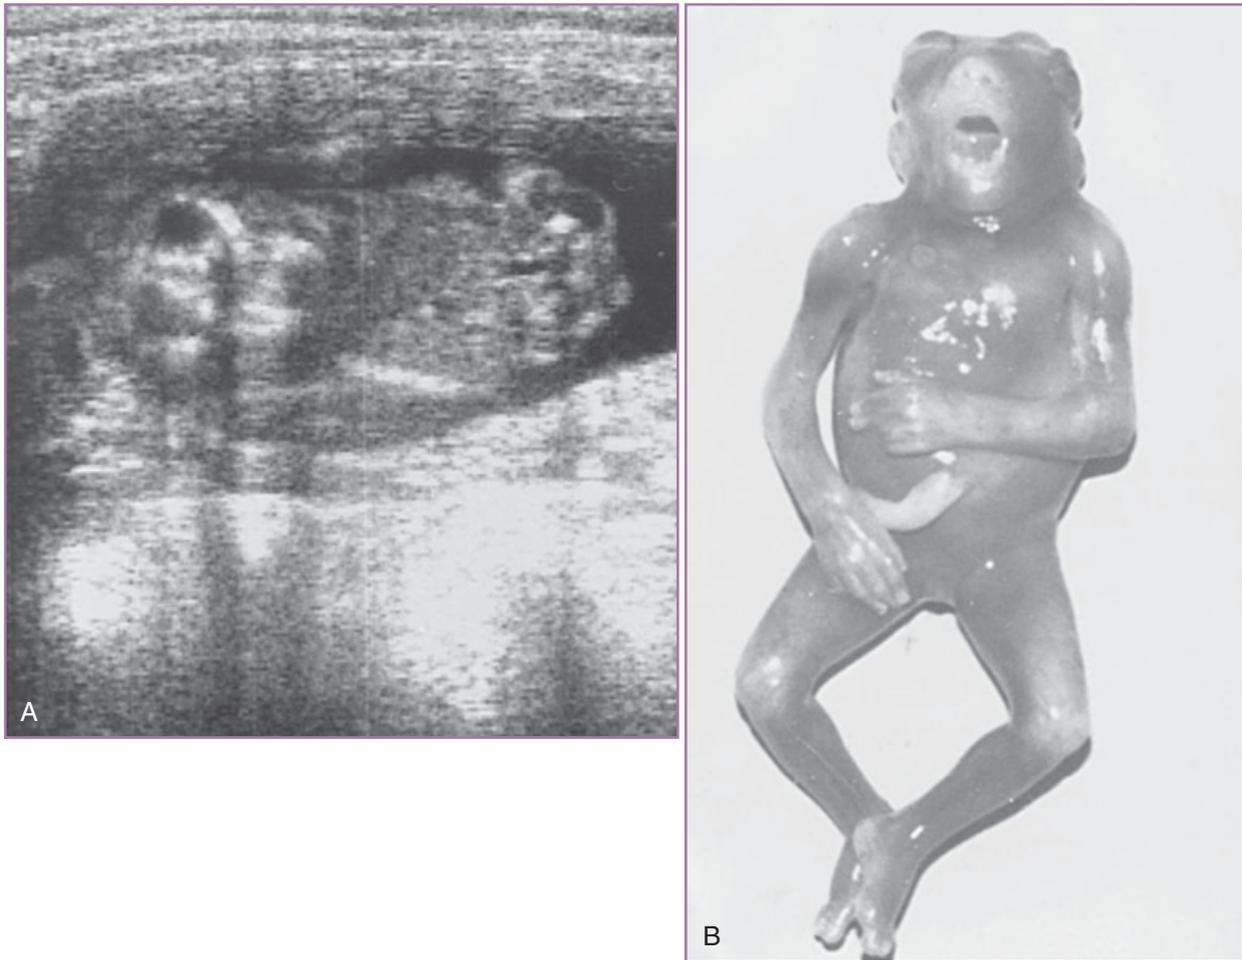

FIGURE 18-6 Anencephaly. **A**, An ultrasound view in the longitudinal coronal plane of an anencephalic fetus. The fetal calvarium is totally absent, and the fetal orbits appear relatively large and prominent. **B**, Same anencephalic fetus as in **A**. Note the prominence of the eyes and the complete absence of the calvarium.

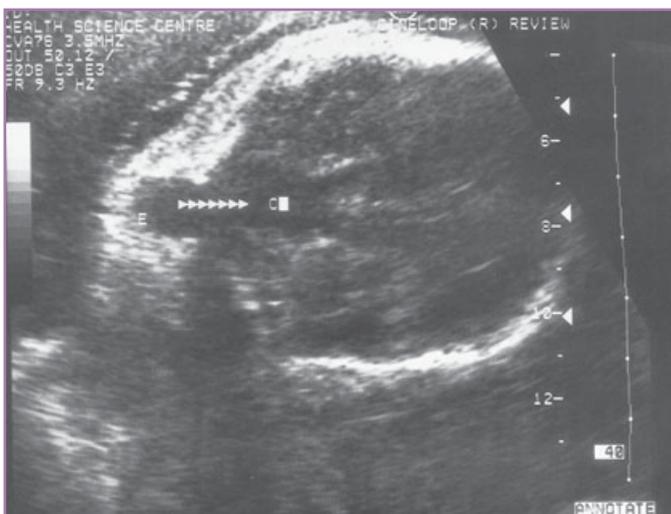

FIGURE 18-7 Posterior encephalocele. The echolucent mass (E) is the meningeal sac protruding through a defect in the posterior occiput. No elements of brain tissue were identified in this mass.

myelomeningocele.^{66,68-70} In utero repair probably reduces the need for postnatal shunting of ventriculomegaly (to 50% in treated patients versus 85% in untreated patients). In utero treatment does reverse hindbrain herniation but does not prevent or halt ventriculomegaly,⁷⁰ and it does not prevent cortical mantle thinning.⁷¹ There is no evidence that in utero repair prevents or moderates lower limb paresis. Postnatal bladder function is not improved,⁷² and in one study it was worse.⁷³ There is no evidence that neurodevelopmental outcome at age 2 years is improved with in utero treatment.⁷⁴ Serious complications have been reported with in utero open surgery for myelomeningocele, including fetal and neonatal death⁶⁹ and abruption.⁷⁵ The results of an ongoing multicenter prospective randomized trial should make it clear whether the surgery is warranted.

Fetal Intracranial Cystic Lesions

Holoprosencephaly

Diagnosis. Holoprosencephaly occurs as a result of failure of normal development of the prosencephalon. The anomaly has three

FIGURE 18-8 The “lemon sign” in spina bifida. This transverse scan of the fetal head in the plane of the biparietal diameter demonstrates collapse of the anterior calvarium, which results in the lemon sign. The collapse of the frontal bone plates of the skull occurs because of downward movement of the frontal lobes, in turn a result of tethering of the spinal cord. The lemon sign is pathognomonic for neural tube defect and is present to varying degrees in virtually every case.

FIGURE 18-9 The “banana sign” in neural tube defect. This transverse scan of the fetal head demonstrates the flattening of the cerebellar hemispheres and the relative loss of the space of the foramen magnum. This banana sign is a result of herniation of the brainstem. The banana sign is very commonly but not universally observed in the fetus with a neural tube defect.

variants: alobar, semi-lobar, and lobar. Both alobar and semi-lobar holoprosencephaly have complete absence of normal cerebral cortex but vary only by degrees of disruption. Both feature a common fused lateral ventricle and both are associated with major mid-facial defects including fused eyes (cyclopia), proboscis defect, and facial clefts. The diagnosis can usually be made from as early as 10 weeks.

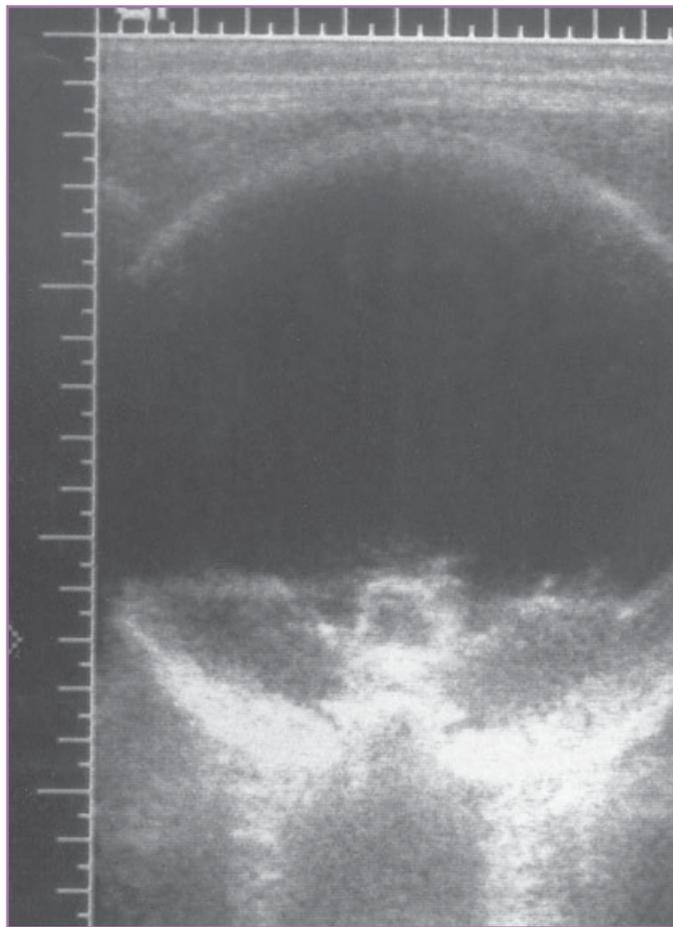

FIGURE 18-10 Holoprosencephaly. In this coronal view of the fetal head, there is complete absence of any cortical structures, including the intercerebral fissure. The brainstem structures are visible. The prognosis for a fetus with this condition is hopeless.

Prognosis. The prognosis is always hopeless. Liveborn infants with alobar holoprosencephaly usually die within the first year of life, and those with the semi-lobar form may survive for longer but always have major neurodevelopmental deficit. Lobar holoprosencephaly is characterized by fusion of the frontal horns of the lateral ventricles and is rarely diagnosed in utero. Holoprosencephaly is associated with trisomy 13 and trisomy 13/15 and less commonly with trisomy 18.

Hydrancephaly and Porencephaly

Diagnosis. Occlusion of cerebral vessels in early fetal life can result in cavitating necrosis of brain tissue. Occlusion of the internal carotid arteries results in loss of both cerebral hemispheres, which are replaced by a fluid-filled cyst (hydrancephaly), whereas occlusion of intracerebral vessels or intracerebral hemorrhage can result in localized cysts distributed in any area of the cerebrum (porencephaly). These lesions are easily recognized on ultrasound as echoluencies without any internal structure. Hydrancephaly can superficially resemble severe hydrocephaly, but with detailed scanning the absence of any midline cerebral structures aids in differentiation (Fig. 18-10).

Porencephaly is recognized with the characteristic isolated round echolucent “holes” in the brain tissue. In contrast, arachnoid cyst and aneurysm of the great vein of Galen, lesions that can also present as cystic structures, are easily differentiated by Doppler ultrasound and

by confirmation of an extracerebral location. Occasionally, a porencephalic cyst may communicate with a lateral ventricle. In most instances, the cause of the vascular occlusion is unknown, but it may result from embolic showers during intrauterine transfusion (my unpublished observations), from infection,⁷⁶ as a consequence of severe acute ischemia in twin-to-twin transfusion syndrome,⁷⁷ from the trauma of fetal invasive procedures such as amniocentesis and possibly chorionic villus sampling,⁷⁸ and from fetal thrombocytopenia.⁷⁹

Prognosis. The prognosis for fetuses with hydrancephaly is uniformly hopeless, and there is no prospect of intact survival. In contrast, the prognosis for fetuses with porencephalic cysts, although generally poor, is much more variable and depends on the location, size, number, and progression.⁸⁰ Differentiation of a porencephalic cyst from an arachnoid cyst is clinically important, because the prognosis of an arachnoid cyst may be excellent.^{81,82} Aneurysm of the great vein of Galen is a very rare fetal anomaly characterized on gray-scale ultrasound as an echolucent cystic mass that lights up with color Doppler. This lesion is usually associated with other vascular malformations and can cause high output failure in the fetus, with resulting hydrops. The long-term prognosis, although not hopeless, is generally poor.⁸³

Intracranial Tumors and Cystic Malformations

Intracranial neoplasms can occur in the fetus and can appear as either cystic or solid lesions or as both, and by mass effect they may distort adjacent normal tissue and cause obstructive hydrocephalus. Intracranial tumors include glioblastoma multiforme,⁸⁴ astrocytoma,⁸⁵ primitive neuroectodermal tumor,⁸⁶ craniopharyngioma, teratoma, and hemangioma.⁸⁷ The prognosis of fetal tumors varies with the cause and size, but it is generally very poor. Specific tissue diagnosis of fetal brain tumor is possible by ultrasound-guided biopsy, but this is rarely if ever indicated.

Choroid Plexus Cysts

Diagnosis. Choroid plexus cysts result from obstruction of the microtubules connecting the fluid-producing cells with the lateral ventricle (Fig. 18-11). These cysts may be unilateral or bilateral, single or multiple, and they are relatively common, occurring in at least 1% of all fetuses.

Prognosis. By themselves the cysts are innocuous and almost always resolve spontaneously. The cyst per se does not cause brain injury, nor is there any direct association between these cysts and postnatal brain dysfunction. The major clinical issue associated with choroid plexus cysts is their association with aneuploidy, especially trisomy 18 and to a much lesser degree trisomy 21.⁸⁸ It is estimated that somewhere between 50% and 66% of fetuses with trisomy 18 have choroid plexus cysts (or a single cyst) as an associated ultrasound finding.⁸⁹ However, choroids plexus cysts are almost never the only anomaly identified in the fetus with trisomy 18. Further, a significant proportion of trisomy 18 can now be accurately recognized in early gestation by nuchal lucency and maternal serum analytes and in the second trimester by detailed survey of fetal hands and the fetal heart. The role of amniocentesis for a fetus with isolated choroid plexus cysts is highly controversial.⁹⁰

Fetal Craniofacial Abnormalities

Microcephaly

Diagnosis. Microcephaly is identified when the fetal head is pathologically small (as opposed to small as a result of normal distri-

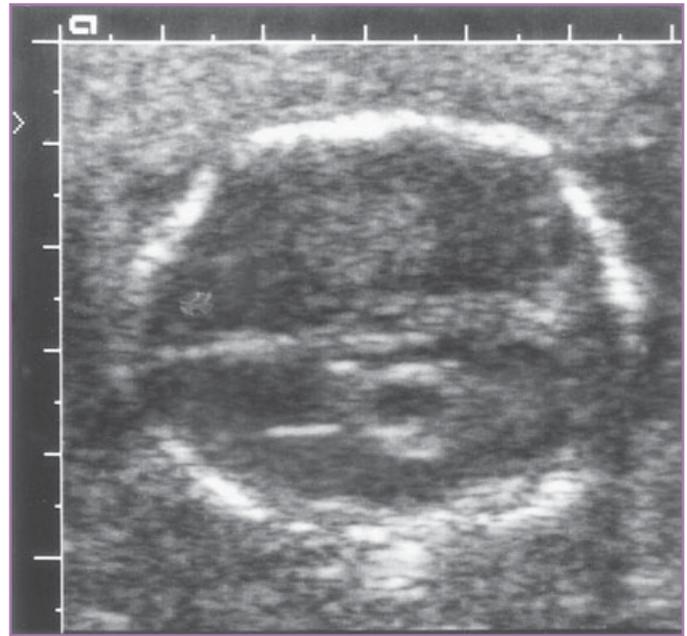

FIGURE 18-11 Choroid plexus cyst. In this transverse view of the fetal head made in the plane of the biparietal diameter, the proximal choroid is normal, and in the distal choroid a solitary cyst is identified.

bution). True microcephaly is diagnosed when fetal head size, as measured in utero by head circumference, is more than 4 standard deviations below the mean. A sloping forehead is a common finding.

Prognosis. Great care must be taken in assigning a prognosis to fetal microcephaly, because 50% of fetuses with a head circumference less than 2 standard deviations below the mean have normal intelligence, and 18% of fetuses with a head circumference less than 3 standard deviations below the mean have normal intelligence.^{91,92}

Craniosynostosis

Diagnosis. Craniosynostosis is the result of early and abnormal fusion of the cranial plates, and it can cause a wide range of abnormal head shapes. Wide separation of the cranial plates can occur with *thanatophoric dysplasia*, and frontal bossing and relative macrocephaly may be observed with *achondroplastic dwarfism*. The intraocular diameter can be measured in utero and standard nomograms³² are available to determine the presence of increased intraocular width (*hypertelorism*) or an abnormally narrow width (*hypotelorism*). Hypertelorism is associated with numerous malformations and syndromes, including facial defects, skull dysplasias, skeletal malformations, and chromosomal abnormalities. Similarly, hypotelorism is associated with conditions such as holoprosencephaly, microcephaly, aneuploidies (including trisomy 13, 18, and 21), and with maternal metabolic disorders such as phenylketonuria.

Prognosis. The prognosis varies with the underlying cause and associated abnormalities.

Fetal Facial Anomalies: Facial Clefts

Diagnosis. Facial clefts are among the most common of all fetal anomalies, occurring with a frequency of approximately 1.2 per 1000 births⁹³ and accounting for about 13% of all reported anomalies, second in incidence only to fetal cardiovascular defects.⁹⁴ The recurrence of cleft lip or cleft palate conforms to a polygenic multifactorial inheritance pattern. With normal parents and one affected infant, or when one parent has the abnormality, the recurrence risk in the sub-

FIGURE 18-12 Two-dimensional ultrasound image of the fetal face in the transverse plane. Note the bilateral facial cleft. (Courtesy of Dr. Christopher Harman.)

sequent fetus is about 4%. When both parents are affected, the risk is about 35%. The risk in subsequent fetuses rises as more siblings have the anomaly. Abnormal findings in the parents may be subtle and expressed as a bifid uvula, a submucous cleft of the soft palate, or linear lip indentations. In about 50% of affected fetuses, the facial cleft involves the lip and palate, and the remaining cases are roughly equally divided between isolated cleft lip (25%) and cleft palate (25%). Cleft lip usually cannot be identified before about the midpoint of the second trimester, and isolated cleft palate is infrequently diagnosed in utero.²²

The two-dimensional ultrasound diagnosis of cleft lip requires a frontal view of the lower face at its outmost projection (Fig. 18-12). Because the fetal head is usually flexed, with the chin resting on the anterior thorax, the best imaging of the fetal lips and nose often occurs while the fetal heart is being evaluated. The diagnosis of facial clefts is enhanced with three-dimensional ultrasound⁹⁵ (Fig. 18-13), and specialized views may improve the recognition of cleft palate.^{96,97} However, overall routine ultrasound screening is relatively poor in detecting cleft lip or palate. In prospective studies in the general population, the detection of cleft lip ranged from 44% to 60%.^{94,98}

Prognosis. About one third of fetuses with a cleft lip or palate have an associated major anomaly, such as Goldenhar syndrome (oculoauriculovertebral dysplasia), Pierre Robin syndrome (micrognathia), and Treacher Collins syndrome (mandibulofacial dysostosis), and aneuploidies, especially trisomy 13 and less frequently trisomy 18. In the absence of associated anomalies, the prognosis for cleft lip or palate is good, and remarkable postnatal cosmetic repair is achievable.

Anomalies of the midface such as fused orbits (cyclopia) and nose anomalies (in the extreme form, proboscis lateralis) are typically associated with trisomy 13 or more rarely are a manifestation of hemifacial microsomia and otocephaly. The diagnosis of micrognathia is usually made by visual assessment, but nomograms for mandibular length per gestational age are published.⁹⁹ The Pierre Robin syndrome is characterized by a short mandible (micrognathia), a posterior displacement of the tongue (glossoptosis), and a U-shaped cleft palate. These facial abnormalities can lead to feeding problems in the newborn. Other conditions associated with micrognathia include Treacher Collins syndrome and various aneuploidies including triploidy.

FIGURE 18-13 Three-dimensional ultrasound of the fetal face. In the frontal view, the bilateral facial clefts are clearly visible. (Courtesy of Dr. Christopher Harman.)

Anomalies of the Neck and Chest

Fetal Lung Anomalies

By about day 26 of fetal life, the endodermal primordia of the fetal lung derive from the respiratory diverticulum arising from the floor of the pharynx, and by about day 28 the two lung buds grow out from the caudal end of the diverticulum and draw along the splanchnic mesenchyme. These two components ultimately form the functional lung, with the endoderm complement giving rise to the bronchial tree and alveoli and the mesenchyme giving rise to the vascular component. Abnormal development of the lung buds can lead to three major lung anomalies: bronchogenic cyst, bronchopulmonary sequestration (BPS), and congenital cystic adenomatoid malformation (CCAM).

Bronchogenic Cyst

Diagnosis. A bronchogenic cyst is a rare anomaly (incidence, approximately 1 in 15,000 live births) that develops when a component of the growing lung bud becomes isolated from the main bifurcation process. These cysts are thin walled and usually located in the mediastinum near the membranous portion of the posterior trachea, but they can occur anywhere throughout the lung and can be attached to the pericardium, the mediastinum, below the diaphragm, and in the upper airway including the mouth. The interior of the cyst often contains cartilaginous nests, mucous glands, and primitive respiratory epithelium. Typically there is a single cyst, but multiple cysts can occur. The ultrasound diagnosis of bronchogenic cyst is quite straightforward. It is usually seen as a simple round empty cystic structure prominent in the fetal lung. The cyst can be multilobular and is often large (Fig. 18-14).

Prognosis. The cyst per se is benign but the compressing effect on contiguous tissue can cause fetal compromise. Compression of the esophagus can occur, with subsequent hydramnios and preterm labor. Compression of a mainstem bronchus, evident as increased echogenicity in the distal lung, can result in airway compromise at birth. Fetal hydrops appears not to be a complication of bronchogenic cyst, and accordingly the fetal prognosis is excellent. In most instances postnatal resection of the cyst is required.

Bronchopulmonary Sequestration

Diagnosis. A pulmonary sequestration is a rare sporadic lung anomaly arising as a echogenic mass of lung tissue that has no connection to the trachea and receives blood supply from one or more anomalous vessels. The sequestered mass is thought to derive from an aberrant secondary lung bud developing in the embryonic fetal foregut distal to the tracheobronchial bud. As the aberrant lung bud develops, it brings its own splanchnic blood supply and can develop a separate pleural membrane. BPS can occur anywhere in the distribution of the primitive foregut, but in most cases (75%) the semisolid mass is confined to a lobe of the lung, and in about 25% of cases it is extralobar, either within the mediastinum or below the diaphragm. The key diagnostic points are the recognition of an echogenic mass (often extremely dense) and a separate feeding vessel demonstrated with Doppler ultrasound (Fig. 18-15). Pleural effusion, displacement of the mediastinum,

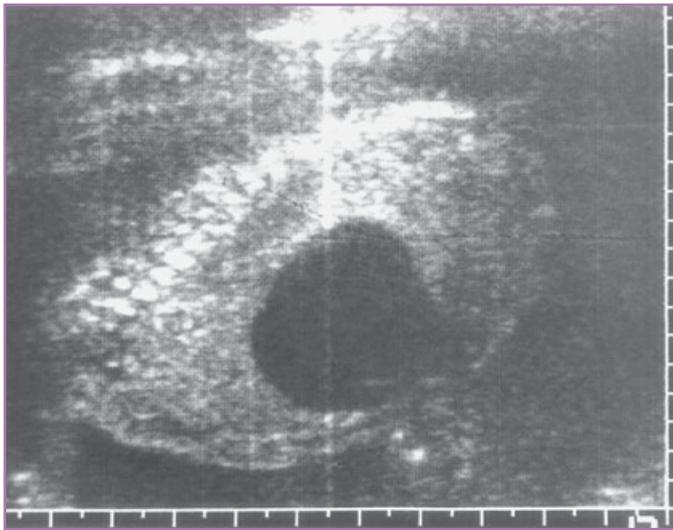

FIGURE 18-14 Bronchogenic cyst. This large simple cyst is in the left hemithorax.

hydrops, and hydramnios are frequently associated ultrasound findings.¹⁰⁰

Prognosis. Initially, it was reported that BPS was lethal in the majority (66%) of cases overall and in all cases when hydrops was present.¹⁰¹ It is now understood that BPS may evolve along three pathways. First, in some cases, BPS may resolve spontaneously in utero.^{102,103} The mechanism for resolution appears to be occlusion of the feeding aberrant vessel and subsequent involution, although reestablishing a connection with the main tracheobronchial tree is a remote possibility. In utero resolution is not associated with any postnatal consequences. Second, in some cases, the lesion remains relatively stable in utero and causes no fetal consequences. Postnatal resection is required in most cases but usually can be delayed until the infant is at least 6 months old.^{104,105} Postnatal survival in these infants is at least 95%.¹⁰⁶

Third, in about 20% of cases, generalized hydrops develops in association with BPS. The mechanism for hydrops is unknown but may be related to compression of veins and lymphatics. The development of hydrops with BPS gravely affects the prognosis. In the absence of intervention, most if not all of these fetuses die. Treatment options vary according to gestational age. In the fetus at or beyond 26 weeks, the treatment of choice includes steroids, delivery, and postnatal care. In the grossly immature fetus, open in utero resection of the mass is an option: Grethel and colleagues¹⁰⁶ reported a 50% survival (15 of 30 cases) with open surgery, compared with a 3% survival (1 of 33) in those managed conservatively. Ultrasound-guided laser fulguration of the feeding vessels of the sequestered mass has been reported to be an effective and less invasive method of treatment.¹⁰⁷ Extralobar sequestration can undergo torsion, causing pleural effusion, which when progressive and severe may require pleuroamniotic shunting.

Congenital Cystic Adenomatoid Malformation

Diagnosis. Congenital cystic adenomatoid malformation is an uncommon lung lesion that appears to arise with an arrest in development of a lobule of the lung. The mass is almost always singular, unilobular (in 90% of cases), and unilateral (in 99% of cases), and it always communicates with the parent tracheobronchial tree, although the connections are minute and tortuous. The arterial and venous blood supply arises from the normal pulmonary circulation (as

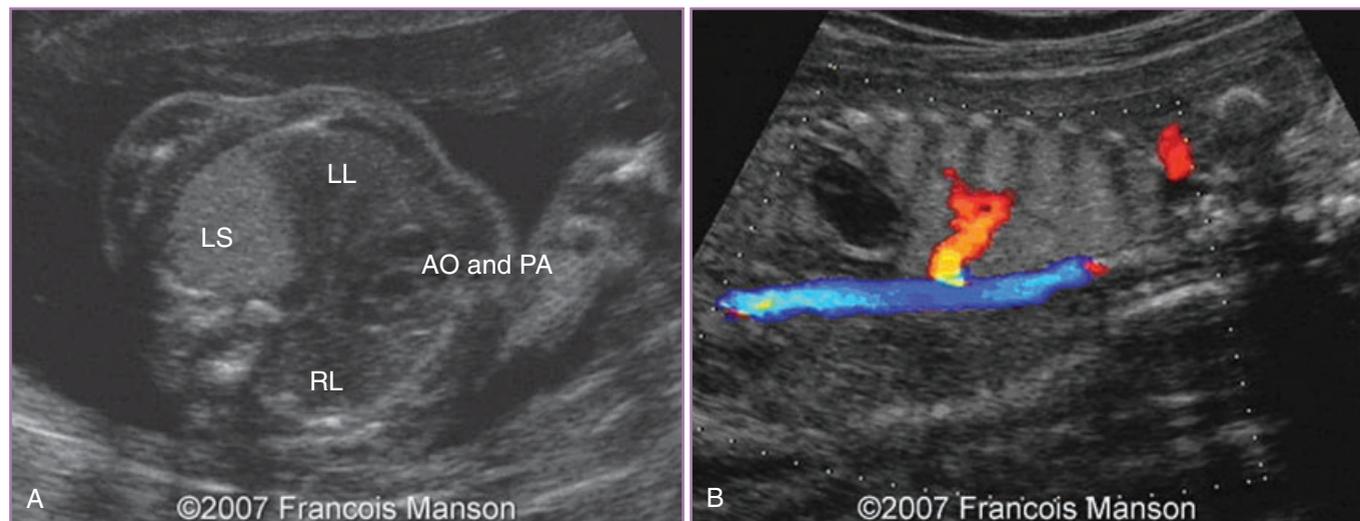

FIGURE 18-15 Bronchopulmonary sequestration. **A**, The echodense mass occupies a significant portion of the lower hemithorax. **B**, Color Doppler image of a single large feeding vessel arising from below the diaphragm. AO, aorta; LL, left lung; LS, lung sequestration; PA, pulmonary artery; RL, right lung. (Courtesy of Dr. Phillipe Jeanty.)

FIGURE 18-16 Congenital cystic adenomatoid malformation of the lung, type 1. This echodense mass occupies almost the entire hemithorax. Note the mass effect resulting in a slight mediastinal shift. (Courtesy of Dr. Phillippe Jeanty.)

opposed to the aberrant blood supply seen in BPS). The macroscopic, histologic, and ultrasound appearances of CCAM vary according to the time that development was arrested.¹⁰⁸ Type I CCAM (Fig. 18-16) mimics late lung development and has the characteristic features of large (up to 10 cm), single or multiple simple cysts. Type I is the most commonly observed variant of CCAM (50% of postnatal cases) and has an excellent prognosis. Type II CCAM resembles the pseudoglandular phase of lung development and is characterized by the presence of multiple small (typically between 3 and 10 mm in diameter) cysts within the mass. About 40% of all CCAMs are classified as type II lesions. Type III CCAM resembles the very early developing lung and is composed of regularly spaced bronchiole-like structures and primitive alveolar sacs. Type III lesions are characterized by the absence of visible cysts and the appearance of a large echodense mass usually involving the entire lobe of the lung (Fig. 18-17). Microcysts can be identified by histologic examination. Type III CCAM is the least common type (approximately 10%), and it is the most lethal.

Associated anomalies are rare with type I lesions. In contrast, associated anomalies such as truncus arteriosus, tetralogy of Fallot, and jejunal atresia occur in about 15% of fetuses with type II lesions and an even higher proportion of fetuses with type III lesions.¹⁰⁸

Prognosis. The natural outcome varies according to CCAM type and ranges from excellent (near 100% survival) with type I, to good survival in type II (the outcome depends mostly on the presence or absence of associated anomalies), to poor with type III, to hopeless with type III with hydrops. At least 15% of cases of CCAM resolve spontaneously in utero.¹⁰⁹ The prognosis can be improved with in utero therapy, including open resection of the lesion and reduction of lung compression by placing a pleuroamniotic shunt. Adzick and coworkers¹⁰² reported outcomes in 120 fetuses with CCAM (of all types). The 101 fetuses who did not develop hydrops were managed conservatively (observation/intervention at fetal maturity) and all survived (100% survival). Of the 120 fetuses, 38 (31.5%) developed hydrops (most with type III lesions). In this group, 25 fetuses were managed conservatively and all died (100% mortality), and 13 were treated in utero by open resection and eight survived (61%). An additional six with a very large solitary cyst and without hydrops received

FIGURE 18-17 Congenital cystic adenomatoid malformation, type III. Note the extreme displacement and compression of the fetal heart. (Courtesy of Dr. Phillippe Jeanty.)

a percutaneous procedure to place a shunt between the cyst and the amniotic cavity, and five of these six fetuses survived.

In a reported British experience of 67 fetuses,¹⁰⁴ 35 cases were microcystic (CCAM types II and III), 27 cases (40%) were macrocystic (predominantly CCAM type I), and five cases (8%) were mixed (type II). Fetal hydrops was uncommon, occurring in only five fetuses (7%). None of these fetuses had open surgery. Survival was 96% (64 of 67 fetuses). Most (63%) required postnatal surgery.

Diaphragmatic Hernia

In the developing fetus, the mesenchymal muscular diaphragm closes before 9 weeks' gestation and before the midgut retreats into the abdomen from its temporary umbilical cord herniation. If the midgut returns to the abdomen before the diaphragm closes, there is the potential for herniation of the viscera, including the liver, typically through a posterior lateral defect into the thoracic cavity, resulting in a congenital diaphragmatic hernia (CHD).

Diagnosis. Congenital diaphragmatic hernia is a relatively uncommon anomaly occurring at a frequency of about 1 per 7000 live births, and more frequently in stillborn infants.¹¹⁰ In at least 40% of cases, CDH is associated with other major anomalies including aneuploidy (18% of cases) and cardiac defects.^{111,112} Only about half of all cases of CDH are diagnosed prenatally. The classic ultrasound diagnostic features of CDH are the presence of a cystic mass in the hemithorax (usually the left) and often with evident peristaltic movements, the absence of the normal fluid-filled stomach "bubble" sited in the fetal abdomen, the presence of a scaphoid abdominal wall, a shift of the mediastinum, lateral deviation or kinking of the umbilical portion of the portal sinus, and varying degrees of hydramnios (Fig. 18-18). The actual diaphragmatic defect is almost never identified by ultrasound.

Prognosis. The prognosis for fetuses with CDH is determined almost exclusively by the presence and degree of pulmonary hypoplasia, which in turn appears to be a direct result of compression of the lung by the herniated viscera. The degree of pulmonary hypoplasia depends on the timing of the herniation (the earlier the hernia, the greater the degree of hypoplasia), the volume of the herniated viscera (pulmonary hypoplasia is greatest when the left lobe of the liver is

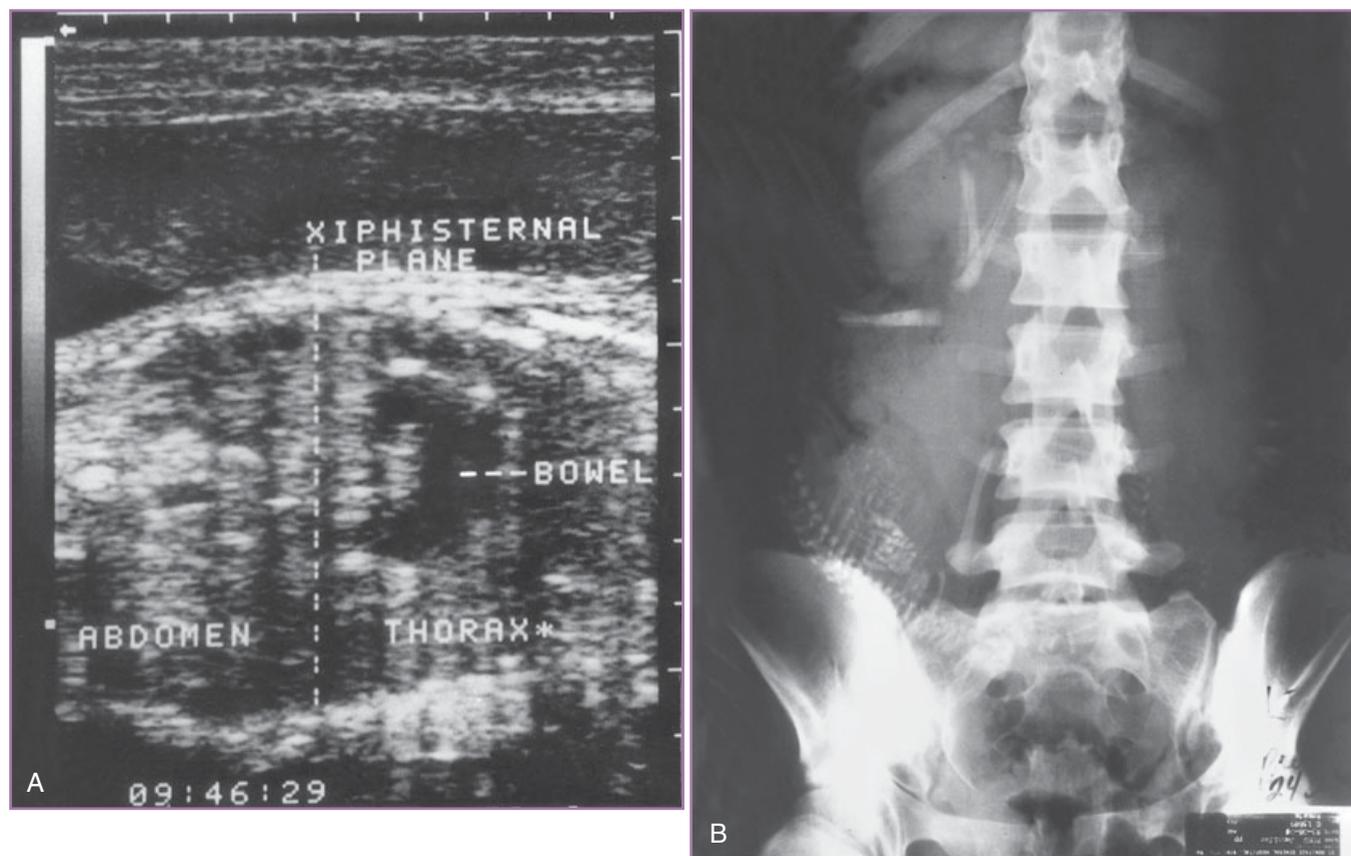

FIGURE 18-18 Diaphragmatic hernia. **A**, Longitudinal view of the fetal chest and abdomen demonstrates an echolucent mass in the fetal chest (stomach and small bowel). Note the absence of stomach in the abdomen and the relative scaphoid anterior abdominal wall. **B**, This maternal abdominal radiograph demonstrates a fetus in cephalic presentation with the fetal spine to the maternal right. In this case, Renografin had been introduced into the amniotic fluid, was swallowed by the fetus, and is concentrated in the small bowel. The radiopaque Renografin outlines the fetal small bowel and clearly confirms its presence within the fetal thorax.

herniated into the chest and least when the hernia is only stomach and small bowel), and on the persistence of the hernia. Paradoxically, in some instances, the diaphragmatic defect may allow a sliding type of hernia, in which case the risk of pulmonary hypoplasia is very low. When CDH is present but not recognized despite prenatal ultrasound screening (in about 50% of cases), the implication is either that the hernia is of the sliding variety or it is relatively small and does not contain liver. The perinatal survival when CDH is diagnosed after birth is reported to be in the range of 66%, compared with 33% in those cases of CDH diagnosed prenatally.¹¹¹ Polyhydramnios is an important prognostic feature: 11% of fetuses survive when hydramnios is present, whereas 55% survive when amniotic fluid volume is normal.¹¹³

Open fetal surgery to reduce the hernia and close the diaphragm defect was advanced as a novel and potentially effective therapy. In a series of elegant experiments in sheep and primate fetuses, Harrison and colleagues¹¹⁴ were able to demonstrate that creating a diaphragmatic hernia could cause lethal pulmonary hypoplasia, and that subsequent repair of the iatrogenic hernia would restore lung growth and allow for survival of some of the experimental animals. Unfortunately, these observations have not translated into effective treatment in the affected human fetus. In an initial human clinical trial involving 14 fetuses treated by open surgery before 24 weeks' gestation, five died intraoperatively (often when a herniated left lobe of liver

could not be reduced), three died in utero despite apparent successful repair of the defect, and two delivered prematurely and died. The overall survival was 28.5%.¹¹⁵ The survival rate for patients referred to the same center but electing to defer surgery was 41%. In a subsequent randomized trial, survival was not improved by in utero repair of CDH and accordingly the procedure is now no longer accepted or practiced.¹¹⁶

It remains clear, however, that fetuses with CDH containing the left lobe of the liver are at greatest risk for death from pulmonary hypoplasia. Furthermore, it has been reported that the ratio of the right lung to the head circumference (LHR) might be useful as a sonographic predictor of the degree of pulmonary hypoplasia and survival in the fetus with CDH.¹¹⁷ In 55 affected fetuses, there were no survivors when the LHR was less than 0.6, all fetuses survived when the LHR was greater than 1.35, and 61% of fetuses survived when the values were intermediate. In a more recent study, Jani and coworkers¹¹⁸ noted that the LHR was a good predictor: survival with an LHR of 0.4 to 0.5 was 17%, between 0.6 and 0.7 it was 62%, and between 0.8 and 0.9 it was 78%. The prognostic value of LHR is disputed. Heling and colleagues¹¹⁹ reported no prognostic value of this ratio among 22 fetuses with isolated CDH, and Arkovitz and coworkers,¹²⁰ in a study of 28 fetuses, could find no correlation of the LHR to outcome.

As it has been known for some time that occlusion of the trachea can result in exaggerated lung growth,¹²¹ in utero tracheal occlusion

has been advocated to treat this most severe form of CDH. Initial attempts at open tracheal occlusion have been unsuccessful, with only five of 15 fetuses (33%) surviving.¹²² An initial clinical experience with fetal tracheal occlusion using a fetoscopic approach to place an occluding clip appeared more successful, with six of eight fetuses (75%) surviving, compared with 15% survival in those treated by open surgery to occlude the trachea and 38% survival in affected fetuses managed conservatively.¹²³ However, in a subsequent prospective trial of fetoscopic tracheal occlusion for severe congenital diaphragmatic hernia conducted in 24 randomized patients (11 to fetoscopic tracheal occlusion and 13 to observation only), there were no observed differences in outcome (73% survival treated versus 77% survival not treated). The trial was stopped and it was concluded that tracheal occlusion did not improve survival or morbidity rates among a cohort of fetuses with the most severe form of congenital diaphragmatic hernia.¹²⁴ Subsequently, in a nonrandomized trial, Deprest and colleagues¹²⁵ reported that survival rate to discharge was 50% for 20 fetuses with severe CDH treated by fetoscopically placed balloon occlusion of the trachea (fetoscopic endoluminal tracheal occlusion [FETO]). The consensus of the published data to 2007 suggests that tracheal occlusion remains experimental, and any conclusions as to its value await more extensive randomized trials.

Chylothorax and Other Fetal Pleural Effusions

Diagnosis. Accumulation of fluid in the pleural cavity of the fetus can occur either because of abnormal lymphatic drainage of the pleural space (chylothorax), as a result of local pathology in or adjacent to the pleural space (diaphragmatic hernia, extralobar sequestration), or as a result of a generalized disease process associated with hypoproteinemia, anemia, or increased venous compression (immune and non-immune hydrops). Chylothorax is usually bilateral, is usually not associated with any mediastinal shift, and has a good prognosis (Fig. 18-19).

The pathognomonic diagnostic feature in the newborn—chyle-stained (milky white) pleural drainage—does not occur in the fetus. Fluid aspirated from the fetus with chylothorax is clear, and when it is examined microscopically, it exhibits a high proportion of lymphocytes, nearly always more than 80% and often almost 100%. Chylothorax is usually a late-onset disease in the fetus and is seldom seen before 30 weeks' gestation.

Prognosis. The condition is relatively benign for the fetus but life threatening for the newborn. Treatment can include either thoracocentesis immediately before delivery or continuous drainage by ultrasound-guided percutaneous placement of a pleuroamniotic shunt. Because lymphatic fluid accumulates quickly, there is no benefit to serial fetal thoracocentesis.

The prognosis for fetuses with chylothorax is very good, with at least 85% surviving without long-term morbidity. Pleural effusions from causes other than chylothorax have a very different outcome. These effusions are associated with an abnormal karyotype in at least 5% of cases and with severe congenital heart disease in about 5% of cases. Secondary pleural effusions associated with or resulting from hydrops carry a very poor prognosis, mostly as a result of the underlying cause of the hydrops. The reported mortality of secondary pleural effusions is 53%,¹²⁶ although more recent reports indicate improved survival, which is now in the range of 75%.¹²⁷ Despite in utero treatment by chronic pleuroamniotic shunting, the outcome of fetuses with pleural effusion and hydrops still remains guarded. In a study of 16 fetuses with pleural effusions associated with hydrops treated in utero, seven survived (44%) and two procedure-related deaths occurred.¹²⁸

FIGURE 18-19 Pleural effusion. Sagittal scan of the thorax in a 31-week fetus with bilateral pleural effusions. The effusion is greater in the right hemithorax, and there is no associated ascites or skin edema. In this fetus, the discovery of pleural effusion was incidental, and it was the result of chylothorax. It is likely that this observation was critical to the survival of this perinate.

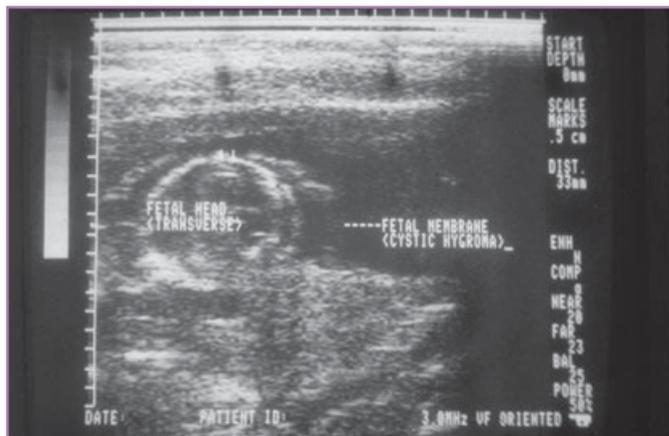

FIGURE 18-20 Cystic hygroma. In this transverse view of the fetal head in the plane of the biparietal diameter, bilateral large echolucent cysts are evident. This fetus had a normal karyotype but developed large hydrops and died in utero.

Cystic Hygroma

Diagnosis. Cystic hygroma (also termed lymphatic hamartoma or cystic lymphangioma) consists of loculated tissue sacs distended with lymphatic fluid (Fig. 18-20). These lesions are most commonly in the region of the posterior neck, but they can also occur in the mediastinum and the axilla. The lesions may be huge and extend from the neck to the entire dorsum of the fetus, or extend around the fetus to engulf

the head. The cause of cystic hygroma is not certain, but in most instances it is thought to be the result of abnormal communication between the primitive jugular lymphatic and the internal jugular vein. There is no communication between the hygroma and the normal lymphatic drainage.

Prognosis. The mortality rate associated with cystic hygroma diagnosed before 30 weeks' gestation is high (93%) and most of the fetal deaths (84%) are associated with progressive nonimmune hydrops.¹²⁹ There is a high rate of association between cystic hygroma and aneuploidies, especially trisomy 21, Turner syndrome, and Noonan syndrome. Occasionally, a cystic hygroma resolves spontaneously in utero and is associated with survival and normal outcome. Pregnancy termination is a common management option, however. In the patient electing pregnancy continuation, amniocentesis is strongly indicated. If the amniocentesis result is normal and nonimmune hydrops does not develop, expectant management is reasonable. It is important to determine the relationship between the edges of the hygroma and the trachea and upper airway, as obstruction can occur at birth. Ex utero intrapartum treatment (EXIT) may be indicated in such cases and may enhance survival.¹³⁰

Anomalies of the Gastrointestinal Tract and Abdominal Wall

Esophageal Atresia and Tracheoesophageal Fistula

Esophageal atresia, although among the most commonly observed anomalies of the gastrointestinal tract, is a relatively rare defect occurring at an estimated frequency of 1 per 4000 live births.¹³¹ The esophagus and trachea both develop as a common diverticulum from primitive foregut and then separate into the two separate structures as a result of proliferation of the endodermal components. This process is completed early in gestational life, and by about 26 days the esophagus and trachea appear as separate structures.

Disruption of the normal separation of the esophagus and the trachea results in a spectrum of anomalous variations (Fig. 18-21), of

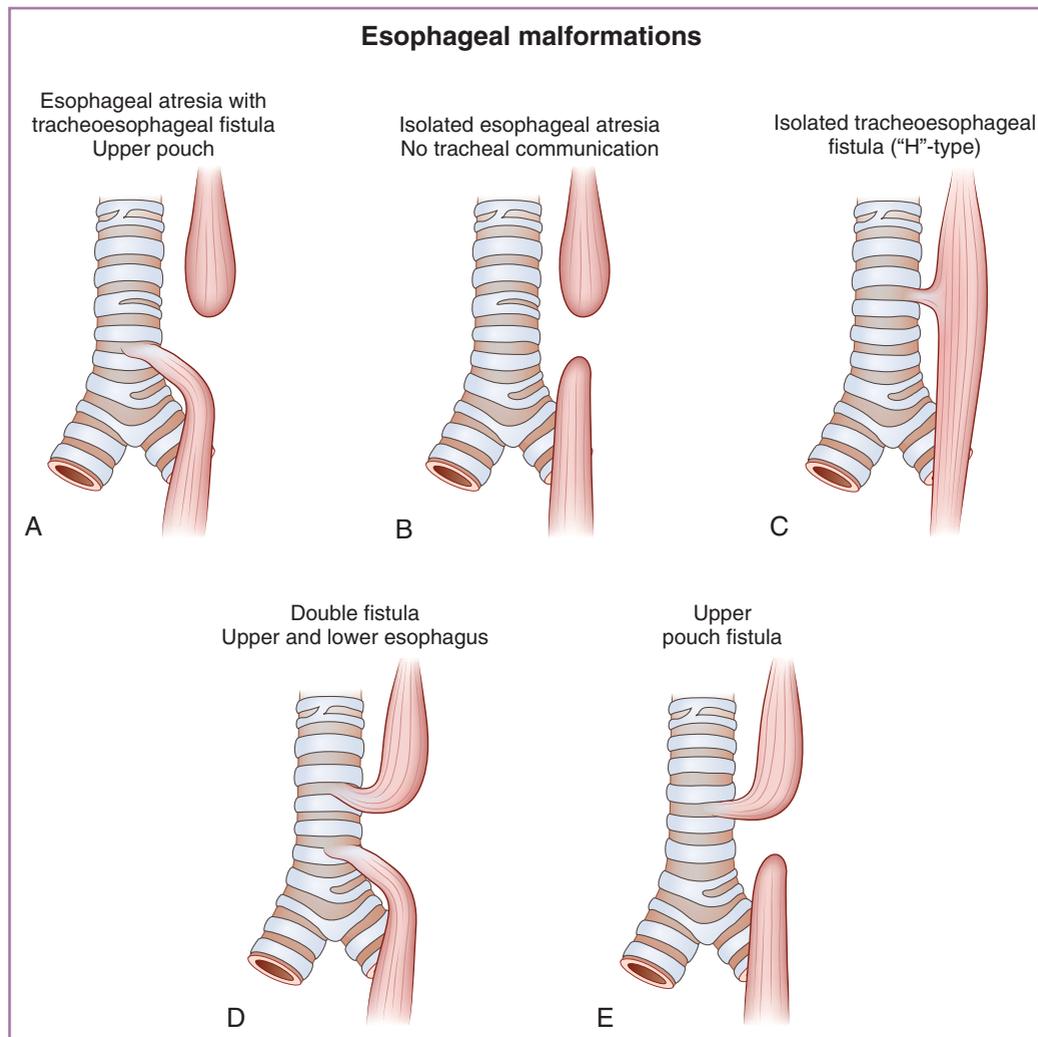

FIGURE 18-21 Variations of tracheoesophageal anomalies. Of the five types (A, B, C, D, and E), B is by far the most common.

which the most common (90% of cases) is a blind upper esophageal pouch, with the separated lower esophagus communicating with the trachea via a short fistulous connection. The esophageal atresia–tracheoesophageal (TE) fistula complex has no direct fetal effects, and growth and development are normal. However, there is a strong association between this anomaly and anomalies of other organ systems. Major cardiac anomalies are present in at least 25% of fetuses with esophageal atresia–TE fistula, and about 5% of affected fetuses have aneuploidies, most commonly trisomy 13, trisomy 18, and less commonly trisomy 21.¹³² Esophageal atresia–TE fistula complex is also found in association with other anomalies of the gastrointestinal tract, heart, vertebrae, kidneys, and limbs, and these anomalies often occur together with a specific spectrum of anomalies known as the VACTERL association: vertebral abnormality, anal atresia, cardiac defect, tracheoesophageal fistula, renal and radial limb abnormality.

Diagnosis. The diagnosis of esophageal atresia–TE fistula is usually made by inference from the ultrasound findings of hydramnios and absence of a visible stomach bubble *made over serial observations*. A normal fluid-filled stomach is routinely seen by 15 weeks' gestation, and although physiologic emptying of the stomach does occur, complete emptying is unusual and refilling is rapid.¹³³ Neither of these findings is specific to the condition, but persistence increases the probability of the diagnosis. Occasionally, the blind dilated proximal esophageal pouch can be visualized,¹³⁴ and it is pathognomonic for esophageal atresia. Furthermore, in affected fetuses observed with real-time ultrasound, it is not uncommon to see repetitive swallowing efforts and intermittent episodes of rapid egress of fluid from the mouth (my

personal observations, 2007). As imaging methods have improved, the diagnosis of the condition is more common.

Prognosis. Khorshid and coworkers¹³⁵ reported on an experience of 78 cases diagnosed antenatally. Fetal prognosis varies according to associated anomalies. Usually, the hydramnios is moderate and preterm delivery is not a common problem. The newborn is at risk for reflux and aspiration. Long-term sequelae include a high incidence of metaplasia of the esophageal mucosa, and esophageal cancer in young adulthood has been reported.¹³⁶

Duodenal and Small Bowel Atresia

Anomalous luminal occlusion can occur as an isolated or a repeated defect anywhere in the small bowel, but it most commonly affects the proximal duodenum. Small bowel atresias appear to be the result of failure of recanalization of the invading epithelial core. Swallowed and secreted fluid accumulates proximal to the obstruction and distends the bowel. Furthermore, the more proximal the obstruction is, the less swallowed amniotic fluid is absorbed and accordingly the greater is the degree of hydramnios.

Duodenal Atresia

Diagnosis. Duodenal atresia is by far the most common small bowel obstruction. The classic ultrasound findings are echolucent distended proximal duodenum coupled with a normal or moderately distended stomach, producing the “double-bubble” sign (Fig. 18-22). The signs of duodenal atresia are relatively slow to develop, but rarely

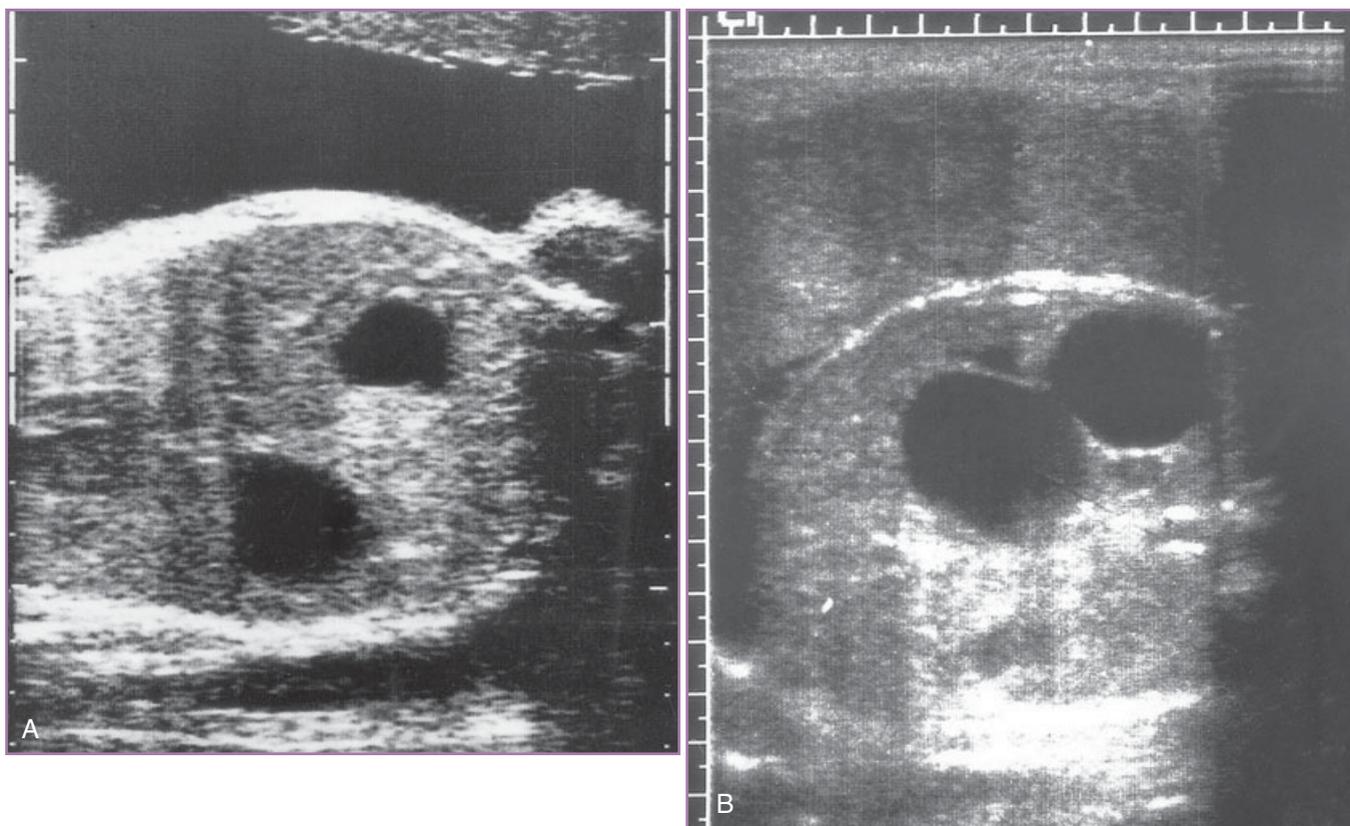

FIGURE 18-22 Duodenal atresia. **A**, Longitudinal view of the abdomen of a fetus with duodenal atresia. Note the two discrete cystic structures. The inferior structure is the dilated stomach, and the cystic mass to the upper right is the distended proximal duodenum. **B**, Transverse view of the fetal abdomen in a fetus with duodenal atresia.

they may be present as early as 15 weeks.¹³⁷ It is much more typical for them to appear in the late second trimester. The associated hydramnios usually has an insidious course, although occasionally it may appear as massive acute distention of the uterus. Other anomalies are present in at least 50% of fetuses with duodenal atresia, and cardiac anomalies are the most commonly associated structural defects. At least 25% of fetuses with duodenal atresia have trisomy 21.¹³⁸ A detailed anatomic survey and an amniocentesis are required aspects in the management of the fetus with duodenal atresia.

Duodenal obstruction can occur for causes other than atresia, and the ultrasound findings may be identical to those observed with luminal atresia. Other causes of duodenal obstruction in the fetus include annular pancreas,¹³⁹ duodenal web, occlusion by an anomalous portal vein crossing over the duodenum,¹⁴⁰ and an abnormal location of the common bile duct.¹⁴¹ Rarely, the proximity of other intra-abdominal cysts, such as a choledochal cyst, renal cyst, or mesenteric cyst to the duodenum, can lead to the wrong diagnosis of duodenal obstruction.

Prognosis. When the duodenal atresia is an isolated finding and the karyotype is normal, the long-term prognosis is excellent. The hydramnios associated with duodenal atresia is usually slowly progressive and rarely causes maternal distress or compromise. Symptomatic hydramnios can be treated either with serial-reduction amniocentesis or with maternal indomethacin therapy, or with both. Preterm delivery related to hydramnios is a common complication and occurs in at least 46% of cases.¹⁴² Postnatal surgical repair is usually very successful, with survival rates in the range of 90%, although intraoperative mortality of up to 4% is reported¹⁴³ and late mortality occurs in up to 6% of affected infants.¹⁴³

Small Bowel Obstruction (Intestinal Atresia)

Diagnosis. Intestinal atresia can occur at any level below the duodenum but is most commonly seen in the jejunum and less commonly in the ileum. Obstruction of the small bowel is characterized by multiple echolucent loops of small bowel proximal to the areas of obstruction (Fig. 18-23). Unlike duodenal atresia, jejunal and ileal atresias are usually isolated findings and are rarely associated with aneuploidies and other organ anomalies. The cause of small bowel atresia is usually not known, although in some cases segmental arterial occlusion is observed. The lumen of terminal ileum can be obstructed with viscous meconium, especially in infants with cystic fibrosis.¹⁴⁴

Prognosis. Hydramnios is usually absent or mild with intestinal atresia, and the pregnancies usually continue to term. Surgical repair is necessary in the early neonatal period, and postnatal survival is excellent.¹⁴²

Echogenic Bowel

Diagnosis. The finding of speckled or echogenic bowel is a common ultrasound observation (Fig. 18-24). The condition is characterized by increased echodensity of the small bowel. The diagnosis is subjective, and as the quality of ultrasound imaging has improved, an accurate diagnosis has become more difficult and overdiagnosis has become very common. The essential pathologic ultrasound sign is *echogenicity of the small bowel approximating the echodensity of long bones and the sacrum*.

Prognosis. True echogenic bowel is associated with cystic fibrosis, fetal infection (e.g., by cytomegalic inclusion virus),¹⁴⁵ and splanchnic ischemia associated with dysmature intrauterine growth restriction.¹⁴⁶ Echogenic bowel may be associated with swallowing of fetal blood from the amniotic cavity and thus may be a transient finding.¹⁴⁷ The

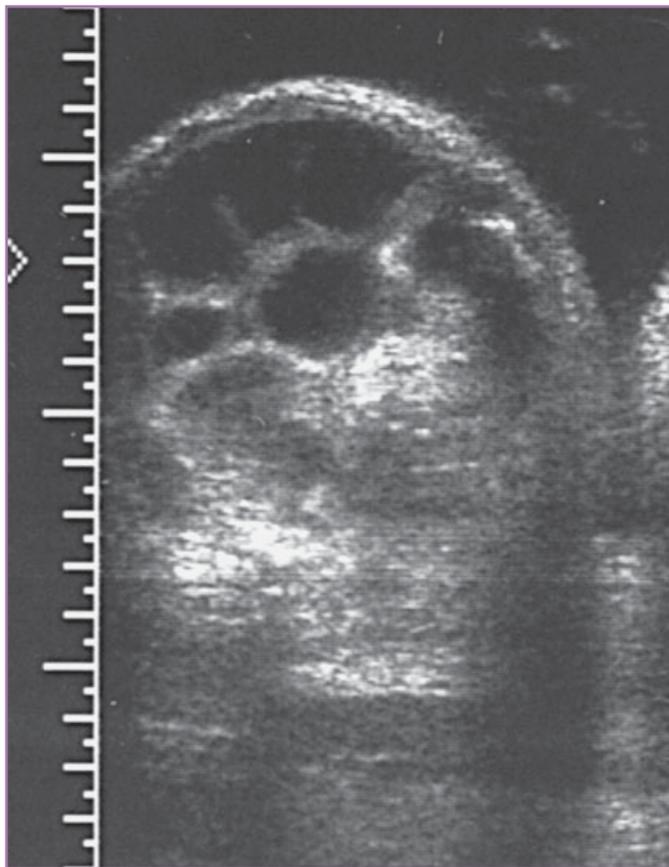

FIGURE 18-23 Small bowel obstruction. Transverse view of the fetal abdomen in a fetus with distal ileal atresia. Note the multiple loops of dilated small bowel. During real-time ultrasound scanning, hyperperistaltic activity in most of the dilated bowel loops was observed.

FIGURE 18-24 Echogenic bowel. A transverse scan of the abdomen in a 19-week fetus demonstrating intense echogenicity of the small bowel. The bowel echogenicity is comparable to that of bone.

association of echogenic bowel with aneuploidies, especially trisomy 13, 18, or 21, is very tenuous, and the occurrence of echogenic bowel as the *only marker of trisomy 21 probably never occurs*.¹⁴⁸

Large Bowel Obstruction

Diagnosis. Obstruction of the fetal colon is uncommon and is notoriously difficult to diagnose by ultrasound. In the normal fetus, meconium normally accumulates in the colon with advancing gestational age, and it can produce an ultrasound image not dissimilar to obstruction. True large bowel obstruction can occur as a result of a mechanical plug produced by meconium, as a result of abnormal innervation of the large bowel (e.g., with Hirschsprung disease¹⁴⁹), and in association with other anorectal anomalies (e.g., isolated defects such as anal and rectal atresia), or in association with multiple organ anomaly syndromes (e.g., VACTERL association).

Prognosis. Large bowel obstruction rarely if ever results in fetal compromise in utero, and the problems associated with this anomaly are usually confined to the immediate neonatal period. Occasionally, meconium obstruction of the large bowel results in rupture and leakage of meconium into adjacent tissues. The fetal inflammatory response is intense and walls off these areas, which ultimately calcify. Accordingly, multiple calcified echogenic foci scattered throughout the abdomen are a sign of meconium ileus.

Hepatic Masses

Diagnosis. The fetal liver is easily visualized in utero, and the size, shape, and echogenic texture can be assessed. Hepatomegaly in the fetus is almost always secondary to acquired fetal disease such as allo-immune anemia and infections. Liver tumors including teratoma, hamartoma, adenoma, and angiomas can be recognized in utero. Occasionally, these fetal liver tumors become very large and cause vascular compression and fetal death (Fig. 18-25). Fetal infection with cytomegalic virus or *Toxoplasma* can cause focal hepatitis with necrotic calcifications seen as multiple small very bright echoes distributed randomly throughout the liver parenchyma. The fetal gallbladder is

FIGURE 18-25 Cystic mass in the fetal liver. The cause of this large (approximately 8 × 8 cm) semisolid or cystic mass was never determined.

usually easily visualized. Fetal gallstones do occur.¹⁵⁰ Significant anomalies of the fetal biliary tree are uncommon and rarely recognized in utero, with the exception of the *choledochal cyst*. A choledochal cyst appears as an echolucent mass in the right upper quadrant adjacent to but separate from the liver.

Prognosis. Choledochal cysts left undetected can cause progressive and irreversible cirrhosis and liver failure. Neoplastic degeneration can occur in later life. Choledochal cysts may be associated with communicating cavernous ectasia of the biliary tree (Caroli disease) and may ultimately require liver transplantation.

Abnormalities of the Anterior Abdominal Wall

The anterior abdominal wall develops as a thin layer of ectodermal endothelium and mesoderm overlying the abdominal organs. The abdominal wall muscles develop from invading mesenchymal myoblasts, which by the end of about 8 weeks have met and fused at the midline (linea alba). The umbilical vessels pass through the body stalk formed by fusion of the cephalic, caudal, and lateral embryonic body folds.

Omphalocele

Diagnosis. Omphalocele is a *midline* anomalous herniation of abdominal contents through the body stalk at the base of the umbilicus (Fig. 18-26). The herniation may be central or epigastric. Omphalocele has several defining characteristic features. First, the hernia sac is always contained within a peritoneal membrane and, accordingly, contents such as small bowel remain contiguous and contained. Second, the hernia sac can always be traced to a midline origin. Third, liver herniation is almost unique to omphalocele and only rarely is present with other abdominal wall defects. In at least 50% of cases, omphalocele is associated with chromosomal abnormalities, notably trisomy 13 and trisomy 18,¹⁵¹ and more than 80% of affected fetuses have other major structural anomalies.¹⁵² Omphalocele is a component of the pentalogy of Cantrell (midline omphalocele, defect of lower sternum, absent diaphragmatic pericardium, diaphragmatic hernia, and cardiac anomaly) and is a component of Beckwith-Weidemann syndrome (macroglossia, exomphalos, visceromegaly, omphalocele).

Prognosis. The prognosis of omphalocele is extremely poor, with less than 20% of affected perinates surviving. Amniocentesis and detailed repeated ultrasound anatomic surveys are always indicated if the pregnancy is planned to continue. Pregnancy termination is a frequently chosen management option.¹⁵²

Gastroschisis

Diagnosis. Herniation of small bowel and other abdominal contents through a *lateral* abdominal wall defect is termed gastroschisis. This appears to be the result of an ischemic interruption of the closure of the abdominal wall at or near the right umbilical vein (which normally involutes by about 4 weeks' gestation) or the omphalomesenteric artery. As a consequence, the abdominal wall defect of gastroschisis is always a full-thickness defect and is usually located to the *right* side of the midline. The orifice of the defect is usually small and as a result only loops of small bowel herniate. The herniated bowel is not contained in a membrane and thus appears to be free-floating in the amniotic cavity (Fig. 18-27).

FIGURE 18-26 Omphalocele. Transverse view of the fetal abdomen. The mass protruding from the midline of the anterior abdominal wall is an omphalocele. This fetus had trisomy 21.

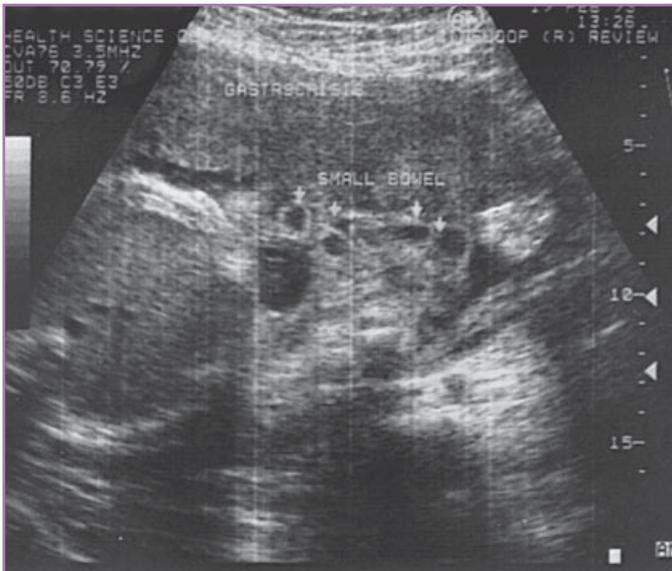

FIGURE 18-27 Gastroschisis. Gastroschisis in a third-trimester fetus. Multiple loops of dilated small bowel float freely in the amniotic fluid. The fetal liver is in the fetal abdomen. By real-time imaging, bowel peristalsis appeared diminished in this fetus.

Prognosis. The free loops of bowel often acquire a fibrinous covering thought to be the result of inflammation induced by amniotic fluid. As a result, the bowel evolves to a matted complex with altered motility. The incidence of aneuploidy is not increased with gastroschisis, nor is there an increase in anomalies of other organ systems. The incidence of jejunal atresia is increased in fetuses with gastroschisis, possibly resulting from a common vascular ischemic mechanism.

Gastroschisis is associated with a 25% or greater rate of intrauterine growth restriction.¹⁵³ There is no reported advantage to delivery by cesarean section.¹⁵⁴ Infants born with gastroschisis require surgical repair, often sequenced, and they are at risk of long-term gastrointestinal complications such as stricture, adhesions, and volvulus. However, long-term intact survival is usually excellent, exceeding 97%.¹⁵⁵

Body stalk anomaly occurs as a result of complete failure of closure of body folds and is characterized by absence of the umbilicus and umbilical cord. Survival is extremely rare with this condition.¹⁵⁶

Bladder Exstrophy

Diagnosis. Bladder exstrophy is an anterior abdominal wall anomaly that occurs as a result of failure of fusion of the caudal components of the ecto-mesodermal body folds. As a result, there is protrusion of the urinary bladder with communication to the amniotic cavity and with separation of the symphysis pubis. Obstruction of the upper urinary tract is commonly associated. The occurrence of normal amniotic fluid, dilated ureter (one or both), and inability to visualize the urinary bladder despite repeated observations at intervals strongly suggests the diagnosis. Bladder exstrophy is associated with abnormalities of the phallus and may occur in conjunction with cloacal exstrophy.

Prognosis. Isolated bladder exstrophy can be corrected after the birth and has a generally good long-term prognosis.¹⁵⁷ In contrast, the prognosis of cloacal exstrophy, either alone or in association with bladder exstrophy, is very poor in terms of both survival and quality of life.¹⁵⁸

Abnormalities of the Fetal Genitourinary Tract

The fetal kidney has three embryonic components, the pronephros, the mesonephros, and the metanephros. The functional fetal kidney arises from the fusion of the ureteral bud, which grows cranially to fuse with the metanephros. The ureteral bud gives origin to the ureter, renal pelvis, papillae, and collecting system, whereas the mesonephros gives rise to the functional nephrons. Fusion of the ureteral bud and the metanephros is completed early in gestational life (by 7 weeks) and the production of urine with drainage to the amniotic cavity begins shortly thereafter.

The kidney continues to grow and differentiate throughout fetal life, and nomograms can be used to differentiate normal from abnormal kidney dimensions for given gestational ages.¹⁵⁹ Because fetal urine is the major source of amniotic fluid from the early second trimester onward, the presence of normal amniotic fluid volume implies normal urine production, whereas oligohydramnios is the hallmark sign of renal dysfunction or obstruction. Fetal urine production can be estimated from measurement of fetal bladder filling and emptying.¹⁶⁰ Because the fetal kidneys are easily visualized by ultrasound, obstruction of urine outflow always results in proximal echolucent dilation, and because oligohydramnios complicates obstruction or decreased

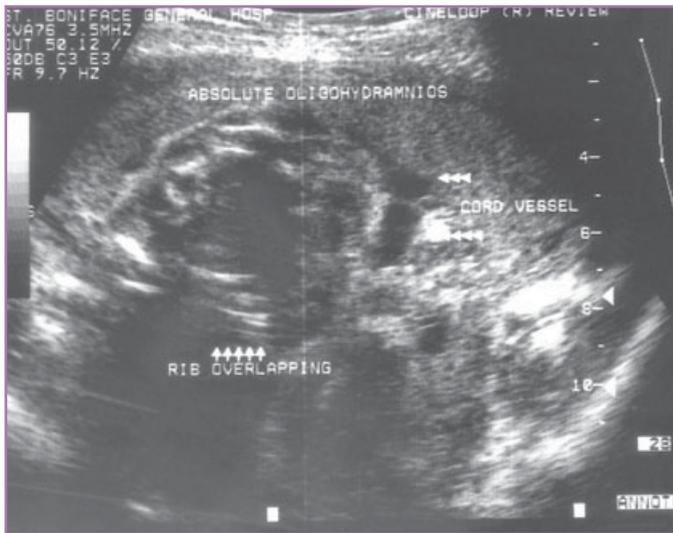

FIGURE 18-28 Absolute oligohydramnios associated with renal agenesis. The only echolucency in the amniotic cavity is produced by bunching of the fetal cord and layering of echolucent segments of the umbilical vein. The renal fossae contain no visible structures.

production of urine, genitourinary anomalies are among the most easily and consistently recognized in utero. Therefore, the detection rate of genitourinary anomalies by ultrasound in the second and third trimesters is at least 80%.¹⁶¹

Anomalies of the Fetal Kidney

Renal Agenesis

Diagnosis. Failure of the fetal kidneys to develop is thought to arise from the failure of development of the ureteric bud and may affect one (unilateral) or both kidneys (bilateral). Unilateral renal agenesis is rarely diagnosed in utero (because of the lack of positive signs) and is associated with a normal prognosis. In contrast, bilateral renal agenesis is easily diagnosed by the constellation of absolute oligohydramnios (Fig. 18-28), failure to identify a urinary bladder on serial observations or in response to administration of furosemide to the mother or directly to the fetus, and the failure to identify normal fetal kidneys. Absence of normal fetal kidneys is difficult to confirm because in the absence of renal tissue, the fetal adrenal expands into the renal fossa and may have an echotexture similar to the kidney.

Prognosis. The oligohydramnios resulting from bilateral renal agenesis causes pulmonary hypoplasia, which is the cause of death in the immediate postpartum or early neonatal period. Oligohydramnios also leads to facial compression, producing Potter facies. Renal agenesis may occur as an isolated anomaly or as part of a syndrome such as TAR syndrome (thrombocytopenia, renal agenesis, hypoplasia of the radius), Fraser syndrome (cryptophthalmos, cleft palate, laryngeal abnormalities), cerebro-oculo-facioskeletal syndrome, and acrorenal-mandibular syndrome. Pregnancy interruption or nonintervention for fetal indications is always indicated for bilateral renal agenesis.

Multicystic Dysplastic Kidney

Diagnosis. Multicystic dysplastic kidney (MDK) results from incomplete union of the ureteric bud to the metanephros, resulting in

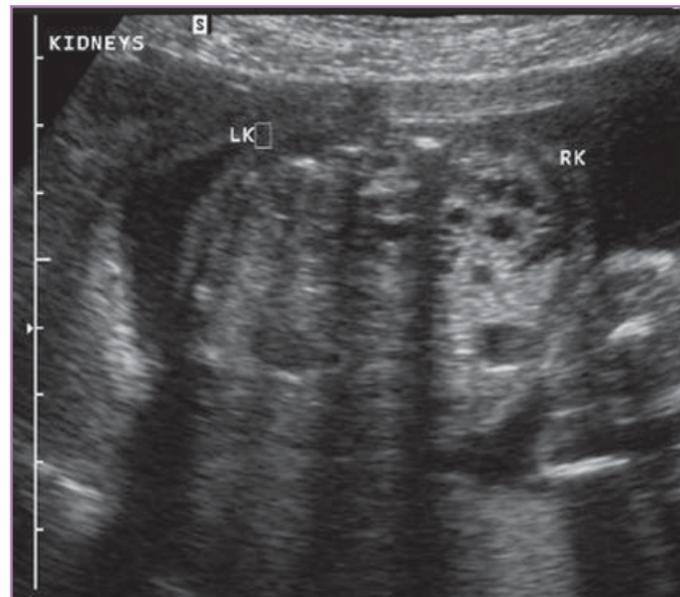

FIGURE 18-29 Multicystic dysplastic kidney. In this axial view through the lower fetal abdomen, the right kidney (RK) has multiple cysts with echogenic renal parenchyma surrounding them. The left kidney (LK) is normal.

dilation of all or some of the collecting tubules in the renal pelvis (Fig. 18-29). On ultrasound, the affected kidney appears enlarged, with multiple cystic and abnormally echogenic foci, some of which may be calcified, distributed throughout the kidney. The dysplastic areas are always dysfunctional. Unilateral disease is associated with abnormalities in the contralateral kidney, most commonly dilation of the renal pelvis (ureteropelvic junction [UPJ] anomaly).

Prognosis. The prognosis for bilateral multicystic dysplastic kidney is hopeless. However, with unilateral disease, the functioning contralateral kidney maintains normal amniotic fluid volume, so pulmonary hypoplasia is not a complication. The unilateral multicystic kidney usually atrophies in childhood and surgical resection is rarely required.¹⁶²

Infantile Polycystic Kidney (Autosomal Recessive Polycystic Kidney Disease)

Diagnosis. Autosomal recessive polycystic kidney disease is characterized by massive bilateral enlargement of the kidneys, with cystic dilation of the renal tubules, often associated with degrees of hepatic fibrosis (Fig. 18-30).

Prognosis. When diagnosed in utero, the prognosis is very poor. Postnatal survival has been reported but only when the cystic degeneration involves only a segment of the kidney. Infantile polycystic kidneys are usually associated with severe oligohydramnios and pulmonary hypoplasia, resulting in fetal or neonatal death. Infantile polycystic kidney anomaly can be diagnosed in utero from as early as the end of the first trimester.¹⁶³

Autosomal Dominant Polycystic Kidney Disease (Adult Polycystic Disease)

Diagnosis. Autosomal dominant polycystic kidney disease rarely manifests first in utero. Renal masses secondary to neoplasia (mesoblastic nephroma, hamartoma, Wilms tumor, neuroblastoma) occur rarely and are evidenced by the unilateral location, size (often massive),

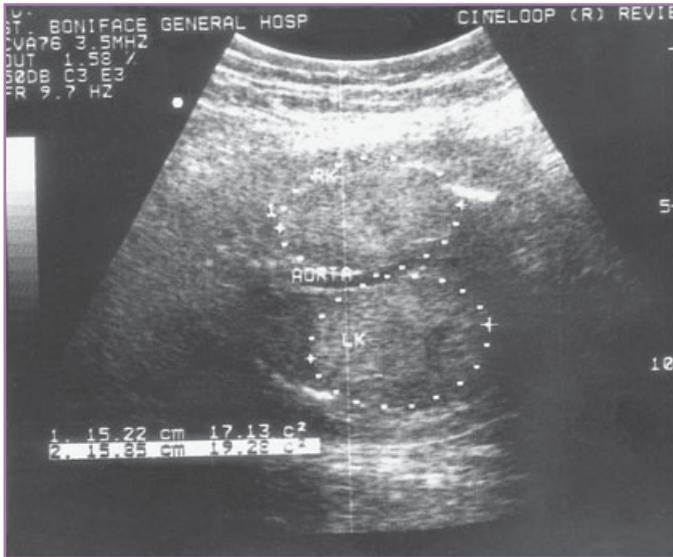

FIGURE 18-30 Infantile polycystic kidney (autosomal recessive polycystic kidney disease). In this coronal view of the fetal abdomen, the fetal kidneys are huge (15 × 19 cm) and have a homogeneous echotexture with recognizable internal structure. Note the associated oligohydramnios. These are the typical findings in the infantile polycystic kidney anomaly. LK, left kidney; RK, right kidney.

and distortion of the renal architecture. Isolated renal cysts can occur and usually have no impact on the kidney unless they are massive.

Ureteropelvic Junction Obstruction

Diagnosis. Ureteropelvic junction obstruction is among the most commonly identified renal anomalies. In the normal fetal kidney, the major renal calyces contain a small amount of urine visible by ultrasound. UPJ obstruction is diagnosed when the anteroposterior diameter of the renal pelvis exceeds 7 to 10 mm at or beyond 28 weeks' gestation (Fig. 18-31). The obstruction is usually unilateral but is occasionally bilateral, and it may progress, regress, or disappear.

Prognosis. In general, the larger the dilation of the renal pelvis is, the more likely the need for postnatal medical or surgical treatment. Postnatal intervention is required in about 50% of fetuses with third-trimester calyceal enlargement of 1.5 cm, and in almost all fetuses when the renal pelvis exceeds 2 cm.¹⁶⁴ Management of the fetus with UPJ is usually conservative, as early intervention has not been shown to reduce morbidity.¹⁶⁵ In utero treatment (needle decompression, shunting) has not been shown to be beneficial and has been associated with fetal complications.¹⁶⁶

Megaureter

Diagnosis. When megaureter occurs as an isolated finding, it is thought to be the result of abnormal enervation of ureteral smooth muscle, resulting in reverse peristalsis. Most commonly, megaureter occurs as a result of obstruction of the ureter as it enters the bladder, as a result of vesicoureteric reflux, or as a result of distal bladder obstruction. The dilated ureter appears as multiple fluid-filled loops in the abdomen. In the absence of bladder obstruction, differentiating megaureter from small bowel obstruction can be difficult.

Prognosis. The prognosis for primary megaureter is excellent, whereas the prognosis for secondary megaureter depends on the

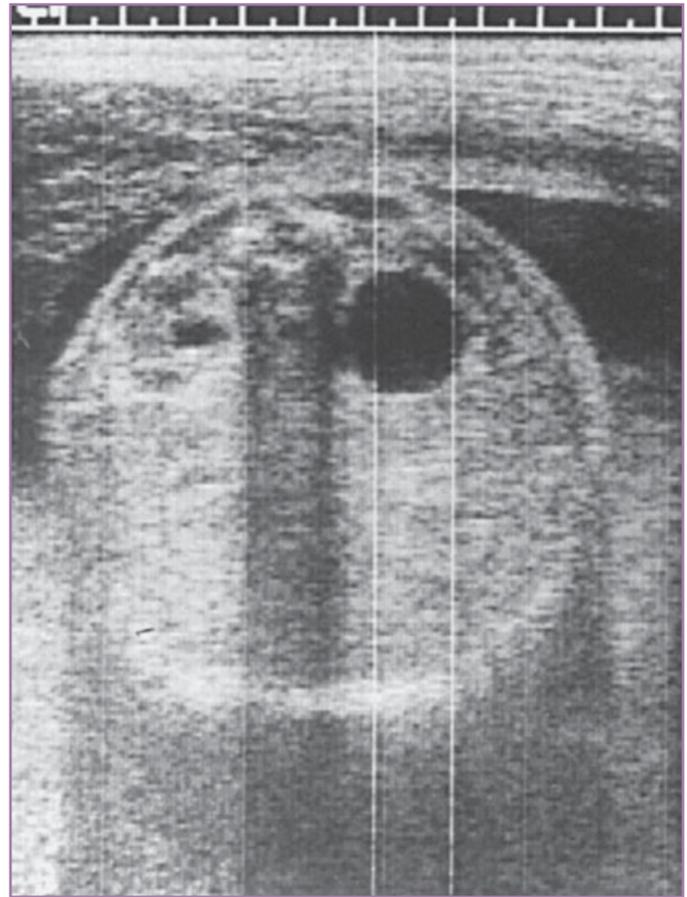

FIGURE 18-31 Ureteropelvic obstruction. Severe bilateral ureteropelvic obstruction at 31 weeks of gestation. Note the asymmetrical dilation of the renal pelvis (greater on the left) and the less pronounced dilation of the calyces. Amniotic fluid volume is normal.

underlying cause. Megaureter secondary to vesicoureteric reflux has a good prognosis, but megaureter in association with bladder outlet obstruction has a much more guarded prognosis.

Megacystis

Diagnosis. Primary megacystis is a subjective ultrasound observation, usually very apparent, and the diagnosis is easily made. Megacystis is the result of absent or abnormal enervation of the bladder associated with conditions such as megacystis-microcolon-intestinal hypoperistalsis syndrome (MMIHS)¹⁶⁷ or a neurogenic bladder associated with meningocele.¹⁶⁸

Prognosis. The prognosis of neurogenic megacystis is generally very poor.¹⁶⁹ Analysis of amniotic fluid digestive enzymes and fetal urinalysis has been proposed as a method for identifying MMIHS. However, although an elevated amniotic fluid digestive enzyme profile, presumed secondary to fetal vomiting, is prevalent in fetuses with MMIHS, it is not a universal finding, and elevated enzymes may also occasionally be present in the fetus without MMIHS.¹⁷⁰

Obstructive megacystis is caused by an obstruction of the outflow tract, secondary to either posterior urethral valves or urethral atresia (Fig. 18-32), and it is almost exclusively an anomaly of male fetuses.

FIGURE 18-32 Magnified view of the bladder and proximal urethra in a fetus with posterior urethral valves. Note the dilation of the proximal urethra and the absence of visualization of the distal urethra. The bladder wall is thickened and relatively echogenic.

The bladder outlet obstruction results in progressive enlargement of the bladder, often to massive proportions, dilation of the ureters and renal pelves, and oligohydramnios.

Posterior Urethral Valves

Diagnosis. Tissue folds at the junction of the urethra and bladder resulting in a “valve” are the most common cause of bladder outlet obstruction. Posterior urethral valves typically occur in male fetuses. The obstructing valves are created by folding of the urethral mucosa distal to the vesicoureteric junction. The dilated proximal urethra creates the classic “key-hole” abnormality. Bladder outlet obstruction can also occur as a result of ureteral stenosis. This anomaly is much rarer than posterior urethral valves and can affect both male and female fetuses.

Prognosis. In utero therapy is a consideration, because left untreated, the bladder outflow obstruction will cause progressive hydronephrosis with loss of renal parenchyma and abnormal fetal urine chemistry, and it can cause severe oligohydramnios, leading to lethal pulmonary hypoplasia. Although this condition is easily recognized in utero, and because it is possible to divert the obstruction by placing a tube between the bladder and the amniotic cavity, effectively bypassing the obstruction,¹⁷¹ or by using a fetoscope to fulgurate the obstructing valves,¹⁷² fetal surgery for bladder outlet obstruction has been attempted; however, its role is uncertain. Sequential analyses of fetal urine chemistry are useful in selecting fetuses most likely to benefit from in utero treatment¹⁷³ and in predicting postnatal renal function.¹⁷⁴

Comparative analyses of outcomes among 35 treated and 46 untreated perinates indicate that survival is worse in treated cases (43% mortality), and that the incidence of postnatal renal disease, stratified by severity, is about 50% and is similar for perinates treated prenatally and those treated postnatally.^{175,176} As of May 2008 there are no randomized clinical trials confirming any significant reduction in mortality and morbidity by any form of fetal surgery for bladder outlet obstruction.

Skeletal Anomalies

The skeleton develops from three components of mesenchymal origin: bone, cartilage, and fibrous tissue. Congenital skeletal anomalies arise as a result of abnormalities of growth, shape, and intrinsic integrity of each of these components, either in isolation or in combination. With advances in molecular medicine, it has become possible to unravel some of the genetic mechanisms that regulate skeletal development and growth, and to identify gene abnormalities underlying some skeletal anomalies. The idea of a genetic basis for skeletal anomalies is important in the field of prenatal diagnosis because it opens the possibility of diagnosis based on DNA analysis rather than the conventional (and confusing) ultrasound-based morphologic classification.

Several DNA sites regulate skeletal growth. The homeobox (*HOX*) genes are active in the growth and shape of bones.¹⁷⁷ The growth of each limb is regulated by a specific sequence of *HOX* genes. For example, upper arm growth is regulated by genes in the 9 to 10 group, the lower arm by the 10, 11, and 12 groups, and the digits by the 11, 12, and 13 groups.¹⁷⁸ In addition to gene sequences, skeletal growth is also regulated by pairing of *HOX* genes, referred to as Pax (paired-like, homeobox-containing) sequences. A second gene sequence, the HMG box, contains gene combinations (*SOX* and *TBX*) that are active in regulation skeletal growth. The *fibroblastic growth factor receptors* (e.g., *FGFR3*) are a group of polypeptide gene products that regulate maturation and function of chondrocytes.¹⁷⁹ Bone mineralization and development is regulated in part by *parathyroid hormone-related protein receptor* (*PTHrPR*). Collagen, the essential component of the extracellular matrix, is regulated by *collagen gene loci* (genes *COL1A1* and *COL2A1*). The noncollagen component of the extracellular matrix, the *cartilage oligomeric matrix protein* (*COMP*), is regulated by a gene sequence located on chromosome 19. Cartilage maturation is controlled by transfer of sulfate groups to the proteoglycans in the extracellular matrix. This process of sulfonation of proteoglycans is regulated by a sulfate transport protein, in turn controlled by a gene combination termed the *diastrophic dysplasia sulfate transporter* (*DTDST*).

Abnormalities in these regulatory genes have been found in a number of skeletal dysplasias (Table 18-4). Abnormalities in these regulatory genes and gene products can be combined with biochemical and radiologic abnormalities to produce a logical classification of the skeletal dysplasias. This molecular, biochemical, radiologic morphology classification contains 372 specific diagnoses arranged in 37 different categories.¹⁸⁰

Diagnosis. The diagnosis of fetal skeletal dysplasia depends on ultrasound findings of abnormalities in bone length, shape, and echodensity (abnormal mineralization), the complete absence of a bone or presence of additional bones, abnormalities of cartilage evident at the epiphyseal ends of bone, and abnormal shapes of complex structures such as the thorax, skull, and face caused by abnormal growth of the bone and cartilage components. Accordingly, ultrasound screening for anomalies should always include assessment of all long bones to determine presence, shape, density, and proportion; of the thorax to determine shape and to assess relative size; and of the skull and face to evaluate shape and proportions.

In almost all cases, the presence of a fetal skeletal anomaly is obvious and it can be identified by gross characteristics. However, recognition of a skeletal anomaly is only a first step, and the final diagnosis and assignment of prognosis depends on detailed measurements of all the long bones and expert assessment of all shape and structural charac-

teristics and associations between abnormalities of long bones, digits, skull, face, chest, and vertebrae. Nomograms are available for all long bones and long bone length ratios, the foot, the mandible, and thoracic dimensions.¹⁸¹ In the individual case, classification of a sporadic or first-affected fetus is challenging. The diagnosis when a sibling is affected is considerably easier and more accurate. Skeletal anomalies are rare, occurring a frequency of about 2 per 10,000 live births, but they are present about 18 times more frequently in surveys of perinatal deaths.¹⁸² The incidence of skeletal anomalies varies by population and may be 10-fold higher when consanguinity is common.¹⁸³

The most commonly encountered skeletal anomalies, in order of decreasing frequency, are thanatophoric dysplasia, osteogenesis imperfecta, chondrodysplasia punctata, camptomelic syndrome (achondroplasia), and osteogenesis imperfecta type I. It is critical to arrive at a correct diagnosis to assign appropriate prognoses. The problem is compounded because the expression (penetrance) of the underlying genetic disorder is variable, and because the fetal age at initial expression varies widely within and between conditions.

Prognosis. Several skeletal dysplasias can be associated with postnatal survival. Heterozygous achondroplasia is a short-limb dystrophy characterized by proximal long-bone shortening (rhizomelic dwarfism), bowing of the limbs (especially the lower limbs), a large skull, and depression of the nasal bridge. The condition is transmitted in an autosomal dominant manner with variable penetrance, so the incidence of an affected fetus is 50% if one parent is affected. If both parents are affected, the incidence of homozygous achondroplasia (uniformly lethal) is 25%, the incidence of heterozygous achondroplasia is 50%, and in 25% of cases the perinate is not affected. Interestingly, achondroplasia is one of the few conditions associated with advanced paternal age.¹⁸⁴ The ultrasound diagnosis depends on identification of bilateral short femurs, modest shortening of the humerus, normal length of radius, ulna, tibia, and fibula, normal mineralization, mild cephalomegaly, and normal thoracic dimensions. Postnatal survival is usual and morbidity is minimal.

Osteogenesis Imperfecta

The multiple syndromes of osteogenesis imperfecta are conditions characterized by inadequate mineralization of bones, making them fragile and subject to fracture, and by generalized diminished long bone growth. The penetrance varies. In two forms of osteogenesis imperfecta (type I and type III), the long bones may be fragile and subject to easy fracture but generally are near normal length, and they (especially the femur) may exhibit slight bowing. Type I and type III osteogenesis imperfecta are not associated with increased perinatal mortality. Type III disease is very minimal and may be evident only postnatally by mild deafness and a bluish sclera. Type I disease is somewhat more severe, with a higher propensity for fracture and again an association with deafness and a blue sclera. The features that distinguish types I and III osteogenesis from the lethal forms (types II and IV) are the presence in the former of normal thoracic architecture, normal or near-normal long bone length, and the absence of in utero fractures.

Other Skeletal Dysplasias

Diastrophic dystrophy is an autosomal recessive disorder characterized by predominantly rhizomelic long bone dysplasia, multiple joint flexures and the classic hand abnormality in which fingers are short and widely spaced and the thumb is abducted (the “hitchhiker thumb”). Frequently associated abnormalities of the face include micrognathia and cleft palate. Postnatal survival is generally not affected, and intellect appears intact. *Mesomelic dysplasia* is an autosomal dominant condition typically characterized by shortening and bowing of the distal limb bones. Prenatal diagnosis is rare. The long-term prognosis is generally good. *Camptomelic dysplasia* is characterized by extreme bowing of the long bones, and the diagnosis is usually obvious. Facial abnormalities including micrognathia, cleft palate, and macrocephaly are almost always present. Prenatal diagnosis is reported and survival is possible but rare: in most instances, early infant death occurs.^{185,186} *Chondroectodermal dysplasia* (Ellis-van Creveld syndrome) is an autosomal recessive condition characterized by acromelia and polydactyly. The condition is frequently associated with major cardiac anomalies, and early infant death is common. Long-term survival with intact intellectual function can occur.

The common lethal skeletal dysplasias typically have a combination of thoracic deformities (thanatophoric dwarfism, short rib-polydactyly syndrome, asphyxiating thoracic dystrophy), extreme limb shortening (osteogenesis imperfecta types II and IV, achondrogenesis),

demineralization (hypophosphatasia, fibrochondrogenesis, achondrogenesis), macrocrania (achondrogenesis), and facial abnormalities.

Bone abnormalities may also occur because of absence of bone development (dysostoses) or abnormal fusions of bones. *Craniosynostosis* occurs when there is premature fusion of the calvarial sutures, resulting in a wide spectrum of abnormal skull shapes. Craniosynostosis is frequently associated with other anomalies, which typically determine the prognosis. *Radial aplasia*, or severe dysplasia as an isolated skeletal anomaly, can be associated with cardiac anomalies (Holt-Oram syndrome) or with thrombocytopenia, often severe (the TAR syndrome mentioned earlier). Congenital contractures with varus or valgus malrotation of the foot (clubfoot) can be an isolated finding or can be associated with numerous syndromes and trisomies. Unilateral absence of digits, foot and hand, or lower limb can occur as a result of in utero amputation secondary to amniotic band syndrome. Abnormal fixation of limbs and joints is a characteristic of arthrogryposis multiplex congenita.

Summary

Congenital abnormalities are among the most common causes of perinatal mortality and of infant and adult morbidity and mortality. As prenatal care improves and mortality of structurally normal perinates declines, the relative importance of identifying congenital anomalies before birth increases. The tremendous advances occurring in fetal imaging and in molecular biology have made the diagnosis of anomalies in utero more accurate and have pushed back the gestational age at which the diagnosis can be made. Advances in postnatal care have improved survival and functional prognosis for many of the structural anomalies, especially the cardiac anomalies. The initial hope that prenatal intervention and surgical repair or reconstruction of anomalies has been more recently tempered with reality, but antenatal intervention remains an important area of future investigation and still holds promise as a means to further reduce the mortality and morbidity of fetal anomalies. The promise for continued advances in the spectrum and quality of care is virtually certain.

Chapter 19

Fetal Cardiac Malformations and Arrhythmias

Detection, Diagnosis, Management, and Prognosis

Mark Sklansky, MD

Over the years, as the practice of fetal ultrasonography has evolved, a consensus has formed among sonographers, radiologists, obstetricians, and maternal-fetal medicine subspecialists: screening for fetal heart disease deserves the dubious distinction of being one of the most challenging and least successful aspects of fetal ultrasonography.¹⁻³ Because of the challenges inherent with screening the fetus for congenital heart disease (CHD), the rate of prenatal detection of even severe forms of CHD remains disappointingly low.^{1,3-7} Furthermore, when a fetal heart defect or arrhythmia is suspected, many professionals feel uncomfortable with much more than referring the patient to someone else for further evaluation.

This chapter aims neither to make everyone involved with fetal ultrasonography into an expert fetal echocardiographer, nor to provide an exhaustive, encyclopedic review of the field of fetal cardiology; such detailed reviews may be found elsewhere.^{8,9} Instead, the chapter takes a distinctive clinical bent, aiming to help those involved with fetal cardiac imaging (1) to become better at screening the fetal heart for CHD, (2) to become better at diagnosing and evaluating common forms of fetal cardiac malformations and arrhythmias, (3) to understand the basic approach to fetal and neonatal management of the most common forms of fetal cardiac malformations and arrhythmias, and (4) to understand the general prognosis associated with the most common forms of fetal heart disease.

After a brief discussion of the epidemiology of fetal heart disease, this chapter reviews the basic approach to screening in low-risk pregnancies for fetal heart disease. The next section reviews the more detailed technique of formal fetal echocardiography in pregnancies at high risk for fetal CHD, including a description of the fetal presentation of fetal congestive heart failure (CHF) and a discussion of the potential role of three-dimensional (3D) fetal echocardiography. The last two sections discuss the diagnosis, management, and prognosis of the most common and clinically important forms of fetal cardiac malformations and arrhythmias.

Incidence of Congenital Heart Disease in the Fetus

CHD represents by far the most common major congenital malformation.^{10,11} Although most studies suggest an incidence of approximately

8 of 1000 live births,¹¹⁻¹³ this figure includes many forms of disease (e.g., secundum atrial septal defect [ASD], mild valvar pulmonary stenosis, and small muscular or membranous ventricular septal defects [VSDs]) that never will require either medical or surgical attention. In fact, 3 or 4 of every 1000 live newborn infants have some form of CHD that is likely to require medical if not surgical intervention.¹ Because cases of fetal heart disease, particularly those associated with aneuploidy or extracardiac malformations, may end in fetal demise, and because many VSDs may close spontaneously before birth,¹⁴ the incidence of CHD during the first and second trimesters should be considerably higher than the incidence at term.

At the same time, some forms of CHD probably have a higher incidence at term than during the first or early second trimesters. Many forms of CHD evolve dramatically from first trimester to term.^{15,16} Mild aortic or pulmonary valve stenosis, for instance, may evolve prenatally into severe forms of critical pulmonary or aortic stenosis or may even adversely affect ventricular development to the point of manifesting as hypoplastic left or right heart syndrome at term. Similarly, cardiac tumors such as cardiac rhabdomyomas or intrapericardial teratomas may not develop significantly until the second trimester,¹⁷ and they may continue to enlarge dramatically from mid-gestation to term. Ductal constriction or closure of the foramen ovale may not develop until late in gestation,¹⁸ and the same may be said for fetal arrhythmias, valvar regurgitation, myocardial dysfunction, and CHF.¹⁶

Risk Factors for Congenital Heart Disease in the Fetus

Inasmuch as most cases of CHD occur in pregnancies not identified as being at high risk,^{19,20} effective screening for CHD in low-risk pregnancies remains tremendously important. Nevertheless, many risk factors (fetal, maternal, and familial) for fetal heart disease have been identified (Tables 19-1, 19-2, and 19-3).²¹⁻³⁶ Some anomalies, such as omphalocele with diaphragmatic hernia and tracheoesophageal fistula,²⁶ cleft lip/palate,²⁵ aneuploidies such as trisomy,^{21,23,30} or maternal CHD,^{24,27,28,31,32} carry significantly increased risks for fetal heart disease. Other associations, such as a family history of CHD,^{24,34} many cases of maternal diabetes,^{23,36} fetal exposure to many of the known

TABLE 19-1 RISK FACTORS FOR FETAL HEART DISEASE**Fetal**

Abnormal visceral/cardiac situs
 Abnormal four-chamber view or outflow tracts
 Arrhythmia
 Aneuploidy
 Two-vessel umbilical cord
 Extracardiac structural malformation
 Intrauterine growth restriction
 Polyhydramnios
 Pericardial effusion/pleural effusion/ascites
 Twins
 Increased nuchal translucency thickness

Maternal

Systemic erythematosus
 Diabetes mellitus
 Phenylketonuria
 Viral syndrome (mumps, Coxsackie virus, influenza, rubella, cytomegalovirus)
 Congenital heart disease
 Teratogen exposure
 In-vitro fertilization?

Familial

First-degree relative with congenital heart disease
 First-degree relative with cardiac syndrome
 DiGeorge syndrome
 Long QT syndrome
 Noonan syndrome
 Marfan syndrome
 Tuberous sclerosis
 Williams syndrome

teratogens,^{23,29,35} and fetal ureteral obstruction or gastroschisis,²⁶ carry only moderately increased risks for CHD. Many syndromes (familial, sporadic, or related to known teratogens) convey variable risks for CHD.²³ Finally, additional risk factors for CHD will undoubtedly be recognized in the future. For instance, increased nuchal translucency thickness in the first trimester (10 to 14 weeks) represents an important newly discovered risk factor for fetal heart disease, even in the presence of normal fetal chromosomes.^{22,33} This subject is addressed in detail in Chapter 17.

A distinction should be recognized between “fetal risk factor for CHD” and “indication for fetal echocardiography.” Because not all risk factors for fetal heart disease are equal, the primary obstetrician or perinatologist should weigh the likelihood of fetal heart disease when considering whether further evaluation is indicated. However, the expertise of primary obstetricians, perinatologists, and radiologists, as well as pediatric cardiologists, in evaluating the fetal heart varies tremendously. Therefore, the determination of which pregnancies to refer for formal echocardiography should depend on the degree of added expertise in fetal cardiac imaging, management of fetal heart disease, and counseling for fetal heart disease offered by the consultant. Ultimately, the decision of whom to refer for formal fetal echocardiography should reflect both the perceived likelihood of fetal heart disease and the additional expertise anticipated from referral.

TABLE 19-2 EXTRACARDIAC STRUCTURAL MALFORMATIONS ASSOCIATED WITH FETAL HEART DISEASE**Central Nervous System**

Neural tube defect
 Hydrocephalus
 Absent corpus callosum
 Arnold-Chiari malformation
 Dandy-Walker malformation

Thoracic

Tracheoesophageal fistula
 Cystic adenomatoid malformation of the lung
 Diaphragmatic hernia

Skeletal

Screening for Congenital Heart Disease in the Fetus

Background

The prenatal detection of CHD in the low-risk pregnancy has long represented the fetal sonographer’s Achilles’ heel.³⁷ Although CHD occurs more frequently than any other major congenital anomaly, the rate of detection has remained disappointingly low.^{1,3-7} This weakness

in fetal screening sonography represents a real problem. Not only is CHD responsible for most neonatal mortality from congenital malformations,¹⁰ but prenatal detection and diagnosis also can improve the outcome of fetuses and neonates with CHD.³⁸⁻⁴³ For these reasons, more improvement needs to be made in prenatal detection of the patient at low risk than in the detailed fetal diagnosis of CHD.^{5,19,44}

For years, those involved with fetal imaging have attempted to improve the prenatal detection of CHD. Soon after the development of two-dimensional (2D) fetal cardiac imaging, investigators proposed the four-chamber view (4CV) as an effective approach to screening the fetus for CHD.⁴⁵⁻⁴⁷ To this day, the 4CV has remained the standard of care for the screening fetal ultrasound evaluation of low-risk pregnancies, although probably not for much longer.^{2,48,49} In practice, the 4CV has not resulted in the high rates of detection initially anticipated.^{1,4,6,50-52}

To improve detection further, others have suggested that color flow imaging, performed along with the 4CV, could improve detection rates,⁵³ but this technique requires specialized expertise and equipment and probably adds little to the detection of major forms of CHD. On the other hand, there has been an important push toward attempting to include visualization of the outflow tracts along with the 4CV,⁵⁴⁻⁵⁹ because many defects (e.g., double-outlet right ventricle [DORV], tetralogy of Fallot [TOF], transposition of the great arteries [TGA], truncus arteriosus) can have normal-appearing 4CVs. Routine inclusion of the outflow tracts has been somewhat problematic, however, in part because the outflow tracts, unlike the 4CV, do not reside in a single plane. Nevertheless, inclusion of outflow tracts along with the 4CV for the low-risk standard fetal ultrasound evaluation makes sense and is swiftly becoming the standard of care.^{2,48,49}

More recently, multiple investigators have suggested that 3D imaging, wherein volumes may be acquired within seconds and subsequently interactively reviewed, allowing the display of virtually any plane, may facilitate and improve the evaluation of both the 4CV and the outflow tracts.⁶⁰⁻⁶² However, image resolution with 3D imaging remains low, and considerable expertise currently is required to evaluate volume data sets, despite a wealth of evolving algorithms and display techniques aimed at facilitating and improving analysis.⁶⁰⁻⁶⁴

Despite these developments, prenatal fetal cardiac anatomy screening remains flawed, for several reasons. First, the practice of prenatal screening for CHD remains heavily dependent on both the expertise of the sonographer^{3,65} and the quality of the equipment. Second, and equally important, effective screening requires an experienced reviewer to evaluate the fetal heart.⁵⁵ And third, although it makes sense to evaluate static fetal structures as still-frame images, it does not make sense—and does not work—to evaluate the heart as a single still-frame image of the 4CV, or even as a series of still-frame images of the 4CV and outflow tracts.³⁷

For these reasons, the beating 4CV (plus outflow tracts) should supplant the 4CV as the centerpiece of screening the fetus for CHD.³⁷ Visualization of valve and myocardial motion facilitates and enhances the evaluation of cardiac structure^{4,66} and makes reviewers less likely to miss a major structural defect. Ideally, screening should also include evaluation of both outflow tracts; however, the addition of just the left ventricular outflow tract (LVOT) would probably effectively detect most major anomalies typically missed with 4CV imaging alone.⁵⁶ The following paragraphs describe the routine (second-trimester) evaluation of low-risk pregnancies for fetal heart disease; descriptions of first-trimester evaluation of the fetal heart may be found elsewhere.^{15,67-70}

Technique

Extracardiac Evaluation

Prenatal screening for CHD should begin with an evaluation for extracardiac abnormalities associated with CHD. The umbilical cord should have three vessels; the heart and stomach should both be on the fetal left (above and below the diaphragm, respectively); and there should be no ascites (Fig. 19-1) or pericardial or pleural effusions. A trivial amount of pericardial fluid may normally be seen adjacent to the right and left ventricular free walls.⁷¹ Abnormalities of any of these findings should raise the suspicion for CHD and prompt more than just a routine evaluation.

Beating Four-Chamber View

The 4CV (Figs. 19-2 and 19-3) always deserves a close, detailed evaluation, even as part of a general screening fetal ultrasound study. In fact, given the current low rates of prenatal detection of CHD,^{1,3-7} the 4CV probably deserves more attention than it has been receiving. Evaluation of the beating 4CV should assess situs, size, symmetry, structure, and squeeze.

SITUS

The heart should be located within the left thorax, with the apex directed approximately 45 degrees to the left. Hearts on the right (dextrocardia), in the middle (mesocardia), or with the apex directed toward the left (left axis deviation)⁷² have all been associated with CHD. Moreover, should the space around the heart be filled with fluid, either circumferentially or with a depth of greater than 2 mm, further evaluation may be indicated.⁷¹

SIZE

The heart should occupy no more than approximately one third of the cross-sectional area of the thorax.⁷³ Alternatively, the circumference of the fetal heart should be no more than approximately half the transverse circumference of the thorax. However, no quantitative threshold outperforms an experienced eye. An enlarged fetal heart, by

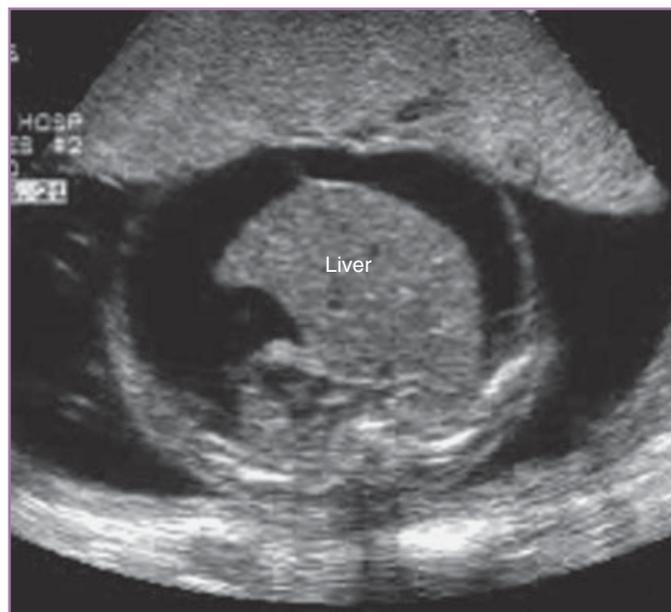

FIGURE 19-1 Fetal ultrasonographic image of severe ascites.

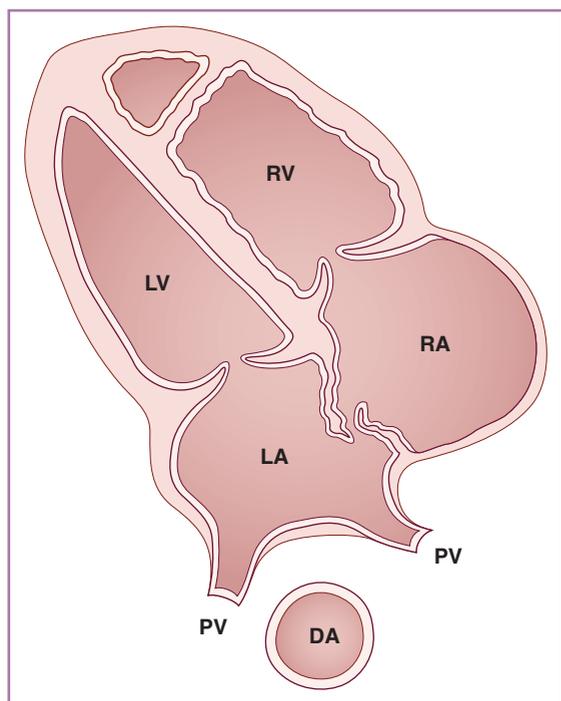

FIGURE 19-2 Schematic diagram of fetal four-chamber view. The right side of the heart appears slightly larger than the left side. The pulmonary veins (PV) enter the left atrium. The flap of the foramen ovale resides within the left atrium. The tricuspid valve inserts onto the ventricular septum slightly apical to the mitral valve insertion. The moderator band characterizes the right ventricular apex. Both ventricles contribute to the cardiac apex. DA, descending aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Diagram courtesy of Irving R. Tessler, M.D.)

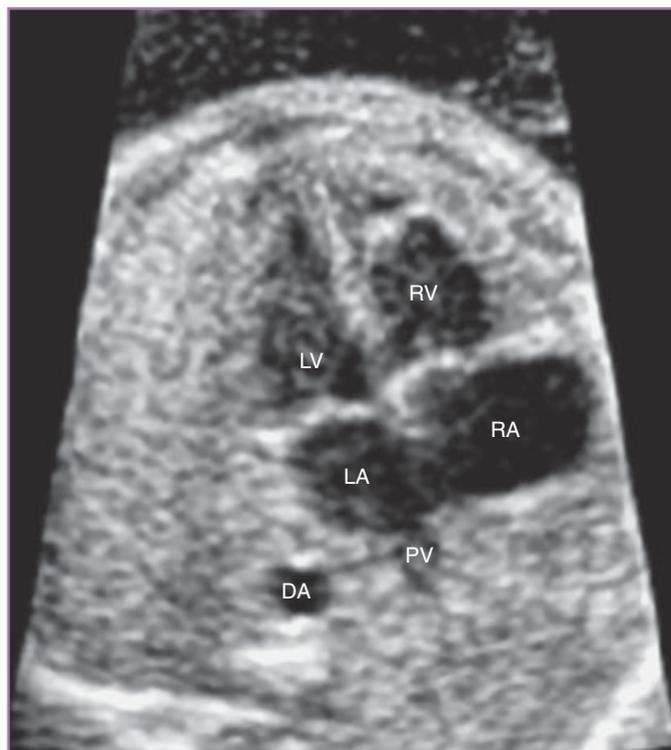

FIGURE 19-3 Fetal echocardiographic image of four-chamber view. Compare with Figure 19-2. The right side of the heart appears slightly larger than the left. A right-sided pulmonary vein (PV) drains into the left atrium (LA). The tricuspid valve inserts onto the ventricular septum slightly more apically than does the mitral valve. The moderator band characterizes the right ventricular apex. Both ventricles contribute to the cardiac apex. DA, descending aorta; LV, left ventricle; RA, right atrium; RV, right ventricle.

any means of measurement, should be considered a strong indicator of CHD and should prompt a more detailed evaluation.

SYMMETRY

The right and left sides of the fetal heart should appear generally symmetrical, with the right side slightly larger. During the third trimester, this right-sided predominance may become more pronounced.⁷⁴ If the left side of the heart appears larger than the right, or if the right side appears substantially larger than the left, further evaluation may be prudent.

Frequently, there is a question as to whether the right side is enlarged or the left side is small. Commonly, it may be a little of both, with fetal cardiac output simply redistributing. In other cases, however, the pathology is truly one-sided. The more important questions to consider may be (1) why is there an abnormal ratio between the right and left sides of the heart, and (2) what is the primary lesion?

STRUCTURE

Even for the purposes of screening for CHD, several aspects of the structure of the 4CV should be evaluated. First, the flap of the foramen ovale should be visualized deviated into the left atrium. This flap may not be well visualized, but certainly a flap that is deviated toward the right atrium should raise the concern for right-sided volume or pressure overload and prompt further evaluation. Second, the lowest portion of the atrial septum, just above the insertion point of the mitral valve, should always be visualized. Third, the septal leaflet of

the tricuspid valve should attach to the ventricular septum slightly more toward the apex than the septal leaflet of the mitral valve does. In practice, this normal offset may be subtle, difficult to appreciate, and honestly not critical to note for the purposes of screening for CHD.

Fourth, the mitral and tricuspid valves should be thin and delicate, with the tricuspid valve slightly larger than the mitral valve, and the valves should open symmetrically during diastole. Fifth, the left ventricle (aligned with the left atrium) should be smooth walled and should extend to the apex. The right ventricle should appear more heavily trabeculated and should extend toward the cardiac apex along with the left ventricle. Finally, the ventricular septum should appear intact with 2D imaging.

SQUEEZE

The 4CV, even for the purposes of screening for CHD, should be evaluated with the heart beating. The heart rate should range roughly between 120 and 160 beats/min, with no pauses and no skipped or extra beats, other than transient bradycardia during deep transducer pressure. The mitral and tricuspid valves should open and close symmetrically, and both ventricles should squeeze well. Abnormalities of rhythm, valvar function, or myocardial motion may reflect important forms of fetal heart disease and may be overlooked with evaluation of only still-frame images.³⁷

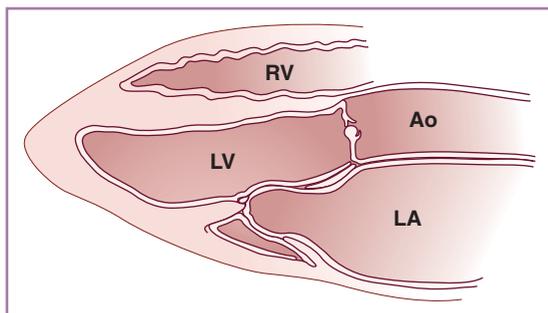

FIGURE 19-4 Schematic diagram of fetal left ventricular long-axis view. Note that it is preferable to obtain the image perpendicular to left ventricular outflow tract. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle. (Diagram courtesy of Irving R. Tessler, M.D.)

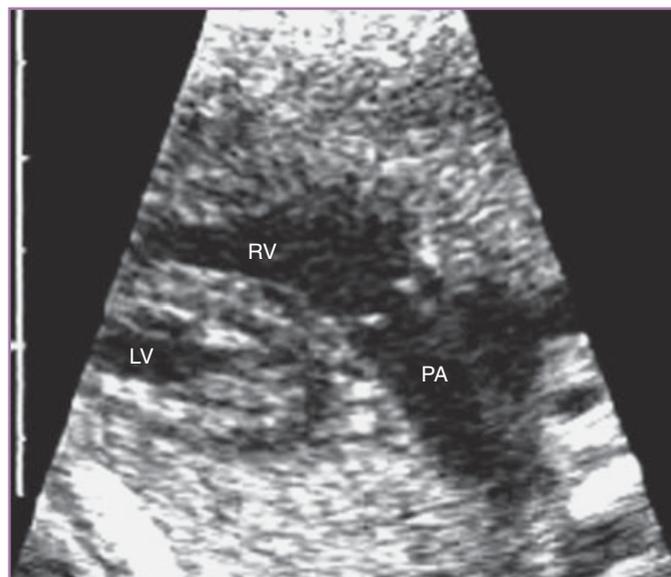

FIGURE 19-7 Fetal echocardiographic image of right ventricular outflow tract crossing view. Note that the pulmonary artery aims to the left of the spine. Compare with Figure 19-6. LV, left ventricle; PA, main pulmonary artery; RV, right ventricle.

Outflow Tracts

Ideally, prenatal screening for CHD should include visualization of both outflow tracts. In practice, appropriate evaluation of the outflow tracts may be more challenging than visualization of the 4CV. Nevertheless, because of the ability of the outflow tract views to detect major forms of CHD not visualized with the 4CV, a serious attempt should be made to evaluate the LVOT at the very least, and evaluation of both outflow tracts is becoming the standard of care.^{2,48,49}

Slight angulation of the transducer cephalad from the 4CV should demonstrate the aortic valve and ascending aorta arising from the left ventricle (Figs. 19-4 and 19-5). The aortic valve should appear thin and delicate. The ventricular septum should be noted to extend, uninterrupted, from the cardiac apex all the way to the lateral aspect of the ascending aorta. The ascending aorta, or aortic root, should point toward the right of the spine. The left ventricular long-axis view should be able to detect most forms of CHD involving the outflow tracts.⁵⁶ However, with just slight further cephalic angulation of the transducer, the right ventricular outflow tract, or RVOT (pulmonary valve and pulmonary artery), can be visualized arising from the right ventricle

and crossing the aortic root (Figs. 19-6 and 19-7). The pulmonary valve should be thin and delicate, and the pulmonary valve and main pulmonary artery should be slightly larger than the aortic valve and aortic root. The main pulmonary artery should point to the left of the spine.

Prenatal Screening Using Three-Dimensional Imaging

Although the current standard for screening the low-risk pregnancy for CHD uses 2D imaging, 3D imaging may ultimately facilitate the prenatal detection of CHD by allowing virtual⁶⁰ or automated^{63,75} evaluation of the entire fetal heart after a simple, short acquisition. When desired, volume data sets may be transmitted electronically to experts at remote locations, who can perform a virtual examination as if actually scanning the patient themselves.⁷⁶ Ultimately, 3D fetal cardiac imaging may make acquisition of fetal cardiac data sets less

dependent on time and operator skill and facilitate evaluation of the 4CV and outflow tracts offline.^{60,77} 3D fetal cardiac imaging is discussed further in the next section, which covers fetal echocardiography in high-risk pregnancies.

Technique of Fetal Echocardiography

Detailed fetal echocardiography in the pregnancy at high risk for CHD provides an in-depth and comprehensive evaluation of fetal cardiovascular structure and function.⁷⁸ In experienced hands, and particularly when performed beyond 18 weeks' gestation, fetal echocardiography has been shown to have high degree sensitivity for almost all forms of fetal heart disease.^{19,79,80} First-trimester fetal echocardiography, performed between 10 and 14 weeks' gestation either transvaginally or transabdominally, does not have the same degree of sensitivity for CHD as second-trimester imaging, in part because many forms of CHD evolve significantly between the late first trimester and term (e.g., aortic and pulmonary valvar stenosis, ventricular hypoplasia, valvar regurgitation, arrhythmias, cardiac tumors, restriction of the ductus arteriosus or foramen ovale).^{16,81,82} Although first-trimester fetal echocardiography undoubtedly will have an increasing clinical role as the technique's resolution improves,^{15,67-70,83} it is not discussed here in any further detail. Instead, this section reviews the technique of fetal echocardiography as performed transabdominally beyond 16 to 18 weeks' gestation. Solely to optimize image quality, fetal echocardiography optimally should be performed between 22 and 28 weeks' gestation. However, because earlier diagnosis may be desired for various management and emerging therapeutic options, fetal echocardiography should be performed generally between 18 and 22 weeks' gestation.

Formal fetal echocardiography involves evaluation of the fetal heart and cardiovascular system using several modalities: 2D imaging, color flow imaging, spectral/continuous wave Doppler evaluation, quantitative assessment of ventricular function, and 3D imaging. In practice, the fetal heart and cardiovascular system is probably best evaluated in an anatomically systematic fashion, using various modalities in combination for each anatomic component of the evaluation. However, the order in which individual components of the evaluation are performed may vary with case-specific clinical and imaging considerations.

Various quantitative measurements^{8,9,84-94} may be performed if an abnormality is suspected, if doubt remains regarding normalcy, or if measurements for a database are desired. Spectral Doppler echocardiography should routinely be used to assess flow across vessels or valves with suspected pathology.^{84,86,91-94} Any structure that appears small or large should be measured several times, with the best-guess measurement plotted on nomograms according to gestational age.⁹⁵⁻¹⁰⁰ Color flow imaging, which is exquisitely sensitive to valvar regurgitation, flow through small VSDs, and pulmonary/systemic venous returns, should be used routinely to demonstrate normalcy and to assess pathology. More sophisticated tissue Doppler studies^{89,101,102} or other quantitative means of evaluation of ventricular diastolic⁹¹⁻⁹⁴ or combined diastolic/systolic^{87,88} function may be used in special circumstances. This section describes a clinical approach to the formal fetal echocardiographic evaluation, with an emphasis on the importance of routine 2D and color flow imaging. Readers should note that this approach might be somewhat less rigorous and comprehensive than that described in previously published guidelines,⁷⁸ but it may also be more clinically practical in many settings.

General Imaging

The formal fetal echocardiogram begins with a determination of the number of fetuses, their levels of activity, their respective positions, and their gestational ages. The number of fetuses and their respective positions matter because the lie, late in the third trimester, may affect delivery plans. With multiple-gestation pregnancies, each fetus should undergo its own detailed fetal echocardiogram, and noting the fetal lie or position helps to distinguish one fetus from another. Gestational age determination (1) enables assessment of fetal growth, (2) may affect counseling or management strategies, and (3) allows assessment of cardiac structures that vary in appearance with gestational age.

Umbilical Cord

Next comes evaluation of the umbilical cord (Fig. 19-8). Spectral Doppler evaluation of the umbilical artery provides information on placental resistance, which may affect fetal cardiovascular function and reflect overall fetal well-being. In cases of suspected placental pathology, calculation of a pulsatility index enables a quantitative assessment of placental resistance. Doppler evaluation of the umbilical vein in free-floating cord is most useful in cases of suspected fetal heart failure.⁸⁶ Normally, the umbilical venous waveform pulsates in response to fetal breathing, but it should not vary with the fetal cardiac cycle. Pulsatile flow in the free-floating umbilical cord, reflecting fetal cardiac contractions, suggests markedly elevated fetal right atrial pressure and represents a manifestation of significant CHF.¹⁰³

Hydrops

Initial evaluation of the fetus itself should assess for the presence of fluid accumulation suggestive of CHF. Normally, no more than a trivial (loculated and <2 mm) pericardial effusion should be present.⁷¹ Greater accumulation of pericardial fluid (circumferential or >2 mm) or the presence of any pleural fluid or ascites (see Fig. 19-1) should be considered abnormal, with a differential diagnosis including CHF, myopericarditis, viral infection, anemia, and aneuploidy.

Visceroatrial Situs

Following the determination of fetal number, position, gestational age, umbilical waveforms, and presence or absence of hydrops, attention should be directed toward the structure and function of the fetal cardiovascular system itself. This assessment should begin with an

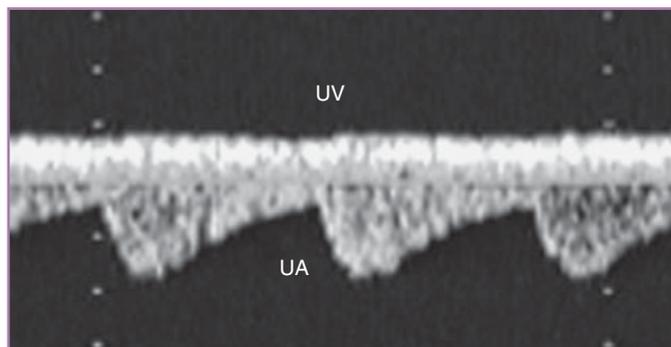

FIGURE 19-8 Spectral Doppler display of flow within free-floating umbilical cord. UA, umbilical artery; UV, umbilical vein.

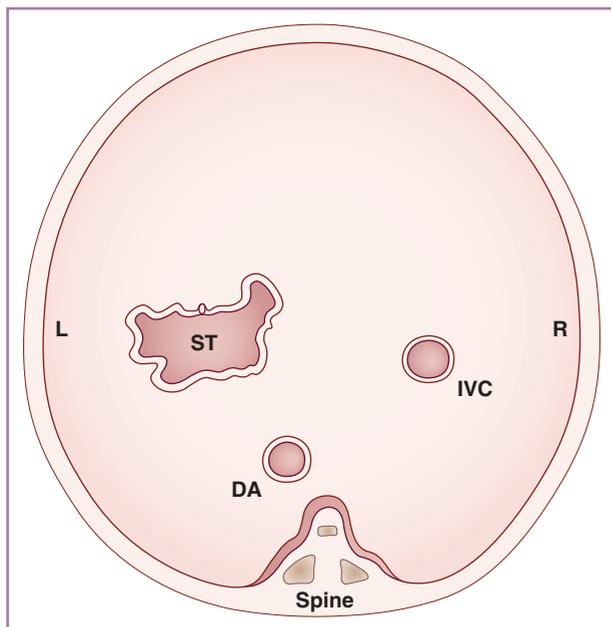

FIGURE 19-9 Schematic diagram of abdominal situs view. DA, descending aorta; IVC, inferior vena cava; L, fetal left; R, fetal right; ST, stomach. (Diagram courtesy of Irving R. Tessler, M.D.)

abdominal assessment of visceral situs (Figs. 19-9 and 19-10). Transverse imaging of the abdomen should demonstrate the descending aorta, in cross section, just anterior and slightly leftward of the spine. The stomach should be anterior and leftward, and the inferior vena cava (IVC) and liver should both be anterior and rightward. A prominent vein (usually the azygos) should not be visualized posterior to the descending aorta. Angulation of the probe from transverse to sagittal imaging should demonstrate the IVC draining into the right atrium. Finally, transverse imaging of the thorax should demonstrate the heart on the left, with the apex directed anteriorly and leftward. Abnormalities of any of these features should prompt further evaluation for situs abnormalities (asplenia or polysplenia) or associated CHD or both.

Beating Four-Chamber View

Central to screening for CHD, the 4CV also represents a critically important aspect of the formal fetal echocardiogram.^{8,9,104} As with screening, detailed fetal echocardiography begins by demonstrating the fetal heart to be in the left thorax with the apex directed approximately 45 degrees to the left (see Figs. 19-2 and 19-3). The heart should fill less than one third of the area of the thorax,⁷³ and the heart's circumference should be less than half the thoracic circumference. These quantitative measurements, like most such measurements in fetal echocardiography, should be considered optional unless an abnormality is suspected, normalcy is in doubt, or measurements are desired for incorporation into a database.

The fetal heart's right-sided structures should be equal to or, more commonly, slightly larger than their respective left-sided structures.⁷⁴ Mild right heart disproportion appears to occur in some cases of trisomy 21, even in the absence of structural disease.¹⁰⁵ With advancing gestation, the right side of the heart becomes progressively more dominant, making the diagnosis of right heart disproportion much more common during the third trimester than during the second.⁷⁴ For this

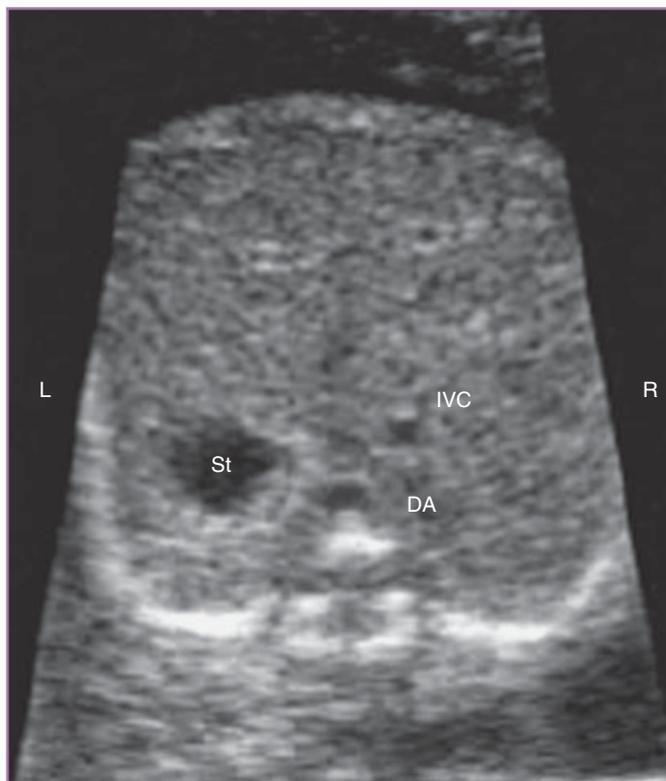

FIGURE 19-10 Fetal echocardiographic image of abdominal situs view. Compare with Figure 19-9. DA, descending aorta; IVC, inferior vena cava; L, fetal left; R, fetal right; ST, stomach.

reason, false-positive diagnoses of coarctation of the aorta occur most frequently late in gestation.

Venous Drainage

Although evaluation of systemic and pulmonary venous drainage may be accomplished with 2D imaging alone, color flow imaging helps to confirm the anatomy and to demonstrate areas of obstruction,¹⁰⁶ and spectral Doppler may help to assess cardiovascular status still further.^{86,90,91,103} With slight inferior angulation or tilting of the transducer from the 4CV, the coronary sinus should be seen coursing from left to right just above the mitral groove (Fig. 19-11). At the level of the 4CV, the coronary sinus sometimes may be seen in cross section laterally, adjacent to the left atrial free wall just above the mitral annulus. However, enlargement of the coronary sinus should prompt evaluation for either a left-sided superior vena cava (LSVC)^{107,108} or drainage of some or all pulmonary veins directly into the coronary sinus. All four pulmonary veins may be seen, but such visualization can be time-consuming and challenging; therefore, visualization by color flow Doppler of even one or two pulmonary veins (Figs. 19-12 and 19-13; see Fig. 19-3) draining normally to the left atrium is generally sufficient^{1,85} in the absence of suspected disease. The presence of a ridge of tissue (normal pericardial reflection, or infolding of tissue between the left atrial appendage and left pulmonary vein) extending a short distance medially from the posterior/lateral aspect of the left atrium helps to rule out total anomalous pulmonary venous return. Color flow imaging should be performed to confirm normal, unobstructed pulmonary venous return to the left atrium. Spectral Doppler analysis may be performed if color Doppler suggests pathol-

FIGURE 19-11 Schematic diagrams of coronary sinus views. **A**, Longitudinal coronary sinus view obtained with slight inferior angulation from the four-chamber view. The coronary sinus (*arrow*) drains along the mitral annulus before opening into the right atrium and can be seen in normal fetuses. **B**, Four-chamber view demonstrating dilated coronary sinus in cross section (*arrow*) at the lateral aspect of the mitral annulus. A normal coronary sinus is usually small or not seen at all with this perspective. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Diagrams courtesy of Irving R. Tessler, M.D.)

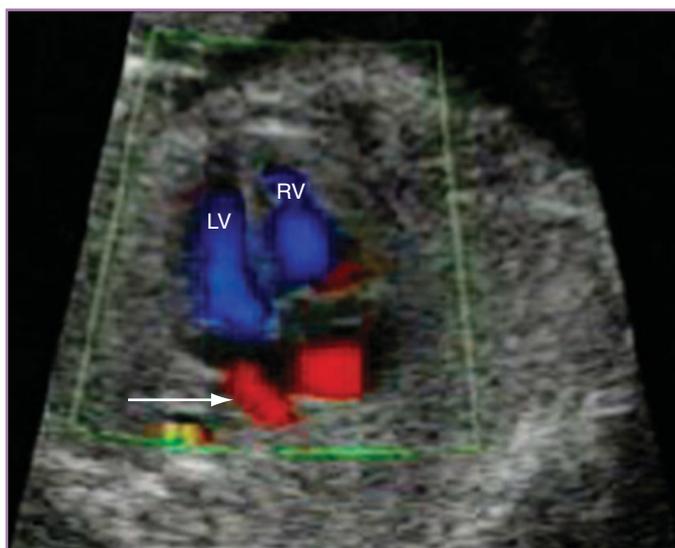

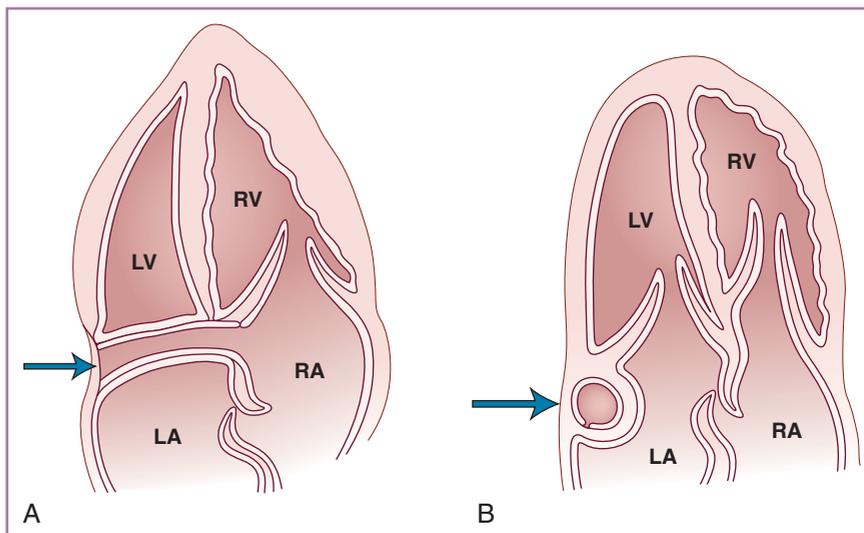

FIGURE 19-12 Fetal echocardiographic image of four-chamber view. Color flow imaging demonstrates a right-sided pulmonary vein (*arrow*) draining into the left atrium. LV, left ventricle; RV, right ventricle.

ogy.⁹¹ Structural abnormalities of venous return raise the possibility of heterotaxy.^{106,109,110}

Atrial Septum

Because the foramen ovale normally shunts oxygenated blood from the right atrium to the left atrium, the flap of the foramen ovale should be deviated toward the left atrium. Although this flap typically moves back and forth during the cardiac cycle, the dominant position should be leftward (see Fig. 19-2). The flap itself should occupy a central position within the atrial septum, and it should extend increasingly further into the left atrium with advancing gestational age. Both the superior and inferior aspects of the atrial septum should appear intact, although the superior rim may not always be seen with routine screening. Occasionally, particularly when dilated, the coronary sinus (seen longitudinally) may generate the appearance of an absent inferior portion of

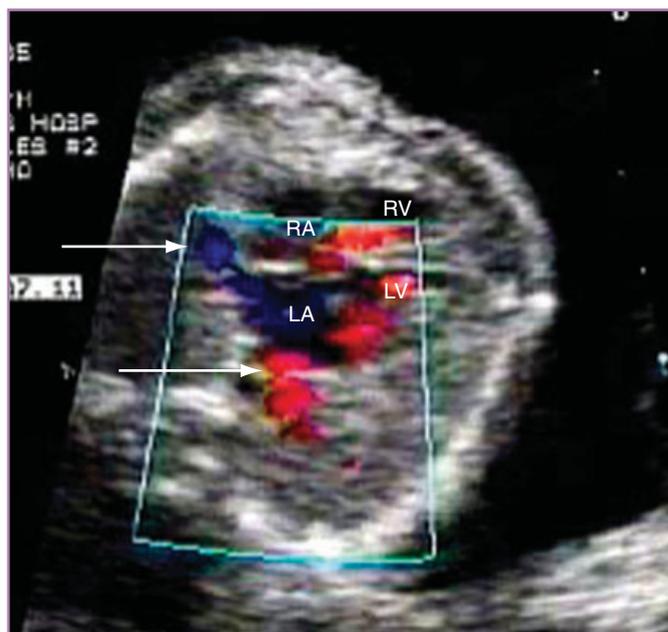

FIGURE 19-13 Fetal echocardiographic image of four-chamber view. Color flow imaging demonstrates right and left pulmonary veins (*arrows*) draining into the left atrium. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

the atrial septum (Fig. 19-14).¹⁰⁷ For this reason, if this portion of the atrial septum appears deficient, care must be taken to confirm that the image plane has not simply been directed too far posteriorly/inferiorly from the 4CV.

Atrioventricular Valves

The atrioventricular valve morphology and function should be evaluated, along with the rest of the heart, during real-time motion. Both valves may be evaluated in their entirety from the 4CV (see Figs. 19-2 and 19-3), although visualization from other views may be useful, particularly if abnormalities are present or suspected. The tricuspid valve annulus should be the same size or slightly larger than the mitral

FIGURE 19-14 Fetal echocardiographic image of dilated coronary sinus, obtained with slight inferior angulation from the four-chamber view. The dilated coronary sinus orifice (*arrow*) mimics ostium primum atrial septal defect.

annulus. The leaflets should appear thin and delicate, with unrestricted diastolic excursion into their respective ventricles. A subtle abnormality of either valve early in the second trimester may progress to a severe abnormality, or even to hypoplastic right or left heart syndrome, at term. The septal leaflet of the tricuspid valve should insert slightly more apically onto the ventricular septum than the septal leaflet of the mitral valve does. The papillary muscles of the tricuspid valve should have attachments to the ventricular septum and right ventricular free wall. In contrast, the papillary muscles of the mitral valve should have no attachments to the ventricular septum. Evaluation of the atrioventricular valves should always include color flow imaging to assess for diastolic turbulence or valvar regurgitation. A trace amount of early systolic tricuspid regurgitation probably is normal,¹¹¹ although many investigators consider any tricuspid regurgitation prenatally to be abnormal.¹¹² Prenatal valvar regurgitation of any other valve is generally considered abnormal. Fetuses with trisomy appear to have an increased incidence of tricuspid regurgitation, even in the presence of a structurally normal heart.¹⁰⁵ Measurement of tricuspid and mitral valve annulus size,^{95-97,99,100} as well as spectral Doppler evaluation of inflow patterns,⁹²⁻⁹⁴ should be performed if an abnormality is suspected, if normalcy cannot be confirmed, or if additions to a database are desired.

Ventricles

The structure and function of both ventricles should be evaluated in detail. The 4CV provides the single best perspective to evaluate ventricular structure (see Figs. 19-2 and 19-3). Both ventricles should extend to the cardiac apex, and both should squeeze symmetrically during systole. The left ventricle should be smooth walled, aligned with the mitral valve, and located leftward and posterior to the right ventricle. The right ventricle should be more heavily trabeculated, should have a moderator band of tissue crossing the ventricle near the apex, should be aligned with the tricuspid valve, and should be located rightward and anterior to the left ventricle. The right ventricle should be equal in size or, more commonly, slightly larger than the left ven-

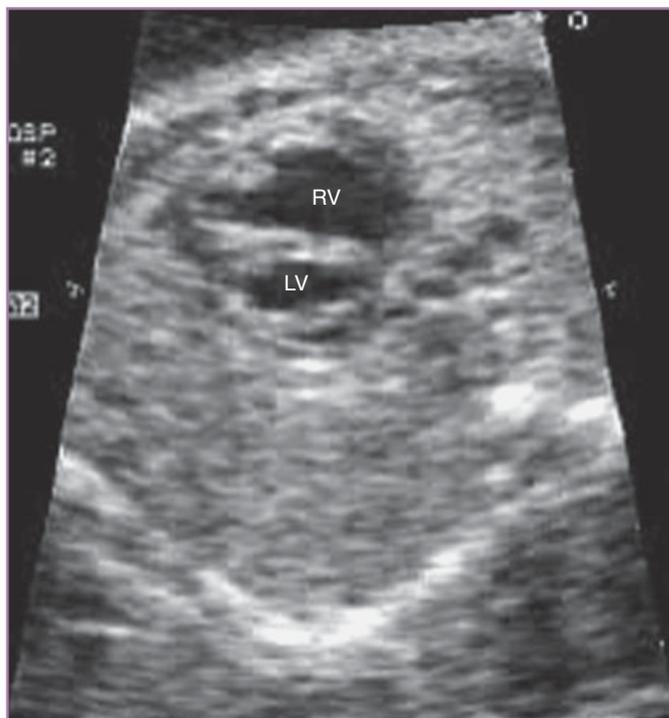

FIGURE 19-15 Fetal echocardiographic image of apical short-axis view. Right ventricular disproportion is demonstrated. LV, left ventricle; RV, right ventricle.

tricle, with right heart predominance increasing normally with advancing gestational age. Mild right heart disproportion (Fig. 19-15) has been associated with trisomy 21.¹⁰⁵ Quantitative assessment of ventricular systolic and diastolic function^{86-89,92-94,102,113} may be performed if an abnormality is suspected, if normalcy cannot be confirmed, or if additions to a database are desired. However, close attention to ventricular systolic function should always be made qualitatively and from multiple views, including the 4CV and basal short-axis view (obtained from a sagittal fetal orientation). Ventricular dysfunction may be isolated and primary,¹¹⁴ or it may be associated with structural heart disease.

The presence of small, circumscribed echogenic densities, foci, or reflectors within the chordal apparatus of the mitral valve (or, less commonly, tricuspid valve) should probably be considered, from a cardiovascular standpoint, as benign variants of normal.¹¹⁵⁻¹¹⁷ If doubt exists regarding the diagnosis, further evaluation should be performed to rule out CHD. Although the data remain somewhat controversial, such echogenic foci do appear to be more prevalent among fetuses with aneuploidy than among those with normal chromosomes.¹¹⁶⁻¹¹⁹

Ventricular Septum

The ventricular septum should be evaluated for thickness, motion, and the presence of a VSD. The ventricular septum should be roughly the same thickness as the left ventricular posterior free wall, and it should contract symmetrically with the left ventricular free wall. Ventricular septal thickness may be evaluated from the 4CV and the basal short-axis view. In cases of suspected septal hypertrophy, the septal thickness should be measured, typically during both diastole and systole. The entirety of the ventricular septum then needs to be evaluated for VSDs. 2D imaging should be performed from multiple views and with multiple sweeps, seeking to identify any defect in any portion of the ven-

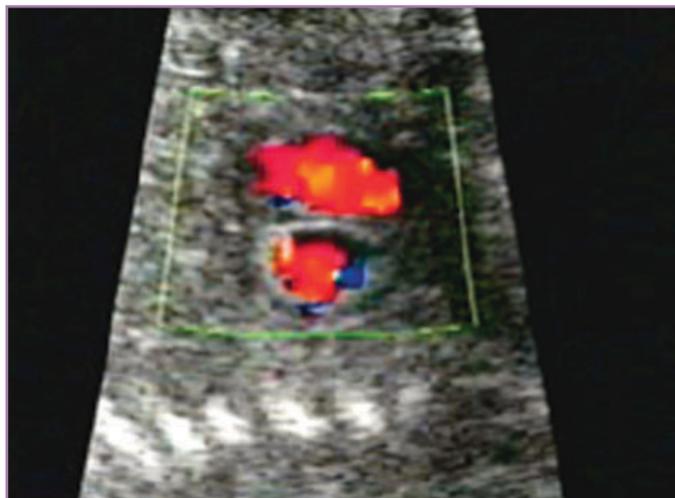

FIGURE 19-16 Fetal echocardiographic image of apical short-axis view. Color flow imaging demonstrates intact muscular ventricular septum.

tricular septum. To avoid false-positive “drop out” in the inlet and membranous portions of the ventricular septum, 2D imaging should be performed as perpendicular as possible to the ventricular septum and with the transducer angled slowly from the 4CV into the left ventricular long-axis view (see Figs. 19-4 and 19-5). Color flow imaging should also always be performed in search of VSDs (Fig. 19-16), using the same perpendicular orientations and sweeps; some defects may not be visualized with 2D imaging alone.

Outflow Tracts in Motion

Semilunar Valves

The semilunar (aortic and pulmonary) valves should be evaluated with the same attention to anatomy and function that is given to the evaluation of the atrioventricular valves. Consistent with the right-sided predominance seen at the levels of the atrium, atrioventricular valve, and ventricle, the pulmonary valve annulus should be equal in size or, more commonly, slightly larger than the aortic valve annulus. The aortic valve may be best visualized with a left ventricular long-axis view (see Fig. 19-5), which is obtained with slight anterior/superior angulation from the 4CV. In addition, ideally, the probe may be rotated slightly from a transverse cut toward a partially sagittal plane. The aortic valve may be evaluated further with a basal short-axis view, which is obtained from a sagittal fetal orientation. The pulmonary valve (RVOT crossing view) (see Fig. 19-7) may be evaluated with slight anterior/superior angulation from the left ventricular long-axis view. In addition, the pulmonary valve may be evaluated further with a basal short-axis view. The aortic valve should arise from the anterior aspect of the left ventricle, and the pulmonary valve from the anterior aspect of the right ventricle. Both aortic and pulmonary valves should be thin and delicate, with unrestricted excursion during systole, resulting in the valve’s practically disappearing from view when fully open (see Fig. 19-5). During diastole, the aortic and pulmonary valves should appear as central points or symmetrical, thin plates. The aortic valve, during diastole, should appear on the left ventricular long-axis view as a thin, central plate, parallel to the axis of the aortic root. The pulmonary valve during diastole, in contrast, should appear on the basal short-axis view also as a thin plate but perpendicular to the axis of the main

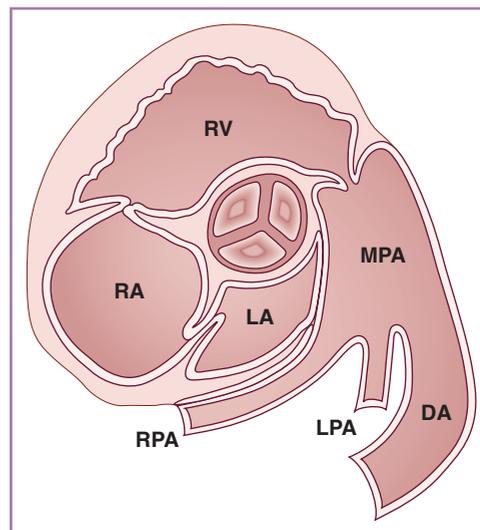

FIGURE 19-17 Schematic diagram of fetal basal short-axis/ductal arch view. The left pulmonary artery and ductus arteriosus commonly appear superimposed in this view. DA, ductus arteriosus; LA, left atrium; LPA, left pulmonary artery; MPA, main pulmonary artery; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle. (Diagram courtesy of Irving R. Tessler, M.D.)

pulmonary artery. A subtle abnormality of either valve during the early second trimester may progress to a severe valve abnormality, or even to hypoplastic left or right heart syndrome, at term. Measurement of aortic or pulmonary valve annulus size, or evaluation of the systolic Doppler flow profile, or both, should be performed if an abnormality is suspected, if normalcy cannot be confirmed, or if additions to a database are desired. However, evaluation of aortic and pulmonary valves should always include color flow imaging to assess for aortic or pulmonary regurgitation (always abnormal) or systolic turbulence suggestive of increased flow volume or anatomic obstruction.

Great Arteries and Ductal and Aortic Arches

The ascending aorta (aortic root) and main pulmonary artery should arise from the left and right ventricles, respectively, and then cross at an angle of roughly 45 to 90 degrees. Demonstration of great artery crossing represents an important finding on the normal fetal echocardiogram. This crossing can be seen either with transverse imaging (slight anterior/superior angulation from the 4CV to left ventricular long-axis view to RVOT crossing view) or with sagittal imaging (slight leftward angulation from sagittal aortic arch view to ductal arch view). In general, the aortic root should point to the right of the spine (see Fig. 19-5), and the main pulmonary artery should point to the left of the spine (see Fig. 19-7). As with other right-left ratios in the fetal heart, the main pulmonary artery should be equal in size or, more commonly, slightly larger than the aortic root. The ductal arch and basal short-axis views (Figs. 19-17, 19-18, and 19-19) should demonstrate the trifurcation of the main pulmonary artery into the right pulmonary artery (which wraps around the aorta in the basal short-axis view), the left pulmonary artery, and the ductus arteriosus (the largest of the three branches).

In cases of suspected pathology, the branch pulmonary arteries should be measured and their Doppler flow profiles obtained. For instance, fetal pulmonary artery diameter may correlate with outcome in cases of congenital diaphragmatic hernia.¹²⁰ In cases of suspected ductal constriction (i.e., tricuspid and pulmonary regurgitation across

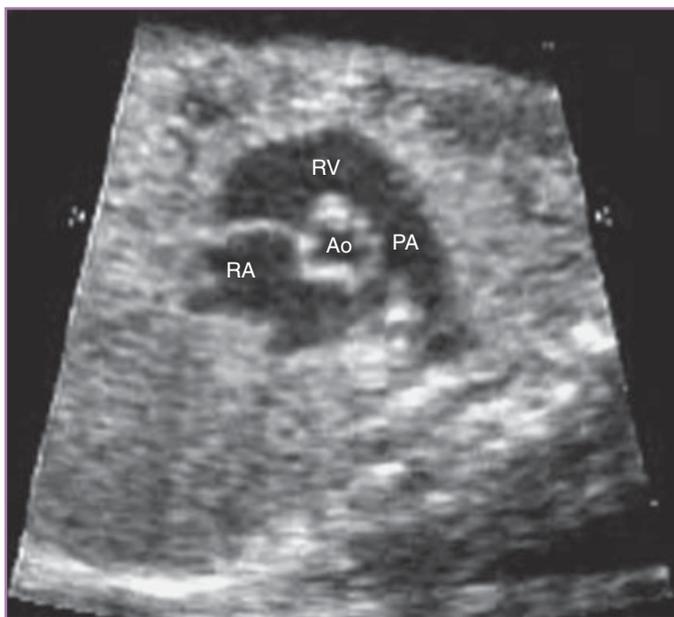

FIGURE 19-18 Fetal echocardiographic image of basal short-axis view during systole. The pulmonary artery bifurcates into the right and left pulmonary arteries. The ductus arteriosus appears superimposed over the left pulmonary artery. The pulmonary valve is open and is closely opposed to the main pulmonary artery. Ao, aorta; PA, main pulmonary artery; RA, right atrium; RV, right ventricle.

onstrates the aortic arch in its entirety, including aortic root, transverse aortic arch, aortic isthmus, and descending aorta. Color flow imaging should always be performed of the entire aortic (Fig. 19-22) and ductal arches. Measurements of aortic dimensions^{95,96,98} should be obtained if an abnormality is suspected, if normalcy cannot be confirmed, or if additions to a database are desired.

Evaluation for Fetal Congestive Heart Failure

Fetal CHF may be related to extracardiac disease (e.g., anemia, cerebral arteriovenous fistula, twin-twin transfusion syndrome) or to fetal

heart disease (Table 19-4). Some of the most severe forms of CHD (e.g., hypoplastic left heart syndrome [HLHS], TOF with pulmonary atresia and ductal-dependent pulmonary blood flow) do not typically generate fetal CHF. Rather, fetal heart disease that causes CHF almost invariably includes one or more of the following^{103,123,124}: sustained tachycardia or bradycardia (i.e., supraventricular tachycardia [SVT] or complete heart block), myocardial dysfunction (i.e., dilated cardiomyopathy), valvar regurgitation (i.e., Ebstein anomaly of the tricuspid valve or TOF with absent pulmonary valve), or restrictive flow across the foramen ovale or ductus arteriosus.¹²² The fetus with absence of a valve (e.g., tricuspid atresia) or absence of a ventricle (e.g., HLHS) generally does better prenatally than one with a poorly functioning valve or ventricle.

Unlike the postnatal diagnosis of CHF, which relies more on clinical signs (tachycardia, tachypnea, hepatomegaly, rales, and peripheral edema) than on radiographic or echocardiographic findings, the prenatal diagnosis of CHF relies exclusively on sonographic findings.^{86,103,123,124} The sonographic findings associated with fetal CHF from any cause include (1) dilated, poorly squeezing ventricle with systolic and diastolic dysfunction; (2) cardiomegaly; (3) pericardial

effusion; (4) tricuspid regurgitation; and (5) increased atrial flow reversal in the systemic veins (Table 19-5). More detailed cardiac and peripheral Doppler evaluation also may be performed.^{86,103,124,125} Severe forms of CHF lead to hydrops and cardiac pulsations within the free-floating umbilical vein. The diagnosis of fetal CHF or hydrops should prompt further evaluation for clues to the etiology, as well as serial follow-up studies, given the potential for progression of disease and even fetal demise.

Three-dimensional Fetal Cardiac Imaging

Background

At the current time, 3D fetal cardiac imaging^{60-62,64,77,126-149} remains predominantly an investigational tool for academic centers seeking to improve and enhance the prenatal detection and diagnosis of CHD. Because of persistent challenges related to image resolution, substantial learning curves, and expensive equipment, 3D fetal cardiac imaging has not yet become an acceptable alternative to conventional 2D imaging.

That said, compared with 2D fetal cardiac imaging, 3D imaging carries important advantages that promise to revolutionize the clinical approach to fetal cardiac imaging.^{60,63,131,140} First, 3D imaging, by acquiring a comprehensive volume dataset within a matter of a few seconds, makes fetal cardiac imaging less operator dependent and less time-consuming to perform. Second, 3D volume datasets may be evaluated interactively offline, enabling virtual examinations of the entire fetal heart, with reconstruction of any plane or sweep, after the initial, short acquisition. Such interactive evaluations may be performed at the bedside, remotely by centers with expertise,⁷⁶ or even, potentially, automatically using evolving algorithms designed to automate the process of screening for CHD.^{63,75} Third, volume-rendering algorithms display data as “surgeon’s-eye views,” enabling visualization of the internal architecture and anatomy of the fetal heart (Figs. 19-23 and 19-24) or great arteries from any perspective. Such displays improve comprehension of complex forms of CHD, leading to improved patient counseling and patient selection for fetal interventions. Moreover, evolving technology allows the 3D visualization of color-flow jets within volume-rendered displays or as stand-alone “angiograms.”^{135,138} Finally, 3D volume datasets enable more accurate quantitative measurements of ventricular size and function,^{139,141} which can translate into improved ability to predict the prenatal and postnatal courses of CHD from early in the second trimester (or even earlier).

Technique

Three-dimensional fetal cardiac imaging may be performed with either a reconstructive^{61,62,126-130,142-144} or a real-time^{60,132,133,136,137,139,145,146} approach. Reconstructive approaches use specialized probes to image

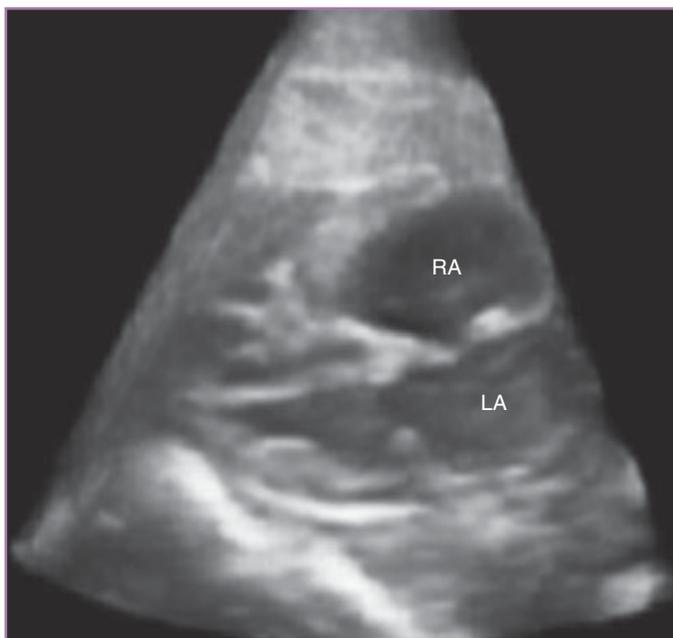

FIGURE 19-23 Fetal echocardiographic real-time three-dimensional rendered image of normal four-chamber view. LA, left atrium. RA, right atrium.

the fetal heart as an automated sweep, acquiring a series of parallel planar images over 7 to 15 seconds. The images and their spatial coordinates are subsequently reconstructed into a volume dataset or, using gating algorithms to view cardiac motion,^{126,129,142,147} into a series of volume datasets for subsequent display and review. Reconstructive approaches have a disadvantage in that they require the fetus and mother to be relatively motionless throughout the acquisition; any fetal or maternal motion distorts the reconstructed volume dataset.

In contrast, real-time approaches use specialized probes to image the fetal heart as a volume, acquiring the entire fetal heart (or portion thereof) virtually instantaneously. The volume data do not require reconstruction, and they do not require gating algorithms (as do reconstructive techniques) to view cardiac motion. Real-time approaches make the most sense for imaging the fetal heart, given their quick acquisition time (2 seconds), relative resistance to artifact derived from random fetal motion, and lack of a need for cardiac gating.^{60,132,136,137,145,146} However, real-time approaches are unable to acquire large volumes in real time, and they have relatively poor image resolution compared with reconstructive approaches.

After volume data have been acquired, via either reconstructive or real-time techniques, volume datasets may be reviewed interactively, displaying any plane,^{62,128} rendered volume,^{60,62,143,144} or sweep of interest and allowing precise quantitative measurements of ventricular size and function.¹⁴⁷⁻¹⁴⁹ Investigators continue to develop new ways to display volume data,^{77,138,144} in an effort maximally to exploit the potential clinical utility of 3D sonographic data (Figs. 19-25 and 19-26).

The Future

Within the next 10 years, 3D imaging (most likely real-time rather than reconstructive imaging) may become the standard of care, both for prenatal screening for CHD and for detailed evaluation of complex CHD using rendered displays, color flow imaging, and quantitative measurements. Ultimately, 3D imaging may automate the display of

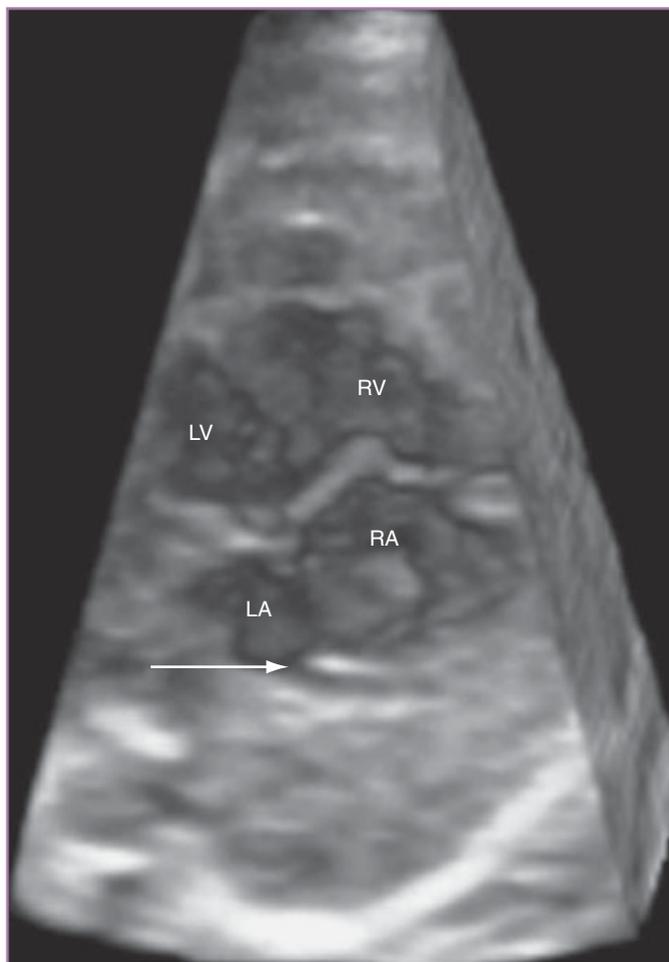

FIGURE 19-24 Fetal echocardiographic real-time three-dimensional rendered image of mitral atresia with hypoplastic left ventricle. Arrow points to right-sided pulmonary vein draining to left atrium. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

important planes and sweeps, representing a novel form of computer-aided prenatal detection and diagnosis of CHD.^{63,75}

Fetal Cardiac Malformations: Diagnosis, Management, and Prognosis

This section aims to help the obstetrician, perinatologist, radiologist, cardiologist, and sonographer to recognize and diagnose the most common and important forms of fetal cardiac malformations (Table 19-6) and to understand their management and prognosis. The embryology of certain defects is described briefly; more detailed descriptions may be found elsewhere.^{8,9,150-153} Likewise, more thorough descriptions of individual defects, as well as lesion-specific management and prognosis, may be found elsewhere in standard texts.^{8,9,152,153}

Readers should keep in mind that any single heart defect may occur in conjunction with other cardiac defects; often, the most difficult fetal cardiac defect to detect is the second one. Because of the

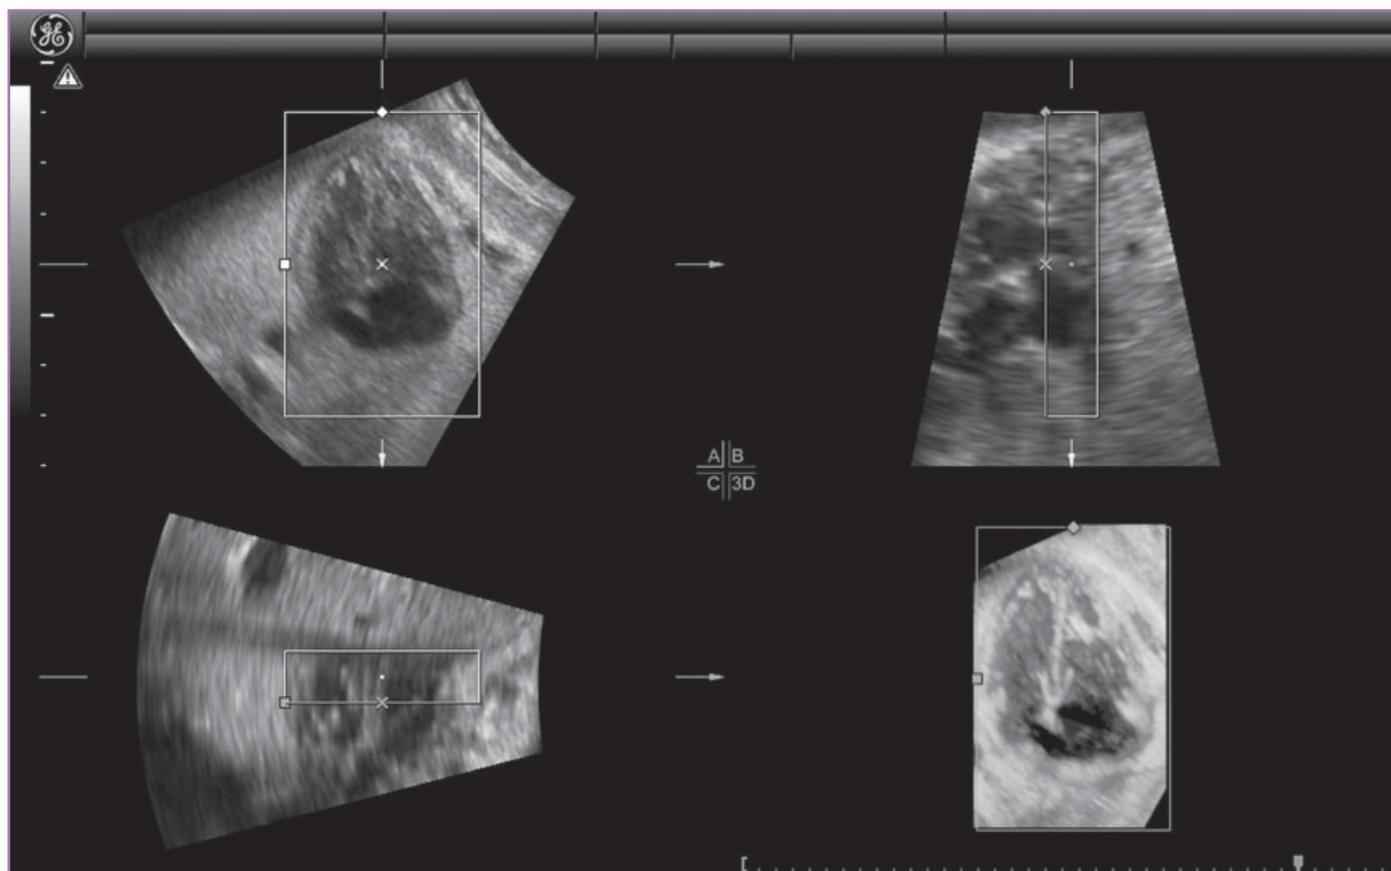

FIGURE 19-25 Fetal echocardiographic reconstructive three-dimensional multiplanar display. Normal fetal cardiac anatomy is demonstrated from three orthogonal planes and in a rendered image at lower right. (Image courtesy of Gregory R. DeVore, M.D.)

complexity of various forms of fetal structural heart defects, as well as their common association with maternal or extracardiac fetal disease, a multidisciplinary team (potentially including an obstetrician, perinatologist, radiologist, pediatric cardiologist, neonatologist, social worker, genetics counselor, nurse, and cardiothoracic surgeon) should jointly manage pregnancies complicated by complex fetal heart disease.

Systemic Venous Anomalies

Persistent Umbilical Vein

Normally, during embryonic development, bilateral umbilical veins course along each side of the fetal liver, carrying oxygenated blood from the placenta to the fetal heart. The right umbilical vein involutes, along with the left umbilical vein's connection to the heart. The persistent portion of the left umbilical vein becomes the fetal umbilical vein, which carries oxygenated blood to the IVC via the ductus venosus. Rarely, the right umbilical vein fails to involute. In such cases, the fetus may be found to have a large, unobstructed vein connecting from the cordal insertion site directly to the right atrium (Fig. 19-27). A persistent right umbilical vein may be associated with structural cardiac defects, right heart disproportion, extracardiac defects, or aneuploidy, or it may simply be an isolated anomaly, usually well tolerated but occasionally associated with CHF.¹⁵⁴⁻¹⁵⁶ Commonly, a persistent right umbilical vein is associated with absence of the ductus venosus.

The finding of a persistent right umbilical vein should prompt a detailed evaluation for other structural defects, cardiac and extracar-

diac, as well as cardiac function.¹⁵⁴⁻¹⁵⁶ Patients also should be advised of the potential for aneuploidy. All cases deserve neonatal clinical and echocardiographic follow-up, although, if the anomaly is isolated, the infant typically does well as the persistent umbilical vein involutes after occlusion of the cord at delivery.

Persistent Left-sided Superior Vena Cava

Normally, during embryogenesis, the right-sided superior vena cava forms from the right anterior cardinal vein and the right common cardinal vein. Abnormal persistence of the left anterior cardinal vein, which normally involutes during embryogenesis, leads to the presence of a persistent LSVC in the fetus and newborn. A persistent LSVC typically drains through the coronary sinus and into the right atrium (Fig. 19-28; see Figs. 19-11 and 19-14). In such cases, a right-sided superior vena cava (normal) may or may not be present (Fig. 19-29).

Cases of persistent LSVC may be detected in the fetus by visualization of an enlarged coronary sinus (see Fig. 19-11) in the 4CV^{106,107} or by direct visualization of the LSVC (see Fig. 19-28). The finding of a persistent LSVC may be isolated, resulting in physiological return of deoxygenated blood to the right atrium, albeit via an abnormal pathway. Such cases represent variations of normal and do not require any intervention, either prenatally or after birth. However, persistent LSVC may be associated with left-sided obstructive lesions (e.g., coarctation of the aorta, valvar aortic stenosis, HLHS),¹⁰⁸ so the finding should prompt a detailed fetal echocardiographic evaluation and, probably, neonatal echocardiographic follow-up. In some cases,

persistent LSVC is associated with extracardiac abnormalities or heterotaxy.^{109,110,157}

Interrupted Inferior Vena Cava

Normally, during embryogenesis, the IVC forms from the right supra-cardinal vein, subcardinal-supracardinal anastomosis, right subcardinal vein, hepatic vein, and hepatic sinusoids. Occasionally, the hepatic portion of the IVC fails to form, resulting in an interruption of the IVC.¹⁵⁴ In such cases, venous return from the lower half of the fetus drains via a so-called “azygos continuation” of the IVC. The azygos vein returns deoxygenated blood to the right atrium via the superior vena cava.

Interrupted IVC with azygos continuation may be diagnosed prenatally from a transverse view of the abdomen (Fig. 19-30). The cross-sectional image will show, in place of the IVC (within the liver), a cross-sectional image of an azygos vein located posterior to the descending aorta. Sagittal imaging confirms the absence of a direct connection from the IVC to the right atrium; only the hepatic veins are seen to connect directly. Using both 2D and low-velocity color flow sagittal imaging, the azygos vein can be seen longitudinally, located posterior to the aorta and coursing superiorly and anteriorly (Fig. 19-31) to its termination in the superior vena cava.¹⁰⁶

The presence of an IVC with azygos continuation does not, in itself, require any treatment, either prenatally or postnatally. However, this finding should prompt detailed fetal and neonatal echocardiographic evaluations because of the association of interrupted IVC with polysplenia^{110,154,157} with or without structural heart disease. The diagnosis of polysplenia may be further suggested by the presence of a midline liver or fetal bradycardia (absent sinus node). All cases deserve neonatal echocardiographic follow-up.

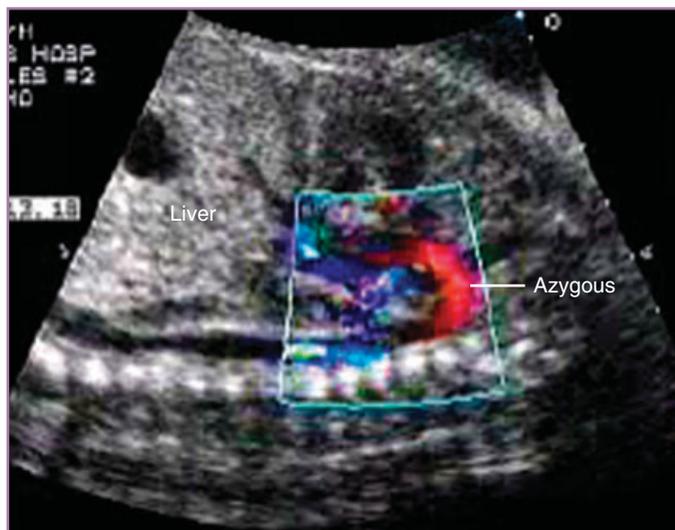

FIGURE 19-31 Fetal echocardiographic sagittal image of azygos vein draining into the superior vena cava. In contrast to retrograde flow into either the aorta or the pulmonary artery (pulsatile), venous flow appears continuous during real-time imaging.

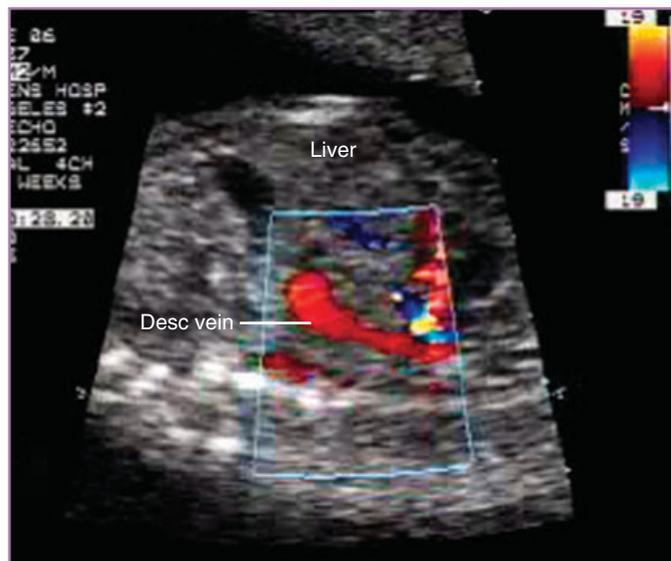

FIGURE 19-32 Fetal echocardiographic sagittal image of infradiaphragmatic total anomalous pulmonary venous return. Color flow imaging demonstrates the descending vein as continuous flow directed inferiorly toward the liver. Desc vein, descending vein.

Pulmonary Venous Abnormalities

Normally, during embryonic development, the common pulmonary vein evolves to form not only four separate pulmonary veins but also much of the left atrium itself. Cases of partial anomalous pulmonary venous return (PAPVR), involving one to three veins, or total anomalous pulmonary venous return (TAPVR), involving all four veins, result from abnormalities of this portion of embryogenesis.¹⁵⁰⁻¹⁵⁴ As with abnormalities of systemic venous return, both 2D and color flow imaging play important roles in the diagnosis of anomalous pulmonary venous return. Color flow imaging can facilitate visualization of normal (see Figs. 19-12 and 19-13) or anomalous (Figs. 19-32 and 19-33) pulmonary venous return when the scale has been adjusted for low-velocity flows. Anomalous pulmonary venous return frequently occurs in association with heterotaxy.^{106,110,157}

Partial Anomalous Pulmonary Venous Return

Because even detailed fetal echocardiography may not routinely demonstrate all four pulmonary veins, many cases of PAPVR may be overlooked prenatally, unless they are associated with other cardiac abnormalities. This section discusses two types of PAPVR that may be detectable before birth because of associated findings. In general, however, PAPVR usually does not require neonatal intervention and carries an excellent long-term prognosis.

Scimitar syndrome represents an unusual form of PAPVR in which the right-sided pulmonary vein (or veins) returns to a vein that descends through the diaphragm before joining the IVC just proximal to the right atrium. Postnatally, this vein may appear radiographically like a sword, or scimitar; hence, the name of the syndrome. In addition, typically, a collateral vessel arising from the descending aorta supplies a separate part of the right lung. Color flow imaging may demonstrate anomalously draining right-sided pulmonary venous return. Further evaluation may demonstrate a collateral vessel arising from the descending aorta and supplying a portion of the right lung. The fetus with scimitar syndrome may have minimal or no right heart disproportion but frequently presents with dextrocardia or mesocardia.¹⁵⁸ Commonly, the syndrome occurs in association with a secundum ASD,

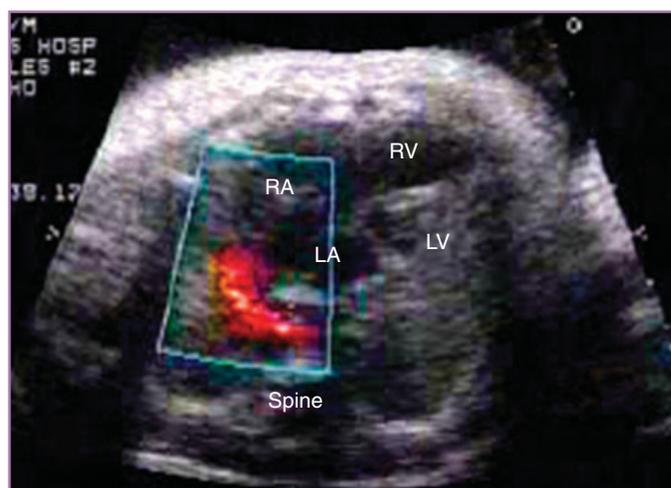

FIGURE 19-33 Fetal echocardiographic transverse image of supracardiac total anomalous pulmonary venous return. Color flow imaging demonstrates the pulmonary confluence draining continuously toward the right atrium. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

which similarly presents a diagnostic challenge prenatally. Fortunately, most infants with scimitar syndrome do quite well, and neonatal intervention is rarely required.

Sinus venosus ASDs (discussed in more detail later) typically occur in association with anomalous pulmonary venous return of one or both right-sided pulmonary veins to the superior vena cava. Although affected fetuses may not present with right heart disproportion, the ASD high in the atrial septum may be detectable prenatally, with an absent superior rim of the atrial septum. Color flow imaging may demonstrate anomalously draining right-sided pulmonary veins. Sinus venosus defects do not generally require intervention during infancy;

ultimately, however, closure of the defect is required, with baffling of the right-sided pulmonary venous drainage to the left atrium.

Total Anomalous Pulmonary Venous Return

TAPVR can usually be diagnosed prenatally.¹⁵⁹⁻¹⁶¹ Although right heart disproportion is present in many cases, in others it is minimal or absent.¹⁶¹ However, affected fetuses do not have the normal infolding of tissue between the left atrial appendage and left pulmonary vein, and color flow imaging will demonstrate absence of pulmonary venous return to the left atrium. Other prenatal sonographic findings in TAPVR depend on the specific type of TAPVR and associated cardiac or extracardiac abnormalities.^{110,157} With intracardiac TAPVR, the pulmonary veins drain to the coronary sinus, causing the coronary sinus to be markedly dilated. Infradiaphragmatic TAPVR may manifest as a dilated IVC, because the pulmonary veins turn below the diaphragm and form a common vein before draining into the IVC. The descending vein, which typically partially obstructs within the liver, should be evaluated with color flow imaging (see Fig. 19-32). Finally, in cases of supracardiac TAPVR, 2D and color flow imaging may demonstrate a large common vein draining cephalad toward a left-sided vertical vein or toward a right-sided superior vena cava¹⁶⁰ (see Fig. 19-33).

Obstructed forms of TAPVR (infradiaphragmatic and some cases of supracardiac TAPVR) usually manifest in the immediate neonatal period with respiratory distress and cyanosis. In such instances, prostaglandin is contraindicated, despite the presence of cyanotic CHD, because the result would be exacerbation of pulmonary venous obstruction and edema. Infants with obstructed forms of TAPVR (usually infradiaphragmatic) are at risk for pulmonary hypertension and usually require surgical repair relatively emergently as newborns. For this reason, delivery should be performed at facilities prepared to manage such high-risk cases. Obstructed TAPVR carries a guarded prognosis, but infants who do well with the initial surgical intervention may have a good long-term prognosis in the absence of significant pulmonary hypertension. Nonobstructed forms of TAPVR usually require repair during infancy, although typically not emergently; occasionally, repair may be postponed for several months.

Septal Defects

This section discusses ASD and VSD, two of the most common forms of CHD. Prenatally, the aortic isthmus normally shunts flow between the right and left heart distributions. The foramen ovale allows oxygenated blood flow to stream from right atrium to left atrium, and the ductus arteriosus directs the majority of right ventricular output toward the fetal body, away from the high-resistance pulmonary circuit. Postnatally, the ductus arteriosus closes via constriction, and the foramen ovale closes via pressure-related closure of a one-way valve or flap-door. Thus, the normal fetus has a right-to-left atrial shunt, as well as a patent ductus arteriosus, but never a communication between right and left ventricles.

Atrial Septal Defect

A secundum ASD represents a deficiency of the middle portion of the atrial septum, in the same general location as the normal foramen ovale. Prenatally differentiating a normal foramen ovale from a secundum ASD can be challenging, if not impossible. Even postnatally, this distinction can be difficult to make. A secundum ASD results, embryologically, from either inadequate development of the septum secundum or excessive resorption of the septum primum. Unlike most forms of CHD, the secundum ASD occurs far more commonly in females than in males. During the second and third trimesters, the flap of the

foramen ovale (septum primum) becomes progressively more aneurysmal and more deviated into the left atrium. In some cases, the flap appears more aneurysmal than normal for gestational age, or the foramen itself appears to occupy a greater proportion of the atrial septum than normal. In such cases, a detailed evaluation for associated cardiac abnormalities, such as right heart obstruction in the case of excessive deviation, should be performed. However, no convincing association has yet been demonstrated between an abnormal prenatal appearance of the foramen ovale and the postnatal diagnosis of a true secundum ASD. Fortunately, isolated ASDs, which are probably more common than currently suspected, usually close spontaneously and rarely require intervention during infancy. If the foramen ovale does appear abnormal prenatally, particularly in association with other cardiac abnormalities or other risk factors for fetal heart disease, elective postnatal echocardiography would be prudent.

Sinus venosus ASDs occur far less commonly than secundum ASDs, and they typically occur in conjunction with anomalous return of the right-sided pulmonary veins to the superior vena cava or right atrium. Unlike secundum ASDs, sinus venosus defects may be readily diagnosed prenatally by demonstrating absence of the superior rim of the atrial septum. Moreover, the right-sided pulmonary veins occasionally may be demonstrated to drain anomalously to the superior vena cava on 2D and color flow imaging. Like secundum ASDs, these defects rarely require any neonatal intervention. Unlike secundum ASDs, however, sinus venosus defects never close spontaneously, and they typically require surgical repair electively during the first 5 years of life. Long-term prognosis is excellent.

The most important ASDs to detect prenatally are the ostium primum ASDs, which are common, always require surgery, and frequently are associated with trisomy 21. These defects can and should be readily detected, even on a standard fetal ultrasound study. Ostium primum defects result from failure of fusion of the septum primum with the endocardial cushions. These defects, also known as partial atrioventricular canal (AVC) defects, commonly occur in conjunction with a cleft mitral valve. However, the most reliable and consistent prenatal sonographic finding is absence of the lower, inferior portion of the atrial septum. Care should be taken to avoid false-positive diagnoses, because posterior/inferior angulation of the probe from the 4CV opens up a longitudinal view of the coronary sinus (see Figs. 19-11 and 19-14), which may appear similar to an ostium primum ASD. The distinction may be made simply with anterior/superior angulation of the probe: A true ostium primum ASD is evident on a true 4CV, whereas the coronary sinus should mimic this defect only with posterior/inferior angulation.

The diagnosis of an ostium primum ASD carries prenatal and postnatal implications. First, these defects carry an increased risk for trisomy 21,^{23,30} so karyotype analysis may be indicated. Second, ostium primum ASDs commonly occur in conjunction with other cardiac and extracardiac abnormalities, so detailed prenatal evaluation should be performed. Finally, isolated defects generally do not require neonatal intervention, but they uniformly require surgical repair, usually during the first 5 years of life. Long-term prognosis is usually excellent, although abnormalities of the mitral valve rarely can persist and may require additional medical or surgical attention.

Ventricular Septal Defect

VSDs probably represent the most common form of CHD, excluding patent ductus arteriosus and bicommissural aortic valve. The size and type (location) of a VSD and its associated cardiac abnormalities, if any, dictate both the prenatal and postnatal clinical implications and the approach to, and feasibility of, prenatal detection.

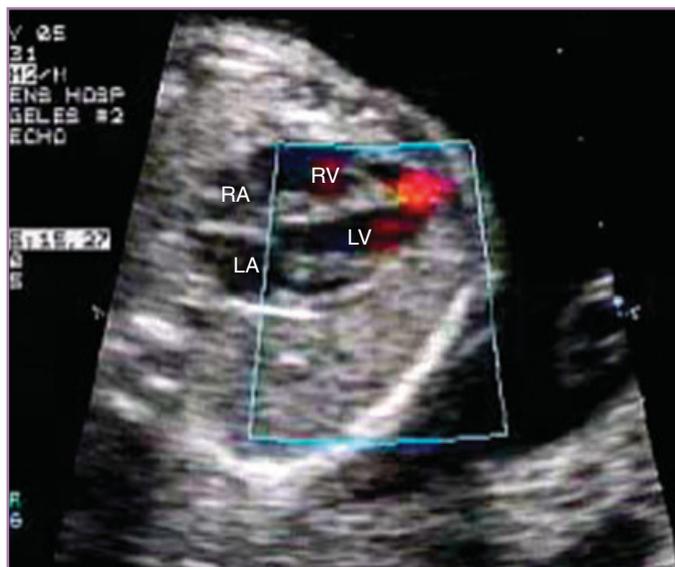

FIGURE 19-34 Fetal echocardiographic image of the four-chamber view. Color flow imaging demonstrates a small apical ventricular septal defect with left-to-right shunting. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

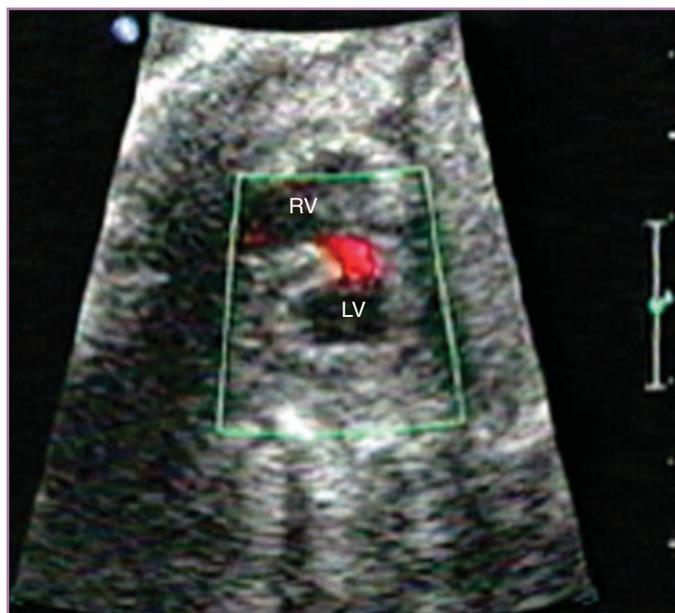

FIGURE 19-35 Fetal echocardiographic image of apical short-axis view. Color flow imaging demonstrates a moderate-sized mid-muscular ventricular septal defect with left-to-right shunting. LV, left ventricle; RV, right ventricle.

The most common forms of VSD (muscular and membranous) represent, fortuitously, the only types known to close spontaneously, either prenatally or postnatally.¹⁴ Muscular VSDs may be visualized on the 4CV (Fig. 19-34) or short-axis view (Fig. 19-35). By definition, muscular VSDs do not reside immediately beneath the mitral and tricuspid valves; such inlet VSDs occur in conjunction with abnormalities of the mitral and tricuspid valves and represent an AVC type of VSD. Inlet defects, although detectable on the 4CV, do not close spontane-

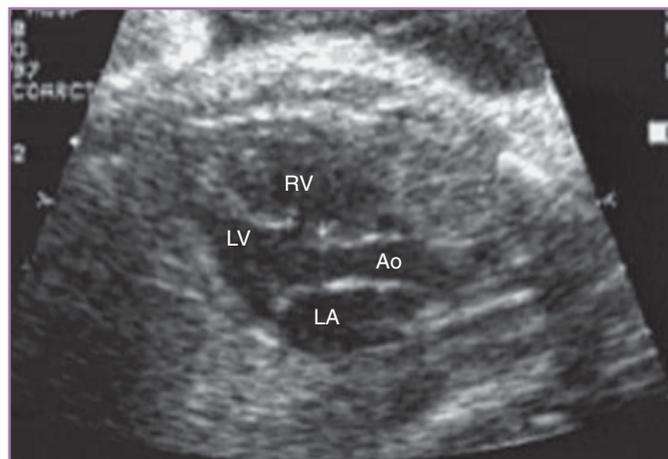

FIGURE 19-36 Fetal echocardiographic image of membranous ventricular septal defect seen in left ventricular long-axis view. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

ously and usually require surgery. Such inlet defects are discussed in detail in the next section.

Muscular VSDs may be demonstrated with 2D imaging if they are moderate or large, but small ones may be difficult to detect without color flow imaging. Color flow imaging helps confirm the diagnosis, but spectral Doppler evaluation should also be performed. Muscular VSDs, like membranous VSDs, usually shunt predominantly left-to-right prenatally (see Figs. 19-34 and 19-35); predominant right-to-left shunting should prompt further evaluation for right-sided obstructive lesions. Small or moderate muscular defects may close prenatally or within the first few years after delivery.

Large, muscular defects manifest in infancy with tachypnea and failure to thrive and may require surgical closure during the first year of life. Because muscular defects occur within a heavily trabeculated portion of the ventricular septum, effective surgical closure can be difficult to achieve. Alternative approaches include pulmonary artery banding, followed by removal of the band once the defect has decreased in size; or, rarely, such VSDs may be closed percutaneously with a device. The long-term prognosis is usually excellent unless delayed surgery has allowed the development of pulmonary vascular disease.

Membranous VSDs, like muscular VSDs, may close spontaneously. However, unlike muscular VSDs, they cannot be visualized on the 4CV. The membranous septum resides anteriorly, a small distance beneath the aortic valve. A left ventricular long-axis view of the LVOT represents the ideal approach for visualizing a membranous VSD (Fig. 19-36). Moreover, because false-positive dropout through the thin (i.e., membranous) septum occurs commonly when the ultrasound beam is oriented parallel with the septum, the diagnosis can best be confirmed with the ultrasound beam perpendicular to the ventricular septum. Small defects may be missed, although color flow imaging and spectral Doppler evaluation are helpful for both prenatal detection and confirmation. Because of the proximity of the membranous septum to the aortic valve, membranous VSDs may cause the gradual development of aortic regurgitation, with or without prolapse of one or more aortic cusps into the defect. Although most membranous VSDs close spontaneously, larger defects may require surgical closure within the first year in infants with failure to thrive or progressive aortic regurgitation. Long-term prognosis is usually excellent unless irreversible

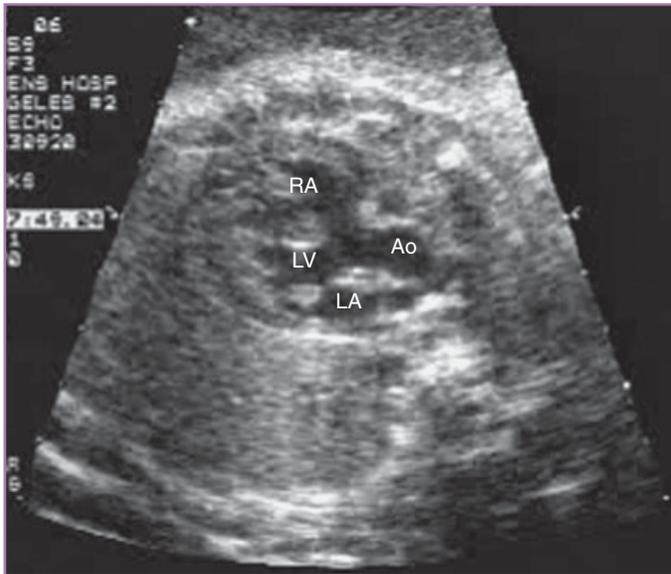

FIGURE 19-37 Fetal echocardiographic image of tetralogy of Fallot seen in left ventricular long-axis view. The aorta overrides the crest of the ventricular septum. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

damage to the aortic valve has occurred. In such cases, aortic valve repair or even replacement may be necessary.

Subarterial VSDs commonly occur in conjunction with other cardiac abnormalities. These defects never close spontaneously and cannot be seen on the 4CV; prenatal detection requires evaluation of the outflow tracts. Subarterial defects may be predominantly under the aortic valve (subaortic) or the pulmonary valve (subpulmonary). Unlike membranous VSDs, which occur close to, but not immediately beneath, the aortic valve, subarterial defects occur immediately beneath one or both semilunar valves. These defects almost invariably require surgical correction within the first year of life. The prognosis, although generally good, relates in part to associated cardiac abnormalities and to any residual aortic or pulmonary pathology.

Malalignment VSDs occur when the upper (conal/infundibular) portion of the ventricular septum separates from the rest of the septum and deviates either anteriorly into the RVOT or posteriorly into the LVOT. Malalignment VSDs secondary to anterior deviation of the conal septum generate RVOT obstruction (subvalvar and valvar pulmonary stenosis and pulmonary artery hypoplasia); TOF is the most common manifestation of such a defect (Figs. 19-37 and 19-38). In contrast, posterior malalignment of the conal septum generates a malalignment VSD in association with LVOT obstruction (e.g., aortic stenosis, bicommissural aortic valve, aortic arch hypoplasia, coarctation of the aorta) (Fig. 19-39). Like subarterial VSDs, malalignment VSDs may appear normal on 4CV, but both the VSD and its associated outflow tract abnormalities should be seen with outflow tract imaging. Management and prognosis depend on the type and severity of outflow tract obstruction. Severe malalignment in either direction may generate severe enough outflow tract obstruction to require maintenance of ductal patency (with prostaglandin) after delivery.

Atrioventricular Canal Defect

Normally, during embryonic development, the septum primum and the endocardial cushions fuse together. Abnormal development of

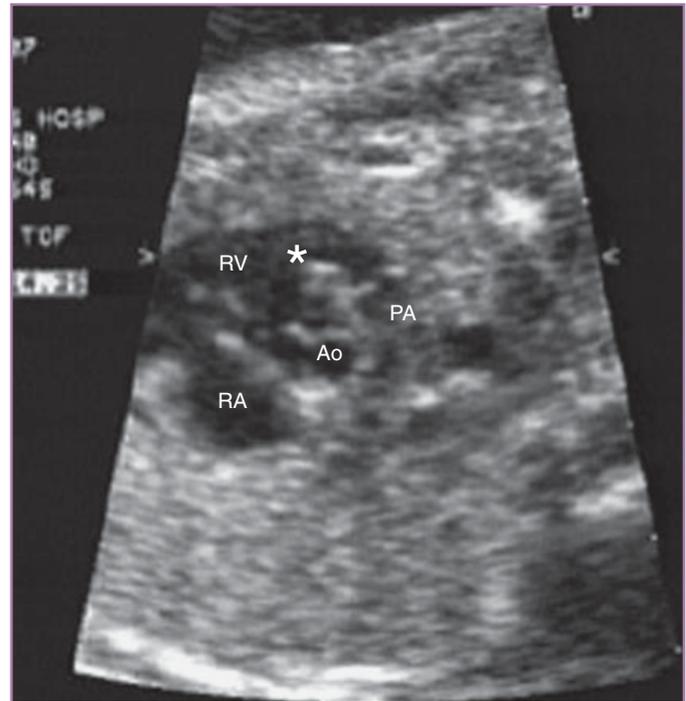

FIGURE 19-38 Fetal echocardiographic image of tetralogy of Fallot seen in apical short-axis view. The conal septum (*asterisk*) deviates anteriorly into the right ventricular outflow tract, causing subvalvar pulmonary stenosis, aortic override, and an anterior malalignment ventricular septal defect. Note that the pulmonary valve appears smaller than the aortic valve. Ao, aorta; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

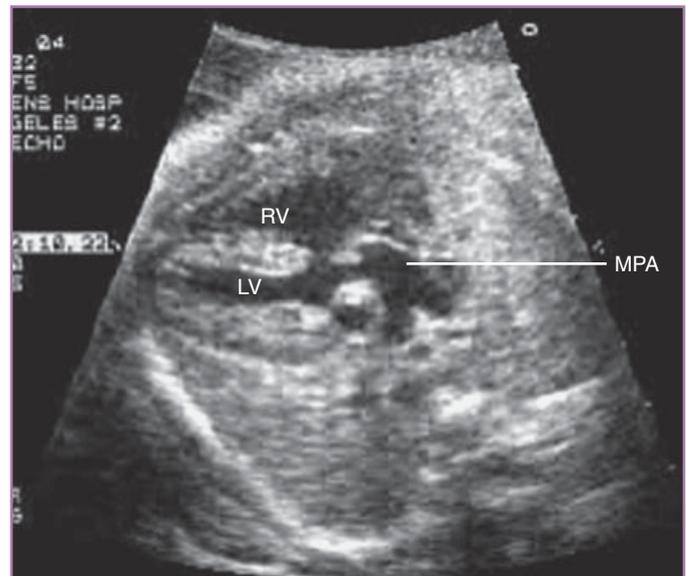

FIGURE 19-39 Fetal echocardiographic image of transposition with subvalvar and valvar pulmonary stenosis seen in left ventricular long-axis view. The conal septum deviates posteriorly into the left ventricular outflow tract, causing subvalvar pulmonary stenosis and a posterior malalignment ventricular septal defect. With normally related great arteries, posterior malalignment of the conal septum would cause aortic rather than pulmonary obstruction. LV, left ventricle; MPA, main pulmonary artery; RV, right ventricle.

these structures results in several forms of AVC defect, all of which should be detected with standard fetal screening ultrasound evaluations as well as with detailed fetal echocardiography. Moreover, all forms of AVC defects ultimately require surgical intervention, and most have relatively high associations with trisomy 21^{23,30} or other cardiac abnormalities.¹⁶² The prognosis is generally good but depends on the associated cardiac and extracardiac abnormalities,¹⁶³ as well as postoperative mitral, tricuspid, and ventricular function.

Partial Atrioventricular Canal Defect

In partial AVC defects, the septum primum fails to fuse with the endocardial cushions. As a result, the fetal heart develops an ostium primum ASD and, typically, a cleft in the mitral valve (with some degree of mitral regurgitation). In part because of this defect's close association with trisomy 21 or heterotaxy,^{23,30,162} great care should be taken not to miss a partial AVC defect on routine screening ultrasonography. Partial AVC defects may be readily detected in the 4CV by the conspicuous absence of the septum primum (the lowest, most inferior portion of the atrial septum). Moreover, the absence of an atrioventricular septum results in absence of the normal apical displacement of the septal leaflet of the tricuspid valve; instead, the septal leaflets of the mitral and tricuspid valves insert onto the ventricular septum at the same level. Care should be taken not to confuse this defect with a dilated coronary sinus (usually secondary to a persistent LSCV), which would be seen in a plane immediately posterior/inferior to the 4CV (see Figs. 19-11 and 19-14).¹⁰⁷ True AVC defects will be noted with anterior/superior angulation of the probe from the level of the coronary sinus into a true 4CV.

Partial AVC defects manifest clinically similar to secundum ASDs, usually with a heart murmur in an asymptomatic child between 2 months and 2 years of age. Many patients have trisomy 21³⁰ or other cardiac disease (heterotaxy).¹⁶² The cleft in the mitral valve typically does not generate signs or symptoms unless it is associated with more severe degrees of mitral regurgitation. The long-term prognosis after surgical closure during the first several years of life is usually excellent, unless significant mitral valve pathology persists.

Complete Atrioventricular Canal Defect

In complete AVC defects, the endocardial cushions fail to fuse, and the septum primum fails to fuse with the endocardial cushions. As a result, the fetal heart has not only an ostium primum ASD and cleft mitral valve but also a large inlet VSD (contiguous with the ostium primum ASD) and a single, common atrioventricular valve. This type of AVC defect should be readily detected with a routine 4CV (Figs. 19-40 and 19-41). Although isolated forms of complete AVC defects carry an exceptionally high association with trisomy 21,^{23,30} complete AVC defects in association with other cardiac abnormalities carry a high association with heterotaxy syndrome.^{162,163} Beyond the diagnosis of complete AVC defect, detailed fetal echocardiographic evaluation should include assessment of atrioventricular valvar regurgitation using color flow imaging and close attention to the relative development of both ventricles and possible outflow tract obstruction.

When complete AVC defects occur with well-balanced right and left ventricles (so-called balanced complete AVC), corrective surgery may be offered at 3 to 6 months of age. Such patients usually have an excellent long-term prognosis in the absence of severe residual atrioventricular valve regurgitation. On the other hand, the fetus with a hypoplastic right ventricle (left ventricle–dominant AVC) (Fig. 19-42) or a hypoplastic left ventricle (right ventricle–dominant AVC) is likely to require single-ventricle palliation, meaning three palliative surgical procedures within the first 2 to 3 years of life. Some of these patients

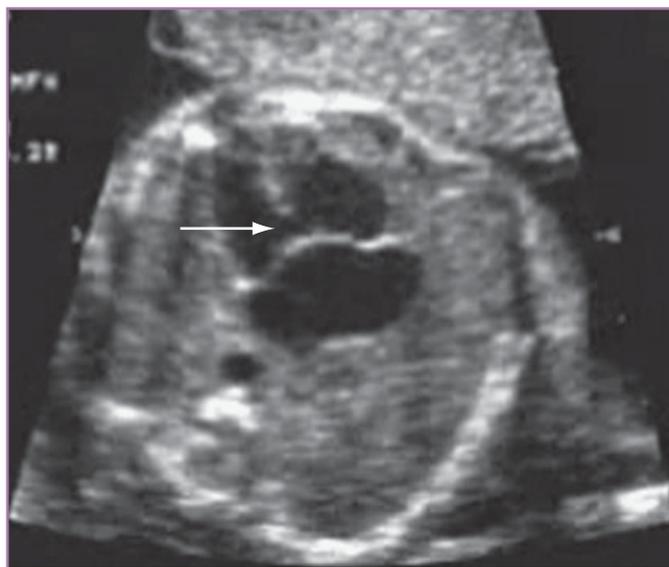

FIGURE 19-40 Fetal echocardiographic image of four-chamber view demonstrating a balanced complete atrioventricular canal defect. During systole, the common atrioventricular valve is closed, and the large atrial and ventricular (*arrow*) defects are readily apparent. Note the absence of the septum primum.

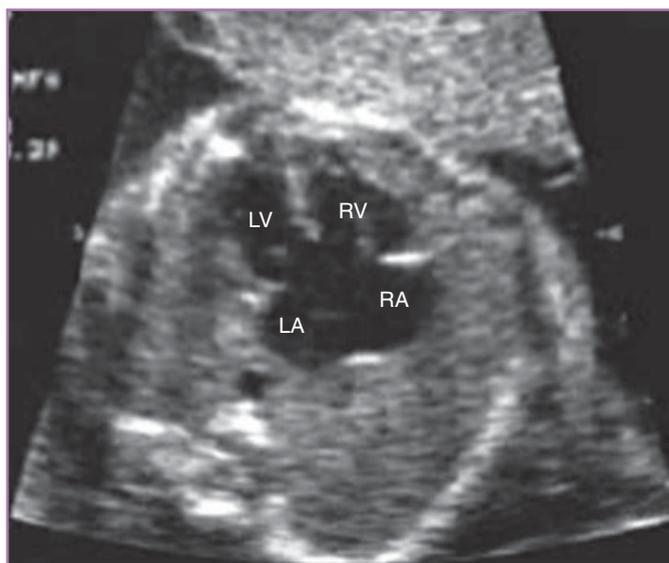

FIGURE 19-41 Fetal echocardiographic image of four-chamber view demonstrating a balanced complete atrioventricular canal defect. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

may undergo early pulmonary artery banding (during the first month after delivery), to provide a controlled source of pulmonary blood flow for the first 6 months and to avoid the development of pulmonary vascular disease. Because single-ventricle palliation involves rerouting of the systemic venous return through the lungs without the benefit of a subpulmonary ventricle, elevated pulmonary vascular resistance may be considered a relative contraindication (or at least a risk factor) for subsequent palliative procedures (i.e., Glenn and Fontan proce-

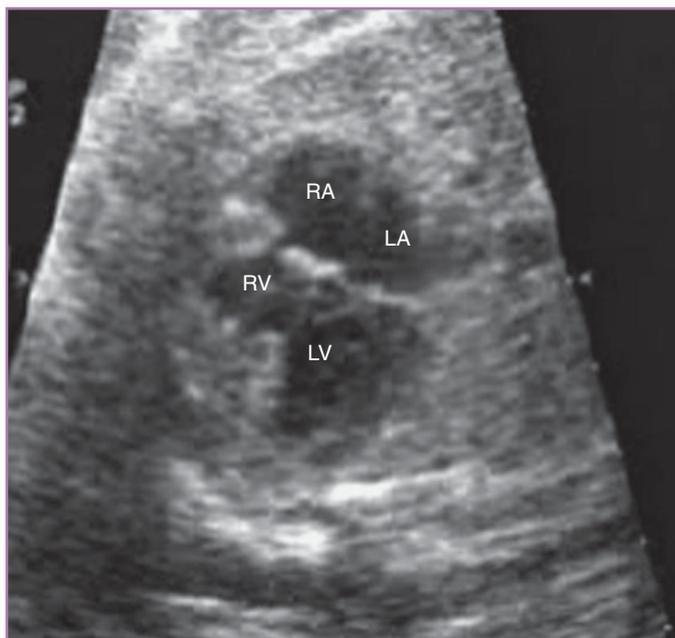

FIGURE 19-42 Fetal echocardiographic image of four-chamber view demonstrating an unbalanced, left ventricle-dominant atrioventricular canal. dures, which redirect, respectively, the superior vena cava or the IVC directly to the right pulmonary artery). In the best of cases, the patient with an unbalanced complete AVC defect faces a much more guarded, palliated long-term prognosis than the patient with a balanced complete AVC defect. Therefore, making such a distinction in a fetus is of great importance.

Transitional Atrioventricular Canal Defect

A transitional AVC defect should be recognized readily from the 4CV. Affected fetuses have an ostium primum defect and, with absence of the atrioventricular septum, the mitral and tricuspid valves insert onto the crest of the ventricular septum at the same level. The mitral valve is frequently cleft, with some degree of mitral regurgitation visualized with color flow imaging. In contrast to a complete AVC defect, transitional AVC defects may have two relatively well-formed mitral and tricuspid valves, and the inlet VSD is only small to moderate in size, largely occluded by mitral and tricuspid valve tissue. Transitional AVC defects, when balanced and not associated with other cardiac defects, typically require a single surgical procedure between 6 months and 5 years of age, and generally carry a good long-term prognosis.

Ebstein Anomaly of the Tricuspid Valve and Tricuspid Valve Dysplasia

Both fetal Ebstein anomaly of the tricuspid valve and tricuspid valve dysplasia carry a wide spectrum of potential outcomes, depending on severity.^{164,165} Fortunately, the more severe cases are those that should be most readily detected on a standard 4CV.

Tricuspid valve dysplasia refers to thickening and distortion of the tricuspid valve leaflets and supportive apparatus, with the primary pathophysiologic manifestation being tricuspid regurgitation. The more severe the tricuspid regurgitation, the more dilated the right

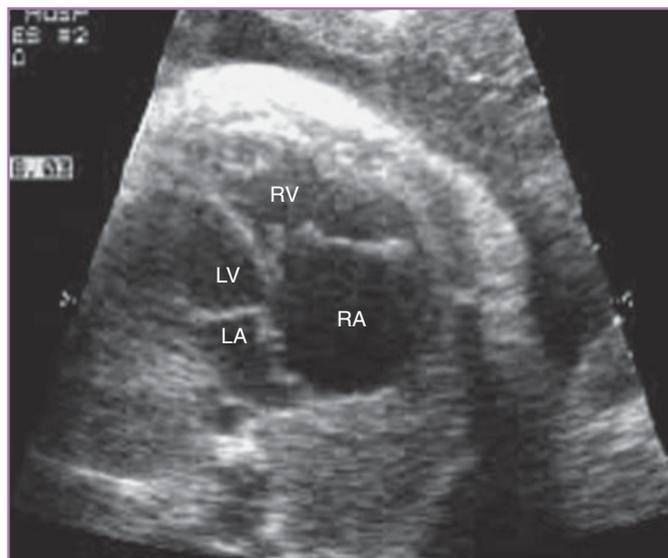

FIGURE 19-43 Fetal echocardiographic image of four-chamber view demonstrating tricuspid valve dysplasia. Note absence of the septal insertion site of the tricuspid valve. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

atrium and right ventricle, the more likely the development of pulmonary valve stenosis/atresia (related to diminished antegrade flow), and the more likely the development of hydrops or pulmonary hypoplasia or both (related to elevated right atrial pressure and right-sided heart enlargement).

Sharing similar pathophysiology, Ebstein anomaly of the tricuspid valve may be considered a subset of tricuspid valve dysplasia. In Ebstein anomaly, the dysplastic tricuspid valve is partially fused against the ventricular septum, causing the coaptation point to be apically displaced within the right ventricle. Both disorders carry an association with episodic SVT and Wolff-Parkinson-White (WPW) syndrome.

Both Ebstein anomaly and tricuspid valve dysplasia may be visualized on the 4CV, with enlargement of the right side of the heart (particularly the right atrium), dysplasia of the tricuspid valve (Fig. 19-43), and apical displacement of the tricuspid valve coaptation point in the case of Ebstein anomaly (Fig. 19-44). Color flow imaging is useful to demonstrate the degree of tricuspid regurgitation (Fig. 19-45), although such information should be suspected from the degree of right atrial enlargement. In cases of severe tricuspid regurgitation, Ebstein anomaly and tricuspid valve dysplasia commonly have some degree of pulmonary valve stenosis, or even atresia, along with hypoplasia of the main and branch pulmonary arteries; such findings should be evident on evaluation of the outflow tracts.

Although Ebstein anomaly and tricuspid valve dysplasia are occasionally associated with fetal exposure to maternal lithium, most cases occur in pregnancies not identified as high risk. The risk for associated aneuploidy is probably mildly increased over that in the general fetal population. Ebstein anomaly represents a common finding in the rare setting of congenitally corrected transposition (discussed later). However, most of the time, the overriding determinants of short- and long-term survival are the degree of fetal heart failure or hydrops, the degree of pulmonary hypoplasia, and the degree of left ventricular dysfunction. Progressive fetal CHF (related to tricuspid regurgitation, SVT, and/or ventricular dysfunction) puts the fetus at risk for hydrops and fetal demise. Newborns with a history of hydrops prenatally may present with diffuse edema or anasarca, and they face significant

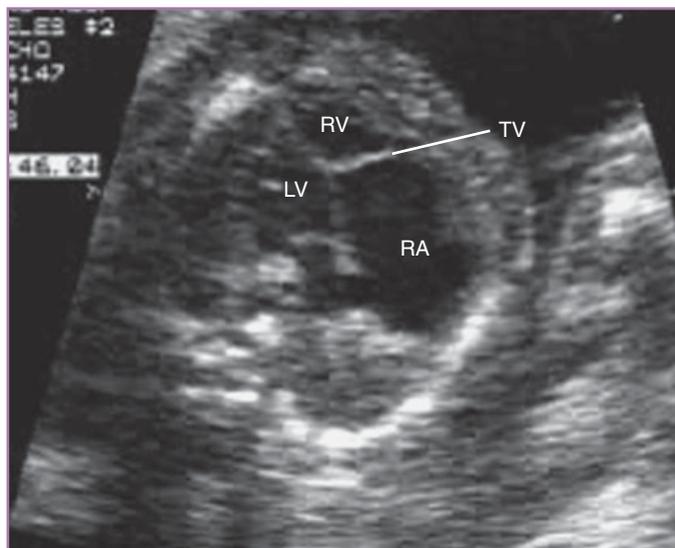

FIGURE 19-44 Fetal echocardiographic image of four-chamber view demonstrating Ebstein anomaly of the tricuspid valve. Note apical displacement of the septal insertion site of the tricuspid valve. Compare with Figure 19-43. LV, left ventricle; RA, right atrium; RV, right ventricle; TV, tricuspid valve.

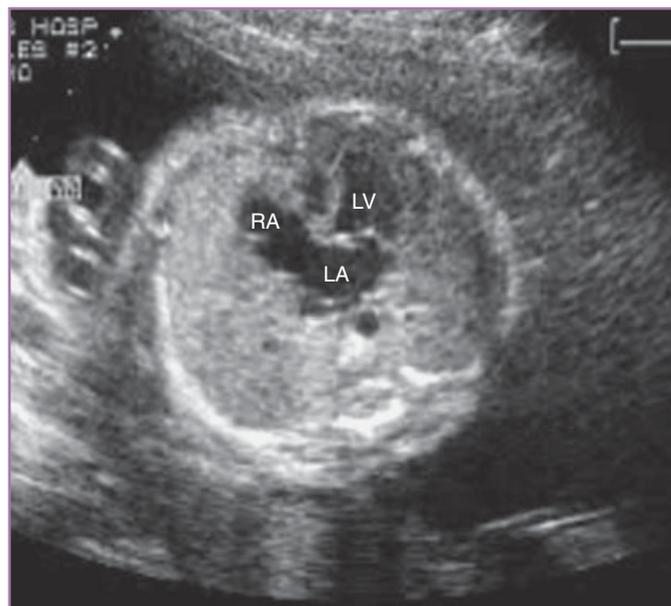

FIGURE 19-46 Fetal echocardiographic image of four-chamber view demonstrating tricuspid atresia. Note hypoplastic right ventricle, atretic and membranous tricuspid valve, and bowing of the atrial septum laterally into the left atrium. LA, left atrium; LV, left ventricle; RA, right atrium.

neonatal morbidity and mortality. Pulmonary hypoplasia, related to marked cardiomegaly, particularly early in gestation, represents the other primary determinant of neonatal survival and may not always be accurately predicted with prenatal assessments. Fetuses with moderate or severe forms of Ebstein anomaly or tricuspid valve dysplasia should be delivered at centers that can provide optimal medical and surgical care for high-risk neonates.

Tricuspid Atresia

Tricuspid atresia represents the most basic form of single-ventricle and generally carries the best long-term prognosis among single-ventricle

disorders. In tricuspid atresia, the tricuspid valve either is not formed or otherwise simply does not open. As a result, all flow entering the right atrium must cross the foramen ovale into the left atrium and, from there, into the left ventricle. From the left ventricle, some portion of the blood exits via the aortic valve, and some passes through a VSD (usually present with tricuspid atresia) and into the pulmonary artery. Because flow into the right ventricle and pulmonary artery must come via the VSD, the right ventricle and pulmonary artery generally appear hypoplastic, and the pulmonary valve is usually stenotic, if not atretic. However, when tricuspid atresia occurs in conjunction with transposition of the great arteries (TGA), the pulmonary valve and pulmonary artery (in this case arising from the left ventricle) are usually well formed, whereas the aortic valve may be stenotic, with a hypoplastic aortic arch and possible coarctation.

In the fetus, tricuspid atresia manifests with an abnormal 4CV (Fig. 19-46), including an abnormal (or absent) tricuspid valve and hypoplastic right ventricle.¹⁶⁶ Rarely, color flow imaging demonstrates the foramen ovale to be restrictive to flow. The outflow tracts also demand close attention, given the close association of tricuspid atresia with TGA or with underdevelopment of the great artery arising from the right ventricle, or both.

After delivery, most affected babies appear cyanotic, but ductal dependency is determined by the amount of pulmonary blood flow (in normally related great arteries) or by the presence of aortic stenosis, coarctation, or inadequate mixing (in TGA). Infants with tricuspid atresia ultimately require palliation with a Glenn procedure (anastomosis of the cephalic end of the superior vena cava to the right pulmonary artery, usually at about 6 months of age) followed by a Fontan procedure (anastomosis of the IVC directly to the right pulmonary artery with interposition graft, usually at 2 to 3 years of age). Whether a neonatal shunt or arch repair is needed depends on the details of the anatomy and pathophysiology. Long-term prognosis for tricuspid atresia tends to be better than for other forms of single ventricle, but

the child will still have increasing risks for heart failure and arrhythmias and possible need for cardiac transplantation in later decades.

Pulmonary Atresia with Intact Ventricular Septum

In pulmonary atresia with intact ventricular septum, the RVOT ends blindly (pulmonary atresia). As a result, during fetal life, the right side of the heart must direct its share of cardiac output entirely through the foramen ovale. In the presence of a competent tricuspid valve (which is typical), the right ventricle hypertrophies in response to the high pressure generated by absence of egress. This lesion may result, in some cases, from prenatal progression of pulmonary stenosis to pulmonary atresia.¹⁶ The right ventricle, along with its tricuspid valve, typically develops some degree of hypoplasia. Those fetuses with markedly elevated right ventricular pressure may develop sinusoidal connections between the right ventricular cavity and the coronary arteries. Such sinusoids may occur in association with significant coronary artery stenoses, placing these patients at risk for acute myocardial infarction.

Pulmonary atresia with intact ventricular septum usually manifests in fetal life with an abnormal 4CV (Figs. 19-47 and 19-48), including an abnormal-appearing tricuspid valve and a hypoplastic, hypertrophied, poorly functioning right ventricle. Occasionally, the degree of tricuspid valve and right ventricular hypoplasia is mild enough to be missed on a cursory 4CV; other cases may mimic tricuspid atresia (compare Figs. 19-46 and 19-47). Color flow imaging should be used to evaluate the tricuspid valve for evidence of tricuspid regurgitation.

Color flow imaging may also detect significant sinusoids within the ventricular septum or right ventricular free wall or both. Careful evaluation of the 4CV in real time should almost always detect some abnormality in size, structure, or function of the tricuspid valve or right ventricle. Imaging of the outflow tracts should invariably demonstrate the pulmonary valve to be atretic, with no prograde flow from right ventricle to pulmonary artery. Detailed cardiac imaging should include evaluation of the continuity and size of the main and branch pulmonary arteries, supplied retrograde through the ductus arteriosus.

After delivery, babies with this lesion require prostaglandin to maintain patency of the ductus arteriosus for pulmonary blood flow. Neonatal surgery is always necessary; it usually includes placement of a shunt, and sometimes reconstruction of the RVOT. Long-term prognosis varies from an excellent two-ventricle repair to single-ventricle palliation, and those patients with coronary artery abnormalities face additional short- and long-term risks of myocardial infarction. Some fetal echocardiographic parameters, including tricuspid valve size and the presence of tricuspid regurgitation, can help predict outcome.^{167,168}

Hypoplastic Left Heart Syndrome

One of the most common and most feared cardiac diagnoses, HLHS represents a heterogeneous constellation of various forms of CHD, the result of which in the newborn infant is a left heart with a surgically resistant inability to sustain systemic cardiac output. Most cases of HLHS carry an increased risk for congenital or acquired central nervous system abnormalities,^{41,169} as well as some increased risk for

FIGURE 19-47 Fetal echocardiographic image of four-chamber view demonstrating pulmonary atresia with intact ventricular septum. Note similarity to tricuspid atresia (Figure 19-46), but with a more normal appearance to the tricuspid valve. LA, left atrium; LV, left ventricle; RA, right atrium.

Color flow imaging demonstrates absence of prograde flow across the tricuspid valve during diastole and right-to-left flow across the atrial septum. LA, left atrium; LV, left ventricle; RA, right atrium.

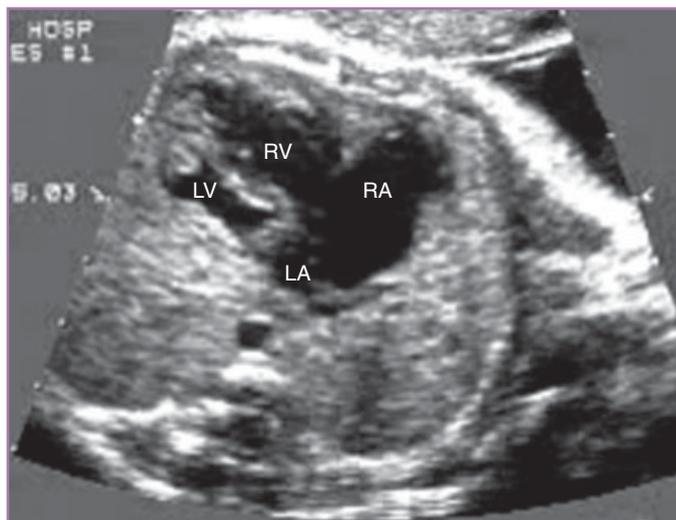

FIGURE 19-49 Fetal echocardiographic image of four-chamber view demonstrating hypoplastic left heart syndrome with mitral atresia and ventricular septal defect. The ventricular septal defect, although not visualized, may be inferred from the presence of a moderately well-formed left ventricle with mitral atresia. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

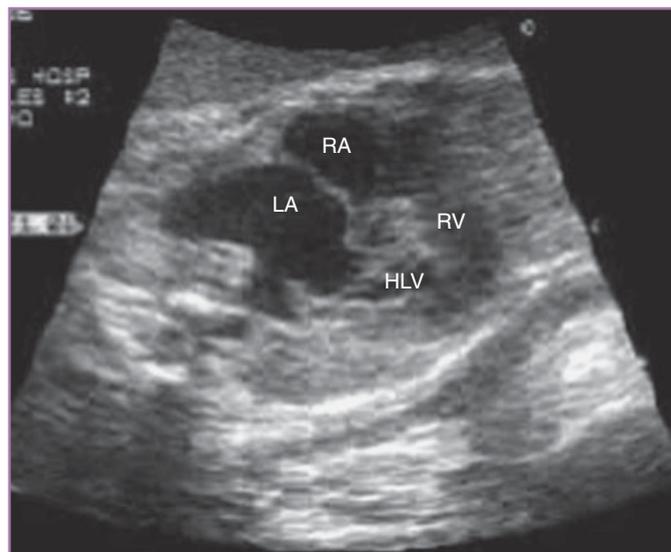

FIGURE 19-50 Fetal echocardiographic image of four-chamber view demonstrating hypoplastic left heart syndrome with restrictive foramen ovale. The left atrium and pulmonary veins appear dilated in response to left atrial hypertension (lack of egress of pulmonary venous return from left atrium). HLV, hypoplastic left ventricle; LA, left atrium; RA, right atrium; RV, right ventricle.

aneuploidy. Some forms of multiple left-sided obstructive lesions (e.g., Shone syndrome) may be corrected with surgical procedures addressing the left ventricular inflow tract, outflow tract, and aortic arch; these cases do not qualify as HLHS. Although this distinction is of tremendous clinical importance, it sometimes is subtle, even postnatally.

This section discusses the most common and classic form of HLHS, mitral and aortic atresia, with the caution that other forms of HLHS may differ in their prenatal appearance and postnatal course. Mitral or aortic stenosis, for example, may manifest with a relatively well-formed left ventricle at mid-gestation but with HLHS at term.^{16,82,170} In fetuses with mitral and aortic atresia, there is a markedly abnormal 4CV at mid-gestation, with no inflow into the left ventricle (effectively no mitral valve) and a severely hypoplastic left ventricle (Fig. 19-49; see Fig. 19-24). The foramen ovale needs close prenatal evaluation with 2D and color flow imaging, because restriction to flow (left-to-right) may lead to pulmonary venous congestion (Fig. 19-50) and irreversible pulmonary vascular disease.¹⁷¹ Such restriction to flow occasionally may not develop until late in the third trimester. Some fetuses with HLHS and a restrictive foramen ovale may be candidates for percutaneous enlargement of the foramen ovale during the second trimester, with the hope of avoiding the development of pulmonary vascular disease and improving long-term survival.¹⁷¹ The aortic arch fills retrograde from the ductus arteriosus (Fig. 19-51), and may be visualized with both 2D and color flow imaging. Tricuspid valve and right ventricular structure and function also require close evaluation, using both 2D and color flow imaging to assess for tricuspid regurgitation and right ventricular dysfunction.

The fetus with HLHS should be delivered at a tertiary care center experienced with complex CHD in newborns. All newborns with HLHS, by definition, are ductal dependent for systemic blood flow, so prostaglandin infusion should be initiated. Supplemental oxygen generally should be avoided, because in these patients it usually worsens pulmonary overcirculation and systemic hypoperfusion. The newborn with HLHS and a restrictive foramen ovale may require emergent atrial

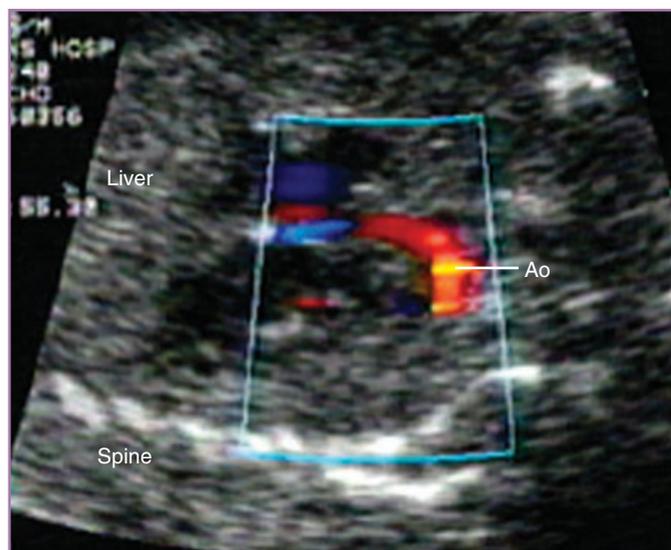

FIGURE 19-51 Fetal echocardiographic sagittal image of aortic arch in fetus with hypoplastic left heart syndrome. Color flow imaging demonstrates pulsatile, retrograde flow into the transverse aortic arch. Ao, aortic arch.

septostomy/septectomy within the first several hours after delivery. In general, infants with HLHS require the first of three palliative surgical procedures (the Norwood operation) within the first week after delivery, followed by a Glenn procedure at approximately 6 months and a Fontan procedure at 2 to 3 years. Some patients undergo cardiac transplantation,¹⁷² and others receive comfort care only.^{172,173} With surgery, the current long-term prognosis begins with a 5-year survival rate of 75% to 80% at the best and largest centers. Although many patients do extremely well early on, long-term data are lacking because the surgical approach is so new.¹⁷²⁻¹⁷⁴ Many survivors have some degree of

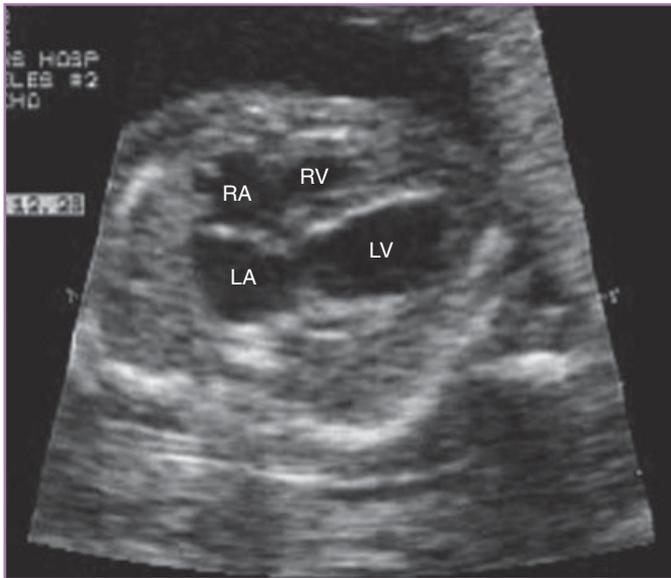

FIGURE 19-52 Fetal echocardiographic image of four-chamber view demonstrating a dilated left ventricle with endocardial fibroelastosis in a fetus with severe aortic stenosis. Note the presence of left-sided heart disproportion. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

neurodevelopmental delay.^{41,169} Long-term survivors with progressive right-sided heart failure may require cardiac transplantation during adulthood.

Valvar Aortic Stenosis

Valvar aortic stenosis, usually secondary to a thickened, bicommissural aortic valve, represents one of the most common lesions known to have the potential to evolve dramatically during the second and third trimesters.¹⁶ Severe cases of valvar aortic stenosis, particularly if present by 18 to 20 weeks' gestation, may adversely affect the prenatal development of the left ventricle, potentially generating a form of dilated cardiomyopathy that then evolves into HLHS.^{170,175} All degrees of valvar aortic stenosis may occur in conjunction with coarctation of the aorta. From a flow-related explanation of CHD, either lesion may actually cause the other.

Mild to moderate valvar aortic stenosis may be detected prenatally by visualization of a thickened, usually small aortic valve on imaging of the LVOT. The 4CV view typically appears normal. Spectral and color flow Doppler imaging may demonstrate flow acceleration with an increased velocity in the ascending aorta; rarely, this lesion may also have some degree of aortic regurgitation.

Severe forms of valvar aortic stenosis may manifest during the second trimester with abnormalities of both the 4CV and the outflow tracts. The 4CV may include a dilated, poorly functioning left ventricle (Fig. 19-52); in some cases, diminished diastolic excursion of the mitral valve, mitral valve regurgitation, and, often, endocardial fibroelastosis (brightened left ventricular endocardium) are present. The foramen ovale may shunt predominantly left-to-right (Fig. 19-53). The outflow tract views may demonstrate a small, thickened aortic valve with diminished excursion, and color flow imaging of the aortic arch may demonstrate retrograde (see Fig. 19-51) or bidirectional flow in the transverse arch. Some cases of severe valvar aortic stenosis may evolve into HLHS by term, whereas others manifest in the newborn period

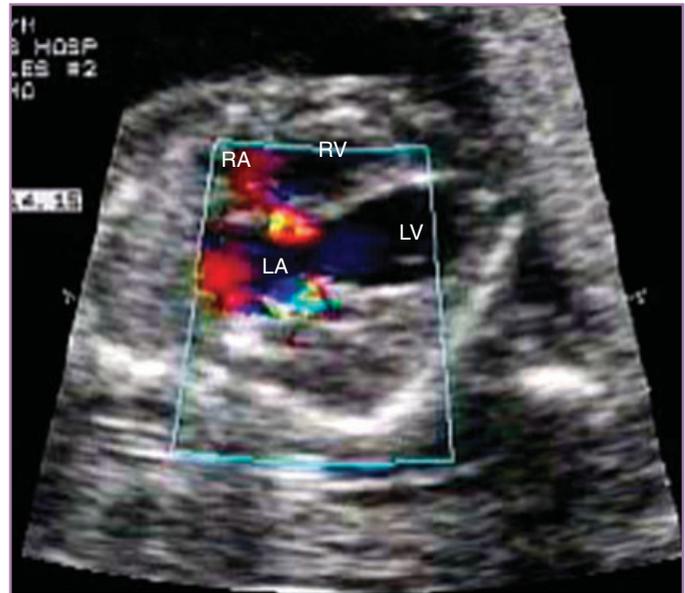

FIGURE 19-53 Fetal echocardiographic image of four-chamber view demonstrating a dilated left ventricle with endocardial fibroelastosis in a fetus with severe aortic stenosis. Color flow imaging demonstrates mitral regurgitation and left-to-right flow across the foramen ovale. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

with valvar aortic stenosis and a well-formed but poorly functioning left ventricle.^{170,175}

In a subset of those cases judged most likely to evolve into HLHS, the fetus may be a candidate for second-trimester dilation of the aortic valve.^{170,175} Such fetal intracardiac interventions may prevent the development of some cases of HLHS and allow a neonatal two-ventricle repair rather than single-ventricle palliation. Some fetuses may also benefit from the procedure's ability to establish prograde, pulsatile flow to the brain. However, the procedure carries risks for both mother and fetus. Although the safety of the procedure and the ability to predict which cases will evolve into HLHS both improve with advancing gestation, the likelihood of procedural efficacy decreases with advancing gestational age. The procedure, and the data to support it, both remain inadequately developed.

After delivery, mild to moderate valvar aortic stenosis usually requires observation over months to years; transcatheter or surgical intervention is postponed until the disease has significantly progressed. In contrast, severe valvar aortic stenosis typically manifests immediately after delivery with poor left ventricular systolic and diastolic function. These newborns require prostaglandin to maintain ductal patency for systemic blood flow. Affected infants undergo, soon after birth, either transcatheter balloon dilation of the aortic valve, surgical aortic valvuloplasty, or the Ross procedure (replacement of the patient's own aortic valve with the patient's own pulmonary valve and placement of a pulmonary homograft into the patient's RVOT). Most cases of severe valvar aortic stenosis ultimately require valve replacement, but the prognosis remains quite good as long as left ventricular function recovers after the initial intervention.

Coarctation of the Aorta

Coarctation of the aorta represents not only one of the most common forms of ductal-dependent CHD but also one of the most difficult

FIGURE 19-54 Fetal echocardiographic image of left ventricular long-axis view demonstrating right heart disproportion suggestive of coarctation. The presence of a bicommissural aortic valve, possibly thickened, would help to support the diagnosis of coarctation. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

cardiac lesions to detect prenatally.^{176,177} Normally, the fetal left ventricle supplies the coronary and cerebral circulations, with only a relatively small component of left ventricular cardiac output crossing the aortic isthmus to supply the lower body. The fetal right ventricle, in contrast, normally supplies most of the lower body of the fetus, with most of the right ventricular output passing right-to-left through the ductus arteriosus and joining the descending aorta just distal to the aortic isthmus. Coarctation of the aorta represents a narrowing of the aortic isthmus, but it frequently may also involve hypoplasia of the transverse and distal aortic arches. Prenatally, coarctation may be difficult to detect as long as the ductus arteriosus remains widely patent. With closure of the ductus arteriosus postnatally, ductal tissue extending circumferentially around the descending aorta and isthmus constricts, allowing a previously unrecognized coarctation to become manifest.

As a result, the prenatal detection and diagnosis of coarctation remains challenging, particularly with relatively discrete forms of the disease.¹⁷⁶⁻¹⁷⁸ Mild and moderate forms of coarctation may appear normal prenatally. More severe forms of coarctation, however, commonly result in abnormalities of the 4CV and outflow tracts (Fig. 19-54). The right atrium and ventricle commonly appear larger than expected (right heart disproportion), probably related to redistribution of flow to the right side of the heart, and color flow imaging may detect some degree of tricuspid regurgitation. A persistent LSVC draining to the coronary sinus represents a commonly associated finding¹⁰⁸ and should increase the suspicion for coarctation of the aorta. Evaluation of the outflow tracts should again demonstrate right heart disproportion. Because a bicommissural aortic valve is another commonly

associated finding, the aortic valve may appear mildly thickened or eccentric. The aortic valve annulus, aortic root, transverse aortic arch, and aortic isthmus may all appear small. Quantitative measurements of the aortic annulus and arch may be useful.^{82,98,178} Finally, in the presence of coarctation, the third main branch of the aortic arch, the left subclavian artery, may have its origin somewhat distally displaced, closer to the isthmus than normal.

More severe forms of coarctation of the aorta represent ductal-dependent lesions requiring initiation of prostaglandin after delivery to maintain systemic cardiac output. These patients require neonatal repair, via either transcatheter dilation or surgical correction. Prenatal detection may prevent the inadvertent discharge to home of a newborn with severe coarctation whose ductus arteriosus has not yet closed.³⁹ Unless end-organ damage occurs at home before the diagnosis is made, the prognosis is generally excellent for isolated coarctation of the aorta. However, up to 50% of cases with neonatal repair require reintervention for recoarctation, and many patients, even with successful repair, have lifelong systemic hypertension.

Tetralogy of Fallot

TOF represents both the most common form of cyanotic CHD and the most common major CHD associated with a normal 4CV. Although most cases of TOF occur in isolation, TOF is also one of the most common forms of CHD associated with maternal diabetes, trisomy 21, DiGeorge syndrome,¹⁷⁹ omphalocele, and pentalogy of Cantrell, among other conditions.²³ TOF comprises a series of four cardiac findings, all believed to be related to anterior, superior, and rightward deviation of the conal septum into the RVOT. As a result of this deviation of the conal septum, TOF manifests with pulmonary stenosis, malalignment VSD, overriding aorta, and, postnatally, right ventricular hypertrophy secondary to persistent exposure of the right ventricle to systemic pressure. The detection, management, and prognosis of TOF depend on details of the anatomy and physiology. The following categories of TOF are discussed in this section: TOF with pulmonary stenosis, TOF with pulmonary atresia (TOF/PA), and TOF with absent pulmonary valve (TOF/APV).

Tetralogy of Fallot with Pulmonary Stenosis

In TOF with pulmonary stenosis, the degree of RVOT obstruction and the degree of hypoplasia of the main and branch pulmonary arteries determine the extent of cyanosis after delivery, the timing for initial surgical intervention, and, to some degree, the prognosis. The pulmonary stenosis in a fetus with TOF usually progresses prenatally, although at a variable rate.^{16,81}

In a fetus with TOF with pulmonary stenosis, the 4CV is usually normal. Occasionally, the right ventricle appears slightly dilated or hypertrophied. Evaluation of the outflow tracts demonstrates a large malalignment VSD beneath the aortic valve and an overriding aorta (Fig. 19-55; see Figs. 19-37 and 19-38).^{180,181} The pulmonary valve appears small and thickened (see Fig. 19-38) in all but the mildest cases, and the main and branch pulmonary arteries typically appear somewhat hypoplastic.

Patients with TOF with pulmonary stenosis may or may not require any neonatal intervention. After postnatal confirmation of the diagnosis, those with mild pulmonary stenosis may be discharged home without neonatal surgery or medical treatment, with definitive repair planned for sometime during the first year of life. Those with more severe pulmonary stenosis will require earlier surgical intervention, either primary intracardiac repair (reconstruction of the RVOT and closure of the VSD) or early placement of an aortopulmonary shunt

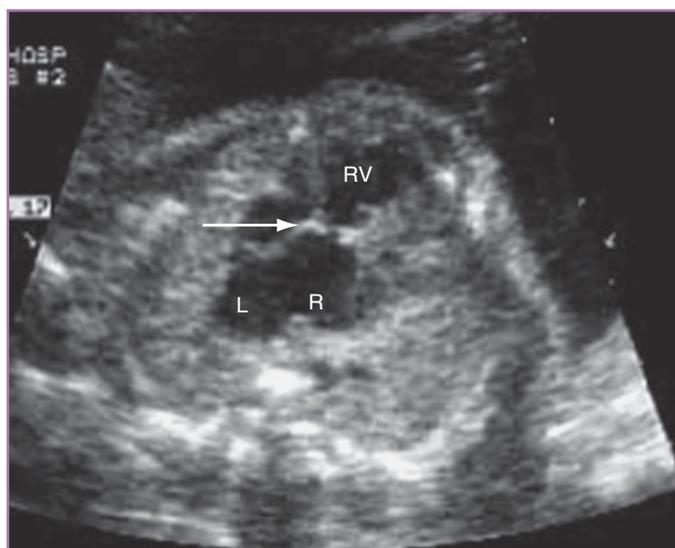

FIGURE 19-57 Fetal echocardiographic image of tetralogy of Fallot with absent pulmonary valve. Primitive tissue at the level of the pulmonary annulus (*arrow*) allows for both pulmonary stenosis and pulmonary regurgitation, which in turn leads to aneurysmal dilation of the branch pulmonary arteries and dilation of the right ventricle. L, left pulmonary artery; R, right pulmonary artery; RV, right ventricle.

generally has little benefit during the neonatal period. Those infants without respiratory compromise need detailed echocardiographic and clinical evaluation to determine the appropriate timing for surgical intervention.

Double-outlet Right Ventricle

DORV represents a heterogeneous group of congenital heart defects that have in common the origin of both great arteries from the right ventricle. Technically, DORV also implies mitral-aortic discontinuity, with conal tissue beneath both great arteries. Because of varying size and location of the VSD, as well as variable degrees of pulmonary stenosis, infants with DORV may present with the pathophysiology of TOF, TGA, VSD, or single ventricle. DORV also commonly occurs in conjunction with other structural defects.¹⁸⁵ Neonatal management and prognosis vary accordingly.

Although some cases of DORV exhibit a large VSD or ventricular asymmetry on the 4CV, virtually all fetuses with DORV have abnormalities of the outflow tracts.¹⁸⁰ The left ventricular long-axis view does not demonstrate the aorta arising from the left ventricle. Instead, the aorta is seen to arise entirely or in part from the right ventricle. The pulmonary artery similarly arises entirely or in part from the right ventricle. If either great artery arises partially from the left and partially from the right ventricle, a VSD will be seen immediately beneath the straddling great artery. In addition, in DORV, the relative spatial relationship between the aortic and pulmonary valves may vary considerably. The great arteries in DORV commonly, but not always, lack the normal crossing seen in hearts with normally related great arteries. Finally, DORV typically manifests with pulmonary stenosis, and rarely with aortic stenosis. As with other cardiac lesions, pulmonary stenosis commonly coexists with pulmonary artery hypoplasia, and aortic stenosis commonly coexists with aortic arch hypoplasia and coarctation of the aorta.

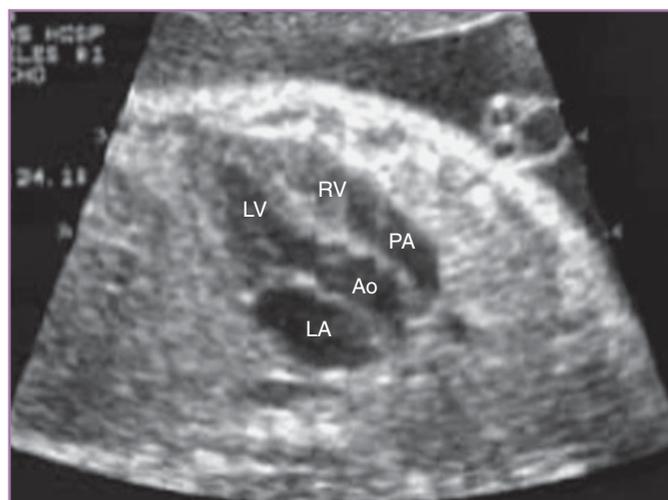

FIGURE 19-58 Fetal echocardiographic image of transposition of the great arteries. Note the absence of crossing of the great arteries. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

The approach to management of DORV in the neonate requires detailed clinical and echocardiographic evaluation after delivery, because details of the anatomy and pathophysiology dictate the medical and surgical approach. Prognosis varies from that of mild TOF (excellent) to that of HLHS with hypoplastic pulmonary arteries (very poor).¹⁸⁰

Transposition of the Great Arteries

In TGA, the aorta arises from the right ventricle, and the pulmonary artery arises from the left ventricle. Management and prognosis vary widely, depending on details of the anatomy and pathophysiology. Two major types of TGA have been described: dextro- or D-TGA and levo- or L-TGA. These are discussed separately.

D-TGA

Generally, D-TGA refers to TGA in which the visceral situs is normal (stomach on the left and liver on the right) and the ventricular looping is normal (D-looped). In D-TGA, the aortic valve is typically anterior and rightward of the pulmonary valve. As a result, systemic venous return passes from right atrium to right ventricle to aorta, and pulmonary venous return passes from left atrium to left ventricle to pulmonary artery. The patient with D-TGA may or may not have a VSD, other cardiac abnormalities, or heterotaxy.^{110,157}

The fetus with isolated D-TGA usually has an entirely normal 4CV but markedly abnormal views of the outflow tracts.¹⁸⁰ Any restriction to flow at the level of the foramen ovale should be noted with spectral and color flow Doppler evaluations,^{18,186} because newborns with restricted interatrial communications may require emergent balloon atrial septostomies, something not available at most hospitals. Unlike normally related great arteries, the great arteries in D-TGA do not cross each other (Fig. 19-58; see Fig. 19-39). Instead, the pulmonary artery arises from the left ventricle and heads posteriorly, and the aorta arises from the right ventricle and heads superiorly to give off the head and neck vessels before joining the descending aorta at the isthmus. In addition, in D-TGA, the pulmonary valve and main pulmonary artery (both arising from the left ventricle) should appear slightly larger than

the aortic valve and aortic root (both arising from the right ventricle). The ductus arteriosus should be evaluated with 2D imaging and color/spectral Doppler for evidence of ductal constriction.^{18,186}

The newborn with D-TGA usually is dependent on the ductus arteriosus for adequate oxygenation. In addition, unless a large VSD is present, oxygenation relies on a large atrial communication. As a result, patients with D-TGA usually require prostaglandin infusion and may require balloon atrial septostomy relatively emergently after delivery. Subsequently, patients with straightforward D-TGA usually undergo the arterial switch operation within the first 1 to 2 weeks after delivery. The prognosis can be excellent but depends largely on associated cardiac (see Fig. 19-39) and extracardiac abnormalities.¹⁸⁰

L-TGA

The term L-TGA describes the heart with normal visceral situs, L-looped ventricles, and TGA. Usually, in L-TGA, the aortic valve sits anterior and leftward of the pulmonary valve. In L-TGA, the systemic venous return passes from right atrium to left ventricle to pulmonary artery, and the pulmonary venous return passes from left atrium to right ventricle to aorta. For this reason, L-TGA has been described as “congenitally corrected transposition.” In many cases, however, L-TGA occurs in conjunction with a VSD, Ebstein anomaly of the left-sided tricuspid valve, heart block, pulmonary stenosis/atresia, or some combination of these. Such associated abnormalities affect the prenatal and postnatal presentation, management, and prognosis.

Typically, L-TGA manifests in the fetus with both an abnormal 4CV and abnormal outflow tracts.^{187,188} L-looped ventricles are present on the 4CV, with a left ventricle anterior and rightward of a posterior and leftward right ventricle (Fig. 19-59). The right ventricle can be distinguished from the left ventricle by the presence of coarse trabeculations

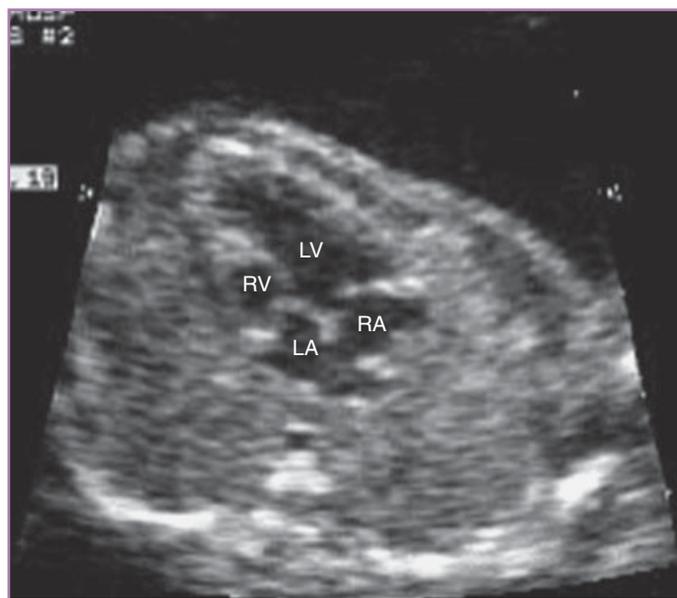

FIGURE 19-59 Fetal echocardiographic image of the four-chamber view demonstrating congenitally corrected transposition of the great arteries. Note the presence of a smooth-walled left ventricle anteriorly and rightward and a more trabeculated right ventricle posteriorly and leftward. The tricuspid valve, associated with the right ventricle, inserts more apically onto the ventricular septum than does the right-sided mitral valve. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

and moderator band, and by a tricuspid valve that inserts onto the ventricular septum slightly more apically than the left ventricle's mitral valve. In addition, those fetuses with associated Ebstein anomaly of the tricuspid valve, which is always associated with the right ventricle, have that lesion's characteristic findings (but with left atrial rather than right atrial dilation). Imaging of the outflow tracts demonstrates absence of crossing of one outflow over the other. The aortic valve, arising anterior and leftward of the pulmonary valve, gives rise to the aorta, which heads superiorly. In contrast, the pulmonary valve, arising posterior and rightward of the aortic valve, gives rise to the pulmonary artery, which heads posteriorly. Pulmonary stenosis or atresia is detectable with 2D and color flow imaging and may affect the development of the main and branch pulmonary arteries. The presence of a VSD may be seen on either the 4CV or outflow tract views, depending on the size and location of the VSD: The more anterior the VSD, the more likely it is to be seen with imaging of the outflow tracts, and the less likely to be seen on the 4CV. Finally, heart block may develop at any time prenatally or after birth and may be documented with 2D imaging, spectral Doppler, or M-mode evaluation (see later discussion).

After delivery, patients with straightforward L-TGA may not require any intervention, even for many years. However, the presence of any associated abnormalities may require neonatal or subsequent medical or surgical intervention. All patients require close clinical, echocardiographic, and electrocardiographic evaluation postnatally. Long-term prognosis varies widely, but, without surgery, all patients remain at risk for heart failure and arrhythmias because of their systemic right ventricle.^{187,188}

Truncus Arteriosus

Truncus arteriosus represents a complex conotruncal malformation wherein a single arterial trunk arises from the heart and gives rise to the systemic, pulmonary, and coronary circulations. Truncus arteriosus arises from abnormal development of the truncal ridges and aortopulmonary septum and carries a strong association with DiGeorge syndrome.²³ Most cases have no ductus arteriosus during fetal life, except in the rare form associated with interrupted aortic arch.

Prenatally, truncus arteriosus exhibits a normal 4CV but markedly abnormal outflow tract views.^{180,189,190} The truncal valve commonly appears mildly thickened, overrides a large VSD, and may have some degree of regurgitation on color flow imaging. The pulmonary arteries arise from the truncal root either as a common main pulmonary artery (Fig. 19-60) or as separate origins of right and left branch pulmonary arteries. It can be difficult to differentiate truncus arteriosus from TOF/PA prenatally. Both lesions show a single semilunar valve overriding a VSD. Both lesions have a normal 4CV, and both have strong associations with DiGeorge syndrome.²³ The distinction may be made, however, by assessing the direction of blood flow within the pulmonary arteries. In the case of TOF/PA, blood flow in the pulmonary arteries is retrograde from the ductus arteriosus (see Fig. 19-56), or it may not be seen at all in the case of collateral-dependent pulmonary blood flow. In truncus arteriosus, blood from the pulmonary arteries is prograde from the truncal root. In addition, whereas the aortic valve in TOF/PA usually appears large but thin and delicate, the truncal valve in truncus arteriosus typically appears somewhat thickened, eccentric, and, occasionally, regurgitant.

After delivery, all patients require close clinical and echocardiographic evaluation, as well as evaluation for DiGeorge syndrome. Commonly, patients with truncus arteriosus undergo surgical repair within the first few weeks after delivery, with VSD closure and placement of a pulmonary homograft into the RVOT. As with TOF/PA, the

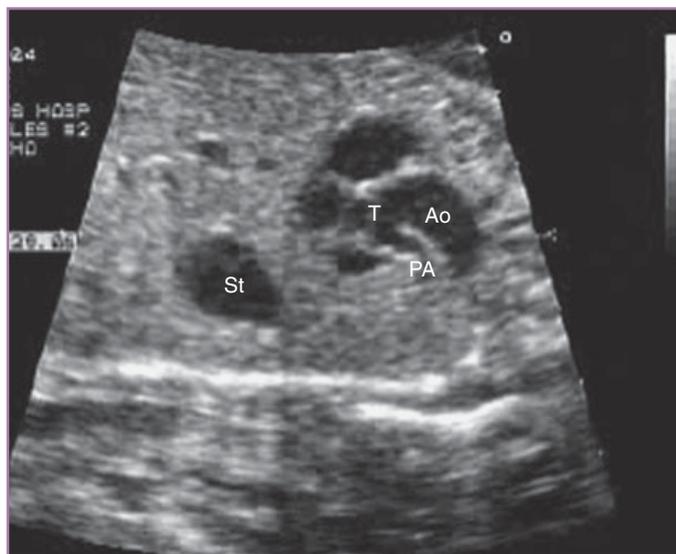

FIGURE 19-60 Fetal echocardiographic sagittal image of truncus arteriosus. The pulmonary artery arises from the proximal truncal root. Ao, aorta; PA, pulmonary artery; St, stomach; T, truncal root.

pulmonary homograft will require multiple replacements during a lifetime. Long-term prognosis depends on the associated abnormalities and truncal valve function but can be quite good if all goes well.^{189,190}

Cardiac Tumors

Fetal cardiac tumors, although rarely malignant in the oncologic sense, may be life-threatening in their own right or may be associated with systemic syndromes. This section reviews two of the most common cardiac tumors seen in the fetus: rhabdomyoma and intrapericardial teratoma. Both appear to have their greatest period of growth from mid-gestation to term. Readers may consult other sources for more detailed discussions of fetal cardiac tumors.^{8,9,152,153,191,192}

Cardiac Rhabdomyoma

By far the most common fetal cardiac tumor,^{191,192} cardiac rhabdomyoma may occur as an isolated, single cardiac mass or, more commonly, as a collection of well-circumscribed tumors. In a substantial percentage of cases, cardiac rhabdomyomas occur as one manifestation of tuberous sclerosis.^{193,194} Although tuberous sclerosis may be associated with significant neurologic disease, including seizures, developmental delay, and cognitive impairment,²³ cardiac rhabdomyomas often do not cause cardiovascular pathology, either prenatally or after delivery. Occasionally, however, cardiac rhabdomyomas may become obstructive to flow in or out of one or both ventricles, may adversely affect myocardial function, may generate atrial or ventricular arrhythmias, and may be associated with WPW syndrome. In the absence of fetal arrhythmias, diminished ventricular function, obstruction to flow, or CHF, the fetus with cardiac rhabdomyomas rarely will develop cardiovascular pathology postnatally, short of SVT in the presence of WPW. In fact, cardiac rhabdomyomas typically regress or remain stable in size postnatally,^{193,194} in contrast to other tumors, which may grow substantially after delivery.

The diagnosis of cardiac rhabdomyomas can generally be made from a 4CV. Most cardiac rhabdomyomas manifest as echogenic, homogeneous, well-circumscribed masses within or extending par-

tially into the ventricular free wall or ventricular septum or both (Fig. 19-61). Rarely, cardiac rhabdomyomas reside predominantly within the walls of the right or left atrium. In contrast, benign echogenic reflectors or foci reside exclusively within the chordal apparatus of the mitral or tricuspid valves and do not extend into the ventricular myocardium.

The fetus with suspected cardiac rhabdomyomas should be evaluated thoroughly for tuberous sclerosis, possibly including sonography, magnetic resonance imaging, and/or genetic means of analysis. After delivery, affected infants should again undergo comprehensive evaluation for tuberous sclerosis, a repeat echocardiographic evaluation, and an electrocardiogram to assess for WPW. Long-term prognosis, from a cardiovascular standpoint, is excellent if no significant rhythm, ventricular dysfunction, or hemodynamic obstruction manifests during the late fetal or neonatal periods.

Intrapericardial Teratoma

The intrapericardial teratoma is probably the second most common primary fetal cardiac tumor. Like the cardiac rhabdomyoma, it may be considered benign in the oncologic sense,^{8,152,191,192} but affected fetuses may develop CHF or hydrops secondary to progressive enlargement of the pericardial effusion. Histologically, the intrapericardial teratoma represents a combination of cystic areas, lined by various forms of epithelium, surrounded by solid areas composed of muscle, nerve, pancreas, cartilage, thyroid, or bone tissues. Intrapericardial teratomas typically arise from the ascending aorta and secrete fluid into the pericardial space. Over time, the expanding pericardial effusion can impede cardiac output, and the resultant tamponade physiology can result in fetal demise. After delivery, mass effect of the tumor may impede cardiac output or cause respiratory compromise by compressing the trachea or mainstem bronchi.¹⁹⁵

The diagnosis of intrapericardial teratoma may be suspected in the fetus with a pericardial effusion in conjunction with a heterogeneous, cystic mass with areas of calcification that arises from the ascending aorta (Fig. 19-62). After the diagnosis is made, affected fetuses require close observation and may benefit from pericardiocentesis for progres-

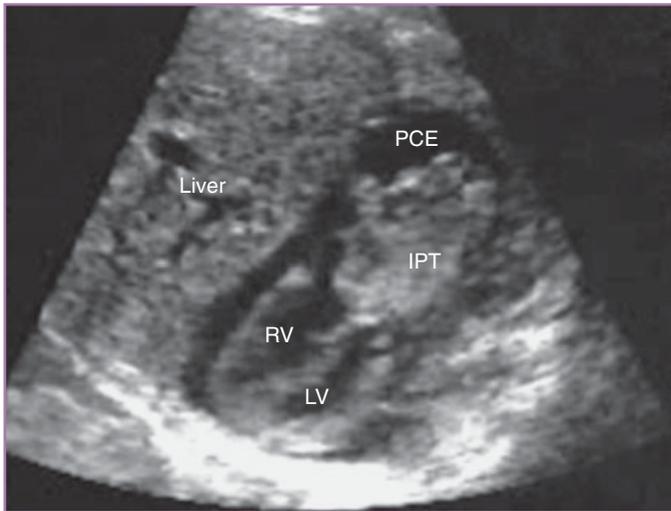

FIGURE 19-62 Fetal echocardiographic image of intrapericardial teratoma arising from the ascending aorta. Note the heterogeneous appearance of the tumor. IPT, intrapericardial teratoma; LV, left ventricle; PCE, pericardial effusion; RV, right ventricle.

sive enlargement of the pericardial effusion and worsening tamponade.¹⁹⁵ Delivery should be arranged to allow for rapid intubation, if necessary, and subsequent early surgical resection of the tumor. Long-term prognosis after expeditious, early resection is excellent, with little chance for recurrence.

Fetal Arrhythmias: Diagnosis, Management, and Prognosis

This section reviews the diagnosis, management, and prognosis of the most common and important fetal arrhythmias (Table 19-7), with a distinctively clinical approach. For more detailed discussions of fetal arrhythmias, readers may refer to other, more comprehensive reviews.^{8,9,152,196-198}

Beyond demonstrating a normal transverse abdominal view, 4CV, and standard views of the outflow tracts, the normal fetal screening

TABLE 19-8 ANTIARRHYTHMIC MEDICATIONS FOR FETAL ARRHYTHMIAS

Fetal Arrhythmia	Potential Treatments*
Premature atrial/ventricular contractions	None
Atrial bigeminy (blocked or conducted)	None
Nonsustained SVT	Usually none (see text)
Sustained SVT	Digoxin Flecainide Amiodarone Propranolol
Atrial flutter	Digoxin Sotalol Propranolol Amiodarone
Ventricular tachycardia	Propranolol Sotalol Mexiletine Amiodarone
First/second/third-degree heart block (positive antibodies)	Dexamethasone?

*Note that all antiarrhythmic medications have the potential for serious, possibly fatal maternal and/or fetal proarrhythmia. Treatment of a specific fetus for an arrhythmia should be done only after careful consideration of anticipated benefits and potential risks and after full disclosure has been made to the mother. SVT, supraventricular tachycardia.

ultrasound evaluation should demonstrate physiologic rate and variability of the fetal heartbeat. The fetal heart rate should be physiologic (120 to 160 beats/min) and should have physiologic variability (small but real changes in heart rate during scanning, with prolonged or severe bradycardia only during periods of deep transducer pressure). Abnormal variability (irregular beats or extrasystoles) and abnormalities in rate (sustained bradycardia or tachycardia) should be noted, evaluated, and, if appropriate, treated. Most fetal arrhythmias are benign, are self-resolving, and do not require treatment.¹⁹⁶⁻¹⁹⁸ Treatment of a fetus for arrhythmia should be undertaken only after careful weighing of desired benefits against potential maternal and fetal complications and after full disclosure to the mother. Table 19-8 lists some of the most common antiarrhythmic medications used to treat fetal arrhythmias.

Premature Atrial Contractions

Premature atrial contractions (PACs), the most common fetal arrhythmia,¹⁹⁶⁻¹⁹⁹ manifest as an irregularly irregular variability in fetal heart rate, usually beginning between 18 and 24 weeks' gestation, but occasionally appearing initially during the third trimester. The diagnosis of PACs typically is made empirically by observing the rhythm with 2D imaging. However, to confirm the diagnosis, spectral Doppler inflow and outflow evaluation of the left ventricle or M-mode analysis should be performed.

Normally, by orienting the ultrasound beam in parallel with both left ventricular inflow and outflow (Fig. 19-63), spectral Doppler evaluation of sinus rhythm will demonstrate a biphasic inflow pattern for every atrial contraction (i.e., early passive filling followed by atrial contraction) and a single, uniphasic outflow pattern after each ventricular contraction (Fig. 19-64).^{200,201} PACs, by definition, come early, and they typically lack the early passive filling component (E wave) of the Doppler waveform (Fig. 19-65). Alternatively, M-mode

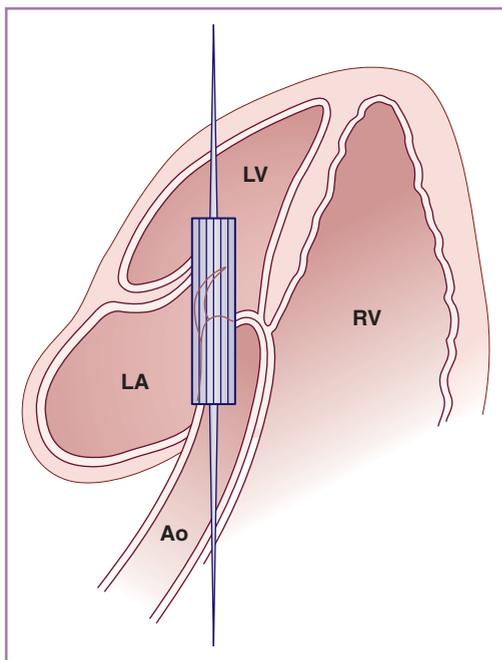

FIGURE 19-63 Schematic diagram of left ventricular inflow and outflow. The Doppler cursor is positioned in parallel with mitral and aortic flows to assist with the diagnosis of fetal arrhythmias. FIGURE 19-64 Fetal Doppler waveform obtained from left ventricular inflow and outflow demonstrating sinus rhythm. The Doppler cursor is positioned as in Figure 19-63. Note the biphasic mitral inflow, with passive early inflow (E wave) followed by atrial contraction (A wave). Each mitral inflow pattern is followed by single outflow. A, atrial contraction; E, early passive filling; V, ventricular contraction.

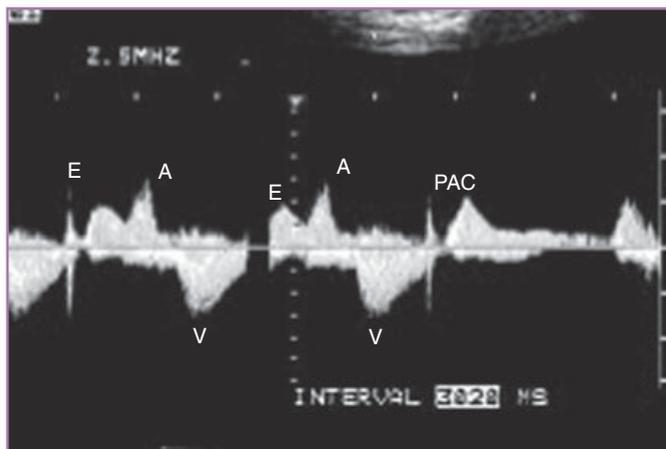

FIGURE 19-65 Fetal Doppler waveform obtained from left ventricular inflow and outflow demonstrating sinus rhythm with premature atrial contraction. The Doppler cursor is positioned as in Figure 19-63. The premature atrial contraction (PAC) comes early and is monophasic; it is blocked (i.e., not followed by ventricular contraction). A, atrial contraction; E, early passive filling; V, ventricular contraction.

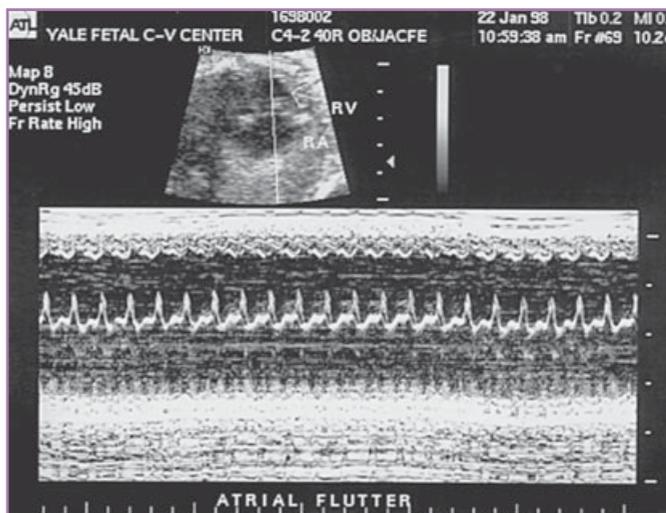

FIGURE 19-66 Fetal echocardiographic image of M-mode analysis of fetal arrhythmia. The M-mode cursor is placed across the right atrium and right ventricle (*inset*). This M-mode image demonstrates atrial flutter. (Image courtesy of Charles Kleinman, MD, Joshua Copel, MD, and Rodrigo Nehgme, MD.)

echocardiography allows visualization of atrial and ventricular contractions simultaneously when, guided by a 2D image, the M-mode sampling line is directed through the fetal atrium and ventricle (Fig. 19-66).²⁰² Other, more sophisticated approaches to evaluating fetal arrhythmias have also been developed.¹⁰¹

Rarely, PACs are associated with intermittent SVT. PACs may be exacerbated by ingestion of caffeine, decongestant medications (stimulants), or tobacco. Typically, PACs resolve spontaneously within 2 to 3 weeks after diagnosis. PACs do not represent any real risk to the fetus, and they do not require treatment. However, a small percentage of fetuses with isolated PACs develop SVT. Referral for further evaluation should be considered if concerns persist regarding the diagnosis or the possibility of additional arrhythmias or structural CHD.

Sustained Bradycardia

A sustained fetal heart rate of less than 120 beats/min represents fetal bradycardia and merits further evaluation. In contrast, fetal bradycardia related to deep transducer pressure or a particular maternal lie might represent a normal fetal response to stress. In such cases, if the fetal heart rate normalizes after relief of transducer pressure or change in maternal or fetal position, no further cardiac evaluation may be necessary.

The differential diagnosis of fetal bradycardia includes sinus bradycardia, atrial bradycardia, blocked atrial bigeminy, atrial flutter with high-degree block, and complete heart block. Treatment approaches and prognosis depend on the precise diagnosis. Sinus bradycardia, manifesting with a slow rate but with physiologic variability and with 1:1 conduction between the atria and ventricles, may represent fetal distress and therefore should prompt a thorough evaluation of fetal well-being and placental function. Particularly if it is associated with some degree of heart block, fetal sinus bradycardia may, rarely, be the first sign of long QT syndrome.²⁰³ Affected fetuses and newborns are at risk for ventricular tachycardia. For this reason, fetuses in good health that demonstrate unexplained sinus bradycardia without fetal distress should undergo electrocardiographic evaluation after delivery. In addition, because long QT syndrome may run in families, a family history for long QT syndrome, recurrent syncope, or sudden infant death syndrome should be sought. In contrast, atrial bradycardia may appear identical to sinus bradycardia, but it actually represents the normal rate of an accessory atrial pacemaker in the absence of an effective sinus node. Such an atrial bradycardia commonly occurs in conjunction with polysplenia, so the suspicion of this rhythm should prompt evaluation for the cardiac and abdominal abnormalities seen with polysplenia.^{106,110,157}

Occasionally, fetal sinus bradycardia represents blocked atrial bigeminy, in which normal sinus beats alternate with blocked PACs. In atrial bigeminy, the premature beats may be blocked if they occur very early, when the atrioventricular node is still refractory. In such cases, only sinus beats conduct, generating a uniform ventricular rate exactly half of the atrial rate. No specific therapy is warranted other than close observation and avoidance of caffeine, decongestant medications, and tobacco. Prognosis is excellent.

In some cases, atrial flutter may conduct consistently 3:1 or 4:1, and such fetuses may present with bradycardia. Close inspection of the heart with 2D imaging, M-mode, or spectral Doppler can diagnose the arrhythmia and assess the degree of conduction. Although atrial flutter usually has an atrial rate of 300 to 500 beats/min, high degrees of atrioventricular block may lead to fetal bradycardia; for example, atrial flutter with a flutter rate of 300 beats/min and a 3:1 conduction would present with a fetal ventricular rate of 100 beats/min. Unlike SVT, atrial flutter rarely manifests as intermittent tachycardia; flutter typically is incessant, although the ventricular response rate may vary. Like other fetal arrhythmias, fetal atrial flutter may be associated with structural heart disease. Treatment of atrial flutter, typically with maternal orally administered pharmacologic therapy (e.g., digoxin, sotalol, amiodarone) can slow the ventricular response rate and decrease the likelihood of development of fetal CHF or hydrops. Some investigators believe that sotalol has emerged as a potential first-line agent for the treatment of atrial flutter.²⁰⁴

Complete heart block (CHB) in the fetus typically manifests with a sustained fetal heart rate in the range of 40 to 70 beats/min (Fig. 19-67). In the fetus with complete heart block, the atrial rate remains normal but atrial contractions do not conduct to the ventricles. As a result, the ventricles depolarize with their own intrinsic rate. Approxi-

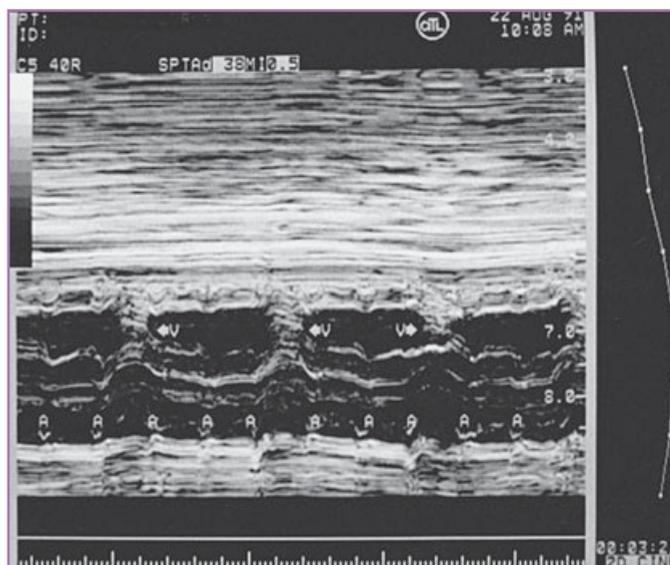

FIGURE 19-67 Fetal echocardiographic image of M-mode demonstration of complete heart block. A, atrial contraction; V, ventricular contraction. (Image courtesy of Charles Kleinman, MD, Joshua Copel, MD, and Rodrigo Nehgme, MD.)

mately 50% of cases of fetal complete heart block occur in the presence of structural heart disease (L-looped ventricles, atrioventricular septal defects, or complex forms of heart disease associated with polysplenia).^{157,196,205} These cases have a relatively poor prognosis, with a high rate of fetal demise related to progressive heart failure and hydrops. Therapy with maternal oral agents such as terbutaline or other sympathomimetics has not been shown to improve the outcome.

The other 50% of cases of fetal heart block occur secondary to damage to the fetal atrioventricular node by maternal anti-Ro and/or anti-La antibodies,²⁰⁵⁻²⁰⁷ usually in the context of maternal systemic lupus erythematosus, Sjögren's syndrome, or related connective tissue disorders. In some of these cases, maternal treatment with dexamethasone has improved fetal outcome, probably by improving myocardial function in the face of presumptive immune-mediated myocarditis.²⁰⁸⁻²¹⁰ Some investigators have used sympathomimetics agents to increase ventricular rates in this setting, particularly for rates that remain slower than 55 beats/min,²¹¹ but sustained increases in fetal heart rate have rarely been achieved. Pregnancies complicated by anti-Ro or anti-La antibodies carry a risk of approximately 1% for the development of fetal heart block,²¹² and the recurrence rate for a second fetus with heart block in antibody-positive pregnancies may be as high as 15%.²⁰⁷ Spectral Doppler evaluation of the fetal PR interval has been shown to be a useful way to identify fetuses in anti-Ro or anti-La antibody-positive pregnancies with evidence of atrioventricular node disease.^{213,214} Treatment of fetuses at risk (first-, second-, or third-degree heart block in antibody-positive pregnancies) with dexamethasone may prevent the progression to CHB or otherwise improve outcome by enhancing myocardial function, but such management remains controversial.^{208-210,215,216}

Sustained Tachycardia

SVT represents the great majority of instances of sustained fetal tachycardia. Sinus tachycardia represents an unusual response to fetal heart failure or distress. Fetal ventricular tachycardia occurs still far less commonly.

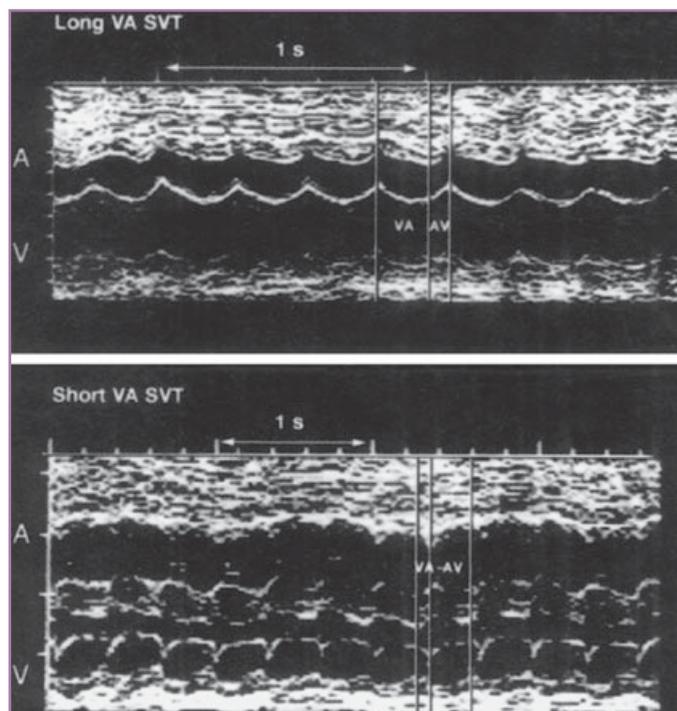

FIGURE 19-68 Fetal echocardiographic image of M-mode demonstration of two types of supraventricular tachycardia. In contrast to ventricular tachycardia, both types (i.e., long- and short-VA SVT) have 1 : 1 atrioventricular association. A, atrial contraction; AV, interval between atrial and ventricular contraction; SVT, supraventricular tachycardia; V, ventricular contraction; VA, interval between ventricular and atrial contraction. (Reproduced with permission from Jaeggi E, Fouron JC, Fournier A, et al: Ventriculoatrial time interval measured on M-mode echocardiography: A determining element in diagnosis, treatment, and prognosis of fetal supraventricular tachycardia. *Heart* 79:582, 1998. Image courtesy of Charles Kleinman, MD, Joshua Copel, MD, and Rodrigo Nehgme, MD.)

Supraventricular Tachycardia

Fetal SVT typically occurs via an accessory pathway, although autonomic forms of fetal SVT also occur relatively commonly. Fetal SVT, usually in the range of 240 to 280 beats/min, occurs most frequently in fetuses with structurally normal hearts and rarely occurs in the setting of structural CHD. However, fetal SVT may be associated with WPW syndrome. The diagnosis of SVT may be suggested by 2D imaging, by spectral Doppler assessment of the left ventricular inflow and outflow tracts (see Fig. 19-63), or by M-mode analysis (Fig. 19-68). Ventricular tachycardia, which is typically slower but less well tolerated than SVT, may be associated with ventricular structural abnormalities or tumors or may occur in the context of long QT interval. Ventricular tachycardia can be difficult to discriminate from fetal SVT, even with M-mode or spectral Doppler analysis,^{196,197,217} although ventricular tachycardia is typically far less well tolerated. Because fetal SVT typically manifests as an intermittent, nonsustained arrhythmia, the presence of PACs or atrial couplets can help strengthen the certainty of the diagnosis. Moreover, unlike ventricular tachycardia, SVT usually conducts 1 : 1 from atria to ventricles.

Although few would dispute treatment of fetal SVT in the face of hydrops and in the absence of lung maturity, no consensus exists on

the approach to the second-trimester (or early third-trimester) fetus with SVT in the absence of hydrops.^{196,197,217-219} As would be expected, SVT in a fetus with structural heart disease is far less well tolerated than SVT in one with a structurally normal heart. However, therapeutic strategies advocated for the nonhydropic, immature fetus with SVT remain largely divergent, ranging from treatment of any documented SVT to treatment only with the development of hydrops.²¹⁷ No consensus has been reached on the exact relationship between heart rate, type of SVT, and development of hydrops in the context of fetal SVT. Antiarrhythmic agents, dosing schedules, and routes of administration represent separate areas of controversy and disagreement, similarly without consensus.

Although each case may be handled somewhat differently, depending on patient characteristics and physician biases, the following represents our institution's approach. The presence of structural heart disease in the context of SVT lowers the tolerance for shortened diastolic filling times and elevated central venous pressure, so such fetuses typically receive treatment earlier than do fetuses with structurally normal hearts. When fetal SVT becomes complicated by hydrops, the threshold for treatment falls much further. In the absence of fetal structural heart disease or hydrops, fetal SVT usually receives treatment if the tachycardia occurs more than 33% of the time. However, beyond 32 to 34 weeks' gestation, many cases of fetal tachycardia may be better approached with delivery than with maternally administered medications, all of which have variable efficacy and carry the potential for both maternal and fetal toxicity. Before treatment, all potential precipitating factors (tobacco, decongestant medications, and caffeine) are withdrawn, and the fetal rhythm is monitored in-house for 8 to 24 hours to assess the percentage of time during which the fetus is in tachycardia. The mother is informed of all possible fetal and maternal risks to therapy, as well as the anticipated benefit to treatment. All antiarrhythmic agents have the potential for maternal and/or fetal proarrhythmia. Because maternal serum factors rarely may react with assays for digoxin,²²⁰ a maternal serum digoxin level is determined, along with a set of electrolytes and creatinine. A maternal electrocardiogram and, ideally, consultation with an adult cardiologist is performed before therapy is initiated. The presence of WPW or other abnormality on the maternal electrocardiogram may contraindicate the use of certain forms of antiarrhythmic therapy (e.g., digoxin).

When indicated, and only in the absence of any contraindication, treatment may begin with a digoxin load, using 0.5 mg intravenously every 6 to 8 hours, with a maternal serum digoxin measurement and electrocardiogram performed before each dose. Loading continues until effect (<25% tachycardia or decreased hydrops or both), therapeutic level (2.0 µg/mL), maternal toxicity (maternal symptoms or electrocardiographic abnormalities beyond first-degree heart block), or fetal toxicity (worsening of arrhythmia) is reached, whichever comes first. After a desired effect has been safely achieved, digoxin is administered orally two to four times daily, usually at 0.25 to 0.5 mg per dose. Often, consultation with the hospital pharmacologist is useful. Patients are discharged after a steady state has been achieved with acceptable control of the fetal arrhythmia, acceptable maternal serum digoxin levels, and absence of maternal or fetal toxicity. However, close outpatient follow-up is essential to confirm continued effect and lack of toxicity, and occasionally to increase dosing as maternal volumes of distribution continue to increase during the second and third trimesters. If digoxin fails to achieve adequate control, second-line agents such as propranolol,^{196,197} flecainide,²²¹ or amiodarone²²² may be substituted or added, but the potential for toxicity increases and the likelihood for efficacy decreases.^{196,197}

Atrial Flutter

In contrast to fetal SVT, fetal atrial flutter ranges between 300 and 500 atrial contractions per minute, with a ventricular rate that may vary from less than 100 to more than 300 beats/min.^{196,197,223} In atrial flutter, the atrioventricular node refractory periods may vary, occasionally producing 1:1 conduction but more typically allowing only every second or third atrial contraction to conduct to the ventricles (2:1 or 3:1 conduction, respectively) (see Fig. 19-66). Flutter usually manifests in a much more sustained fashion than does SVT, which commonly produces intermittent runs of tachycardia interspersed with periods of sinus rhythm. Compared with SVT, atrial flutter has a higher association with structural heart disease, although structural heart disease is still rare in the neonate with atrial flutter.²²⁴ Finally, although flutter may be successfully treated with maternally administered digoxin, recent reports suggest that sotalol is an excellent second-line agent, and some centers have chosen sotalol as their first-line therapy for fetal atrial flutter.²⁰⁴ Propranolol has also been used successfully to control the ventricular response rate in the fetus with atrial flutter.¹⁹⁷

Ventricular Tachycardia

Ventricular tachycardia in the fetus, as in newborns and children, represents a commonly fatal arrhythmia when sustained. In part for this reason, fetal ventricular tachycardia is diagnosed far less often than fetal SVT, although fetal ventricular tachycardia is also far less common than fetal SVT. Fetal ventricular tachycardia usually manifests with fetal rates between 180 and 300 beats/min and, often, poor ventricular function. Discrimination of ventricular tachycardia from SVT can be challenging but is important, because digoxin is contraindicated for ventricular tachycardia. Unlike SVT, ventricular tachycardia has dissociation between atrial and ventricular contractions (Fig. 19-69). Ventricular tachycardia that is associated with structural heart disease carries a particularly poor prognosis. Fetal ventricular tachycardia has been associated with tumors (usually rhabdomyomas), structural heart disease (cardiomyopathy, severe right or left ventricular hypertrophy or coronary abnormalities), prolonged QT interval,²⁰³ and fetal distress or acidosis. Lower ventricular rates (180 to 220 beats/min) may be

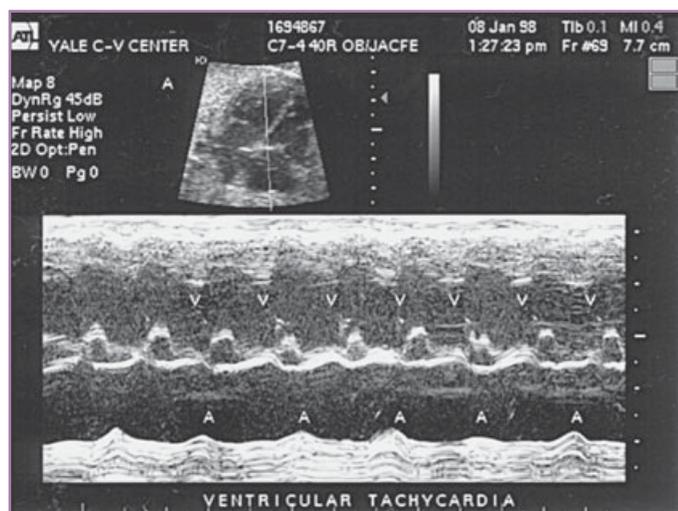

FIGURE 19-69 Fetal echocardiographic image of M-mode demonstration of ventricular tachycardia. Note atrioventricular dissociation, with ventricular rate faster than atrial rate. A, atrial contraction; V, ventricular contraction. (Image courtesy of Charles Kleinman, MD, Joshua Copel, MD, and Rodrigo Nehgme, MD.)

better tolerated, with improved outcomes compared with higher ventricular rates. In some cases, treatment may be attempted with lidocaine (administered directly into the fetal umbilical vein) or with oral maternal administration of propranolol, mexiletine, sotalol, or amiodarone, but the prognosis remains guarded.^{196,197,222}

Conclusions

The detection, diagnosis, and management of fetal structural heart defects and arrhythmias remain important challenges for those involved in fetal screening ultrasonography or detailed evaluation of the fetal heart. The assessment and management of the fetal heart, in both low-risk and high-risk pregnancies, requires attention to detail, experience, and a collaborative effort among multiple specialists caring for the fetal patient.

Chapter 20

Teratogenesis and Environmental Exposure

Christina Chambers, PhD, MPH, and Carl P. Weiner, MD, MBA

A teratogenic agent is defined as one that has the potential to interfere with the normal functional or structural development of an embryo or fetus. A teratogenic exposure occurs when a pregnant woman is exposed to an agent that increases risk. Although teratogenic exposures are generally thought of as those that increase the risk for major congenital anomalies, in the broader sense, teratogenic exposures also increase the risk for a spectrum of adverse pregnancy outcomes, including spontaneous abortion, stillbirth, minor structural anomalies, shortened gestational age, growth restriction, and behavioral or cognitive deficits. However, excess risks for these latter events are much more difficult to recognize.

The currently known teratogenic exposures comprise a wide range of agents, including some prescription and over-the-counter medications, recreational drugs and alcohol, chemicals, physical agents, and maternal diseases. Although studies specifically evaluating human teratogenicity are lacking for most environmental agents, including prescription medications, it is generally estimated that at least 10% of major birth defects are attributable to environmental exposures and therefore are, to some extent, preventable.¹ As a result, the possible teratogenicity of agents to which a woman may be exposed during pregnancy is of great concern to the general public and requires that clinicians develop expertise in evaluating these risks on behalf of their patients.

Historical Perspective

Before the 1940s, it was somewhat naively thought that the placenta provided a protective barrier for the developing embryo and fetus, so that agents to which the mother was exposed could not interfere with normal prenatal development. The revolutionary concept that a maternal exposure could pose a risk to the developing embryo or fetus was first raised, not by a scientist or an obstetrician, but rather by an Australian ophthalmologist, Norman Gregg, who observed in his own clinical practice an unusual number of children diagnosed with congenital cataracts shortly after a rubella epidemic. Gregg's work led to investigations that identified additional features of a variable but characteristic pattern of developmental abnormalities associated with fetal rubella infection, including congenital heart defects, hearing deficits, and endocrine abnormalities, all of which came to be known as the congenital rubella syndrome.²

In the early 1960s, an Australian obstetrician and a German geneticist independently recognized that first-trimester maternal use of tha-

lidomide, a sedative-hypnotic drug, was associated with a dramatic increase in risk for a characteristic pattern of limb reduction anomalies and other defects.^{3,4} Although the drug had undergone premarket testing in rodents, it had not shown any evidence of adverse outcomes in these species. The subsequent recognition that therapeutic agents could induce malformations was a major stimulus for the implementation of the Kefauver-Harris Amendment to the Food, Drug and Cosmetic Act in the United States, which expanded the role of the Food and Drug Administration (FDA) as a regulatory agency charged with ensuring both the efficacy and the safety of products.⁵

Although the thalidomide experience raised public awareness of the potential risks of prenatal exposures, it was accompanied by misunderstandings about how to differentiate exposures that actually cause birth defects from coincidental exposures occurring in women whose pregnancy outcome is abnormal for other, unrelated reasons. A classic example is doxylamine succinate and pyridoxine hydrochloride with or without dicyclomine hydrochloride (Bendectin®), a once popular antiemetic medication used by as many as 30% of American women for the treatment of nausea and vomiting of pregnancy. In 1983, this agent was voluntarily withdrawn from the market after anecdotal concerns for teratogenicity triggered an onslaught of litigation, despite voluminous scientific evidence to the contrary.⁶

Within the last 40 years, research in the field of teratology has advanced, and several new human teratogens have been identified, including several anticonvulsants, selected antineoplastic agents, inhibitors of enzymes in the angiotensinogen-angiotensin pathway, methylmercury, cocaine, alcohol, hyperthermia, tetracycline, warfarin, and isotretinoin.⁷ Work continues to better define the range of adverse outcomes associated with these exposures, the magnitude of the risk for a given dose at a specific gestational age, and the subpopulations of mothers and infants who may be at particularly increased risk because of their genotype. However, major knowledge gaps exist for most agents—few of which have been adequately evaluated in human pregnancy.⁸

Concerns regarding the inadequacy of accurate information for the developmental effects of a majority of therapeutic and over-the-counter agents are critical. Studies indicate that drug exposure during pregnancy is extremely common: in one U.S. health care system sample of 98,182 deliveries, 64% of women were prescribed at least one medication during their pregnancy other than a vitamin or mineral supplement.⁹ In another U.S. population-based sample of women, more than 70% reported the use of one or more over-the-counter medications during pregnancy.¹⁰ Therefore, a theoretical and practical framework

is necessary to aid clinicians in advising patients, who are likely to have experienced several exposures by the time their pregnancy is recognized, and to help support evidence-based clinical decision making in the common situations in which pregnancy exposures can be anticipated.

Principles of Teratology

Wilson and Fraser¹¹ outlined the basic principles of teratology in the early 1970s to aid in identifying those agents with teratogenic potential and to provide a basis for establishing causality. Appreciation of these principles can help clinicians place into context research findings from the literature as well as individual patient histories. The principles discussed here are species specificity, genetic susceptibility, gestational timing, dose response, route of administration, spectrum of outcomes, and specific mechanisms leading to pathogenesis.

The principle of *species specificity*, in combination with the concept of *genetic susceptibility*, holds that agents that are teratogenic in one species may not be so in another. Similarly, the manifestations of a teratogenic exposure may differ across susceptible species, and, even within species, certain strains or individuals may be at higher risk than others.

These two principles have implications for the predictive value of preclinical animal reproductive toxicity studies; for example, thalidomide was not teratogenic in the species initially tested, and only after its recognition as a human teratogen was the most sensitive animal species identified.¹² Variability in susceptibility is also evident within species, including humans, where no teratogenic agent at typical doses has been demonstrated to produce adverse effects in 100% of conceptuses. Even potent, known human teratogens such as thalidomide and isotretinoin affect fewer than 50% of exposed infants. In some cases, this variability in susceptibility has been linked to specific genetic polymorphisms that interact with the agent to create a particularly susceptible subgroup of mothers or fetuses.

For example, women with infants who have cleft lip with or without cleft palate or isolated cleft palate are approximately twice as likely to report heavy first-trimester tobacco use than are mothers of normal newborns; however, women who have a certain transforming growth factor- α (TGF- α) polymorphism and who smoke heavily have a 3 to 11 times higher risk of having a child with an oral cleft, suggesting a gene-environment interaction. Furthermore, this risk appears to be lessened by maternal multivitamin use.^{13,14} Similarly, a low level of epoxide hydrolase enzyme activity influenced by epoxide hydrolase polymorphisms has been implicated as a risk factor for fetal hydantoin syndrome in children whose mothers have taken phenytoin for the treatment of a seizure disorder during pregnancy.¹⁵

The principle of *gestational timing*, or critical developmental windows of exposure, requires that the exposure occur during the stage in development when the maturational process is most susceptible. For example, the critical window for an agent that interferes with closure of the neural tube in the human embryo is approximately the first 3 weeks after conception. Carbamazepine, an anticonvulsant linked to a 10-fold increased risk for neural tube defects, does not produce the defect if maternal exposure occurs after the second month of pregnancy.^{16,17}

A corollary to this principle is that, depending on the precise gestational timing of teratogenic exposure, a range of adverse outcomes may be induced. For example, coumarin-derived anticoagulants are associated with a pattern of nasal hypoplasia and skeletal abnormalities when prenatal exposure occurs during a critical window in the latter

portion of the first trimester, whereas later gestational exposure is associated with central nervous system (CNS) effects.¹⁸ The former abnormality likely reflects a vitamin K deficiency, the latter a complication of fetal bleeding.

Consistent with these concepts, very early gestational exposure, limited in general to the first 2 weeks after conception, is thought to pose little potential for teratogenicity. This is true in part because of the limited biologic availability to the embryo of an agent that is taken and eliminated by the mother before the completion of placentation. Further, pluripotent cells of the early embryo may be resilient in recovering from a teratogenic insult, or, alternatively, they may be particularly vulnerable to a teratogenic exposure, resulting in spontaneous abortion before the clinical recognition of pregnancy.¹¹

The principle of *dose response* suggests that, for those agents that are teratogenic, there is a threshold dose below which no effect is detected, and higher doses produce stronger effects relative to lower doses, with the highest doses being lethal. For example, when the anticonvulsant valproic acid is ingested by a pregnant woman during the critical window for neural tube closure, the risk for that defect increases by approximately 10- to 20-fold, from a baseline risk of 0.1% to a risk of 1% to 2%. However, there is evidence that the risk is dose-related, because valproate-treated mothers who deliver infants with spina bifida on average have taken significantly higher doses than valproate-treated mothers of normal newborns.¹⁹

The principle of *route of administration* is closely linked to the principle of dose response from the standpoint of influencing the effective dose that is biologically available to the embryo or fetus. This is a critical element in the design of animal reproductive and developmental toxicity studies in terms of their comparability to human pregnancy exposures. This principle can be applied to studies regarding the relative toxicity of human exposures resulting from oral dosing versus topical application. For example, retinoids as a class have been identified as human teratogens with effects that depend on the dose and timing of exposure in gestation. Isotretinoin taken as an oral medication is one of the most potent known human teratogens. Exposure to isotretinoin limited to as little as a few days in early pregnancy results in an approximate 20% risk of a pattern of brain, heart, ear, and thymus abnormalities and mental deficiency in liveborn children.²⁰ In contrast, topical retinoids, when used sparingly in the first trimester for blemishes or to reduce signs of skin aging, have not been associated with a measurably increased risk for the same pattern of adverse effects.^{21,22} These findings do not rule out the teratogenic potential of topical retinoids but simply suggest that the maternal blood levels of retinoids delivered via skin absorption may represent a teratogenic risk that is so low as to be undetectable without very large sample sizes.

The principle of *spectrum of outcomes* indicates that, depending on dose and timing in gestation, adverse outcomes associated with a given teratogen may encompass effects ranging from spontaneous abortion or stillbirth to major and minor structural defects, prenatal or postnatal growth deficiency, preterm delivery, and functional deficits or learning disabilities. For example, moderate to heavy maternal alcohol intake, particularly if consumed in a “binge” pattern, has been demonstrated to increase the risks for spontaneous abortion, stillbirth, a characteristic pattern of minor craniofacial abnormalities, selected specific major structural defects including heart defects and oral clefts, prenatal and postnatal growth deficiency, deficits in global IQ, and specific behavioral and learning abnormalities.²³ Animal and human studies consistently support the notion that the entire spectrum of outcomes associated with alcohol may not be manifested in any single affected pregnancy; rather, the results vary by dose and pattern of drinking, differ with gestational timing of exposure, and are influenced

by genetic susceptibility and other modifying factors such as maternal nutrition.

Finally, the principle of *specific mechanisms leading to pathogenesis* specifies that teratogenic agents do not increase the risk of all adverse outcomes; rather, they act on specific targets to produce a characteristic pattern of effects. This principle underlies the methods by which many human teratogens have been recognized; that is, a pattern of abnormalities associated with a particular teratogenic exposure helps to identify that exposure as a cause of the outcome. For example, the characteristic pattern of abnormalities comprising the fetal alcohol syndrome includes minor craniofacial features (short palpebral fissures, smooth philtrum, and thin vermilion of the upper lip) accompanied by microcephaly, growth deficiency, and cognitive and behavioral deficits. The prenatal effects of alcohol, although pervasive, nevertheless represent a constellation or pattern of features that is unlikely to randomly occur without exposure to alcohol in substantial doses and during certain gestational weeks.

It therefore appears likely that there are a few general mechanisms that lead to abnormal development. For example, a teratogenic agent can interact with a receptor, bind to DNA or protein, degrade cell membranes or proteins, inhibit an enzyme, or modify proteins. These mechanisms ultimately manifest as one or more types of abnormal embryogenesis, including excessive or reduced cell death, failed cell interactions, reduced biosynthesis, impeded morphogenetic movement, or mechanical disruption of tissues. For this reason, several specific teratogens may have the same end result on development by acting through a common pathway. For example, some anticonvulsants, trimethoprim, and triamterine may increase the risk for neural tube defects via folate antagonism.²⁴ Angiotensin I-converting enzyme (ACE) inhibitors such as enalapril and lisinopril may induce the risk for ACE-inhibitor fetopathy, which consists of renal tubular dysplasia and hypocalvarium, possibly through the mechanism of drug-induced fetal hypotension leading to hypoperfusion and oligohydramnios.²⁵

Sources of Safety Data on Exposures in Pregnancy

In the ideal world, clinicians would have access to complete information about the human teratogenic potential of all environmental exposures, including medications, recreational drugs, nutrients and nutrient supplements, occupational exposures, toxic exposures or poisonings, household chemicals and cosmetics, environmental contaminants or pollutants, and physical agents such as heat and radiation. Unfortunately, for many if not most exposures, reliable information is limited. Sufficient human data are commonly lacking for even prescription medications whose safety is monitored by the FDA. In one study reviewing the human safety data for prescription medications marketed in the United States over the previous 20 years, Lo and Friedman⁸ concluded there were insufficient data to confirm or rule out teratogenicity for more than 80% of these agents.

There are many reasons for this situation, some inherent to the difficulty of conducting pregnancy outcome research and some related to the lack of a standard surveillance system for studying agents to which women of reproductive age are likely to be exposed. Clinical trials for prescription medications are not typically conducted in human pregnancy, and the pharmaceutical industry has no incentive to do so even when there is an apparent clinical need. Animal reproductive and developmental toxicity studies are used to estimate the

potential for human teratogenicity. For almost all known human teratogens, there is an animal model; however, animal studies are not completely predictive of human pregnancy outcomes due to species sensitivity and differences in dosing and exposure timing.

Adverse Case Reports

When new medications are marketed in the United States, initial reports of pregnancy exposures with adverse outcomes may appear as case reports in the literature, or through safety data provided to the FDA by manufacturers, or in voluntary reports by clinicians or patients. Although individual adverse outcome reports have the potential to generate a hypothesis regarding teratogenicity—especially if the outcome reported is an unusual pattern of malformation—these data sources lack critical information about the number of exposed pregnancies with normal outcomes and therefore can confuse the process of determining whether the adverse event reports represent an excess risk over the baseline for that event.

Pregnancy Registries

Additional sources of pregnancy safety information on new drugs sometimes include pregnancy registries. Registries typically collect data regarding exposures to a specific drug or class of drugs, both retrospectively and prospectively. The outcome of primary interest in traditional pregnancy registries is major birth defects. Registry data are periodically summarized and reviewed for possible “signals” that might lead to recommendations for initiation of a hypothesis-testing study. Strengths of registries include their potential for gathering early information about a new drug and the possibility of identifying a unique pattern of malformation that is associated with exposure to the drug of interest. However, traditional registries lack formal comparison groups and typically have outcome data on relatively small numbers of pregnancies. As a result, they usually have insufficient sample size to detect increased frequencies of specific and relatively rare birth defects.²⁶ Nevertheless, collaborative registry designs such as the Antiepileptic Drugs in Pregnancy Registry have demonstrated success in identifying signals or establishing higher than expected rates for major birth defects after selected exposures.²⁷

Observational Cohort Studies

Another source of pregnancy safety data originates from observational cohort studies that are initiated with the goal of testing a specific hypothesis. These include prospectively designed exposure cohort studies in which women with and without the exposure of interest are enrolled during pregnancy and followed to outcome. Such studies have the ability to evaluate a spectrum of outcomes, including major and minor malformations, and to collect early information on a new drug. They also have the advantage of including a comparison group or groups, allowing for the control of key factors that may be confounders, such as maternal age, socioeconomic status, and alcohol or tobacco use. Such a study design was successful identifying carbamazepine as a human teratogen.²⁸ One disadvantage of this approach is that the sample sizes are typically too small to rule out anything but the most dramatically increased prevalence of specific major birth defects.

Database Cohorts

A variation of the observational cohort involves construction of a historical cohort using archived information in existing databases. For

example, health maintenance organization claims data and records from government-supported healthcare agencies are increasingly being analyzed for information on pregnancies with or without specific medication exposures. The strengths of this approach include the potential cost savings for collecting data for a given number of pregnancies, but the limitations include sample sizes that are too small to detect increased risks for many, if not most, specific birth defects. In addition, because database studies rely on information not collected primarily for research purposes, validation of exposure and outcome, as well as data on some key potential confounders, may be difficult or impossible to obtain. Nevertheless, database cohorts have been used, for example, to identify a possible link between paroxetine and congenital heart defects.²⁹

Case-Control Studies

In case-control study designs, pregnancies are retrospectively selected for having a specific outcome, such as a particular birth defect. The frequency of exposure to an agent of interest among mothers of affected infants is compared with the frequency among mothers whose pregnancies did not result in that birth defect. A major strength of case-control studies is that, with proper numbers of cases and controls, they can provide sufficient power to detect increased risks for rare outcomes. In addition, because they include a comparison group, they can collect information on important potential confounding variables such as age, socioeconomic status, and alcohol and tobacco use. The case-control approach was used successfully to identify the association of misoprostol (used to induce abortion) with a very high risk for a rare congenital facial nerve paralysis, Möbius syndrome.³⁰ Limitations to case-control studies include the lag time inherent in collecting information on a new drug, especially if it is infrequently used by pregnant women. Another limitation is the inability to evaluate an agent for a spectrum of outcomes that are as yet unidentified as part of the anomaly pattern. Finally, it is possible that women who are already aware of a negative outcome of their pregnancy may recall exposures more carefully (or incorrectly) than those who had a normal outcome.

Summary of Data Sources

In summary, the strengths and weaknesses of the methodologies that are available to evaluate for potential teratogenicity reveal that no single approach is sufficient. From the clinical perspective, this means that conclusions drawn from one type of study must be interpreted with caution until they are either confirmed or refuted by other types of studies. This is especially important in recognizing high-risk exposures (and perhaps even more so for identifying agents that are not teratogenic), so that appropriate treatment decisions can be made. From a public health perspective, a combination of complementary study designs is required, one that ideally is initiated in a coordinated, systematic fashion so as to provide clinicians and patients with the best and earliest possible information.³¹

Risk Assessments and Resources

The U.S. FDA established a widely used pregnancy safety category system that is incorporated into the product label with the intent of informing clinicians and pregnant women of the teratogenic risks

TABLE 20-1 FDA PREGNANCY CATEGORIES

Category	Definition
A	Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters).
B	Animal reproduction studies have failed to demonstrate a risk to the fetus and there are no adequate and well-controlled studies in pregnant women.
C	Animal reproduction studies have shown an adverse effect on the fetus and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.
D	There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.
X	Studies in animals or humans have demonstrated fetal abnormalities and/or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, and the risk involved in use of the drug in pregnant women clearly outweighs potential benefits.

associated with prescription drugs. However, this category system is frequently misunderstood by health care providers and patients alike. The categories are summarized in Table 20-1.

In practice, the FDA category assigned to a medication often misrepresents or oversimplifies the actual evidence. For example, the category assignments do not take into consideration factors such as exposure timing in gestation or dose and route of administration. Although several drugs assigned to category X (i.e., contraindicated in pregnancy) are indeed known human teratogens (e.g., isotretinoin), others, such as ribavirin and the “statins,” were assigned to that category based on theoretical concerns or animal data without conclusive human data to establish a teratogenic risk.³² Further, incorporation of new data into the label and classification updates is often slow.

Communication of potential risk to a woman regarding a category X exposure that has already taken place varies substantially from that for an exposure that is anticipated. An example is the communication of information regarding risk from an exposure to ribavirin (to treat hepatitis C) that occurred during an unplanned pregnancy compared with the communication of concern if the clinician and patient are prospectively determining whether ribavirin is an appropriate medication to use. Such nuances are not reflected in the category statements. In recognition of these limitations and weaknesses, the FDA has worked with an advisory committee to develop recommended revisions to the category system and the label format.³³

Other sources of information readily available to the clinician include a number of print resources, each with different approaches to providing summary information. Some of these references are available in hard copy, compact disk (CD-ROM), and personal digital assistant (PDA) versions.^{34,35} Online databases that provide summary statements prepared by experts in the field of teratology and updated on a frequent basis include TERIS and REPROTOX (available at <http://www.micromedex.com/reprorisk> [accessed January 14, 2008]). In addition, the Organization of Teratology Information Specialists

(OTIS) provides individualized information to clinicians as well as the public via toll-free telephone access (see <http://otispregnancy.org> [accessed January 14, 2008]). Clinicians or patients who are interested in pregnancy registries that are open for enrollment can locate a current list at the FDA's Office of Women's Health Web site (available at <http://www.fda.gov/womens/registries> [accessed January 14, 2008]).

Selected Human Teratogens

Table 20-2 presents the potential effects of selected human teratogens, some of which are discussed further in the following sections.

Vitamin K Antagonists

A specific pattern of congenital anomalies referred to as the *fetal warfarin syndrome* has been identified in some children born to mothers who use medications such as phenprocoumon, acenocoumarol, flunindione, warfarin, and phenindione, which are vitamin K antagonists. The features include nasal hypoplasia, stippled epiphyses visible on

radiographs, and growth restriction. Central nervous system (CNS) and eye abnormalities including microcephaly, hydrocephalus, Dandy-Walker malformation, agenesis of the corpus callosum, optic atrophy, cataracts, and mental retardation occur occasionally.^{36,37} The critical period for the warfarin embryopathy appears to be between 6 and 9 weeks' gestation. A systematic review of 17 studies involving a total of 979 exposed pregnancies estimated a 6% incidence of warfarin embryopathy. In addition, 22% of exposed pregnancies ended in spontaneous abortion, 4% in stillbirth, and 13% in preterm delivery.³⁸ A large multicenter study of 666 pregnancies with exposure to vitamin K antagonists reported a significant increase in the rate of major birth defects overall, relative to unexposed healthy comparison women (odds ratio [OR], 3.86; 95% confidence interval [CI], 1.76 to 8.00). In that study, only 2 infants (0.6%) were thought to have warfarin embryopathy. In addition, the rate of preterm delivery was increased (16.0% versus 7.6%; OR, 2.61; CI, 1.76 to 3.86); the mean birth weight of term infants was significantly lower (3166 versus 3411 g); and the rate of spontaneous abortion was significantly higher (42% versus 14%; OR, 3.36; CI, 2.28 to 4.93) with exposure.¹⁸

In one study of 71 pregnancies occurring in 52 women with prosthetic heart valves who were being treated with warfarin, the risk for

TABLE 20-2 EFFECTS OF SELECTED TERATOGENS

Drug	Potential Effects	Comments
ACE inhibitors	Calvarial hypoplasia, renal dysgenesis, oligohydramnios, IUGR, and neonatal renal failure	Risk seen with use in second and third trimester
Alcohol	Syndrome: prenatal and postnatal growth restriction, microcephaly, craniofacial dysmorphism (1-4/1000 live births); renal, cardiac, and other major malformations increased	Risk not limited to first trimester; late pregnancy use is associated with IUGR and developmental delay; incidence is 4-44% among "heavy drinkers"
Antidepressants (SSRIs)	Possible cardiac defects, NTDs, omphalocele; neonatal pulmonary hypertension and withdrawal syndrome	—
Aminopterin and methotrexate	Syndrome: calvarial hypoplasia, craniofacial abnormalities, limb defects; possible developmental delay	Syndrome associated with methotrexate >10 mg/wk
Androgens and norprogesterones	Masculinization of external female genitalia	Labioscrotal fusion can occur with exposure; as many as 50% of those exposed are affected
Carbamazepine	NTDs (1%); possible facial hypoplasia and developmental delay	—
Corticosteroids	Cleft lip/palate increased threefold to sixfold; IUGR increased with high doses	—
Diethylstilbestrol	Clear cell adenocarcinoma of the vagina, vaginal adenosis, abnormalities of the cervix and uterus, testicular abnormalities, male/female infertility	—
Isotretinoin	Syndrome: CNS malformations, microtia/anotia, micrognathia, thymus abnormalities, cleft palate, cardiac abnormalities, eye anomalies, limb reduction defects (28%); miscarriage (22%), developmental delay (47%)	—
Lithium	Small increase in Ebstein cardiac anomaly	—
Penicillamine	Cutis laxa with chronic use	—
Phenytoin	Syndrome: IUGR, microcephaly, facial hypoplasia, hypertelorism, prominent upper lip (10%); possible developmental delay	Full syndrome in 10%; up to 30% exhibit some features
Streptomycin	Hearing loss, eighth nerve damage	—
Tetracycline	Discoloration of deciduous teeth and enamel hypoplasia	Risk only in second and third trimester
Tobacco	Oral clefts: relative risk, 1.22-1.34; IUGR, IUFD, abruption	—
Trimethadione	Syndrome: oral clefts, craniofacial abnormalities, developmental delay (80%)	—
Valproic acid	NTDs (1-2%); facial hypoplasia, possible developmental delay	—
Warfarin	Syndrome: nasal hypoplasia, stippled epiphyses, growth restriction (6%); also increased microcephaly, Dandy-Walker syndrome, IUGR, preterm birth, mental retardation	Greatest risk is at 6-9 wk

ACE, angiotensin-converting enzyme; CNS, central nervous system; IUGR, intrauterine growth restriction; NTD, neural tube defect.

adverse outcome was found to be significantly greater with doses greater than 5 mg/day.³⁹ A review of 85 pregnancies involving exposure to a coumarin drug only after the first trimester reported that 1 pregnancy ended in stillbirth, 3 in spontaneous abortion, and 19 in preterm births; 1 infant had a CNS anomaly, and none had the warfarin embryopathy.³⁸ In addition, in one large study that evaluated the cognitive performance of 307 children prenatally exposed to warfarin, compared with that of nonexposed children, mean IQ scores did not differ significantly, but low intelligence scores (IQ < 80) occurred more frequently in those children whose exposure was limited to the second and third trimester.⁴⁰

Antiepileptic Drugs

As a group, most older drugs used to treat seizure disorders are associated with an increase in the risk of congenital malformations.^{41,42} This has been suggested to indicate that the underlying disease is the teratogenic cause. Newer studies have challenged this concept⁴²⁻⁴⁴; however, it is difficult to separate the effects of the disease from those of treatment, especially for more severe epilepsy, which is unlikely to be untreated during pregnancy. The use of multiple anticonvulsant medications (polytherapy) as opposed to a single drug (monotherapy) is associated with greater risk of structural defects.^{43,45,46} It is unclear whether this is a result of drug-drug interactions, more severe disease in women requiring treatment with polytherapy, or a combination of the two.

Diphenylhydantoin

Phenytoin as a treatment for seizure disorders has been associated with an increased risk for oral clefts and for a pattern of anomalies known as the *fetal hydantoin syndrome*. This pattern is estimated to occur in 10% of infants with prenatal exposure and includes prenatal or postnatal growth restriction, microcephaly, hypoplasia of the digits and nails, and craniofacial abnormalities (i.e., short nose with low nasal bridge, ocular hypertelorism, abnormal ears, and a wide mouth with a prominent upper lip).⁴⁷⁻⁴⁹ Initial reports suggested that mental deficiency was also a common feature of fetal hydantoin syndrome.⁵⁰ However, the limited subsequently published data suggest that neurobehavioral effects may be more mild.⁵¹ For example, Scolnik and colleagues⁵² reported that average IQ scores were 10 points lower in children exposed to phenytoin monotherapy, compared with unexposed children born to mothers who were matched on age and socioeconomic status.

Valproic Acid

Studies over the last 2 decades have associated early first-trimester exposure to valproic acid with an increased risk for neural tube defects, specifically spina bifida. The estimated risk is about 1% to 2%, with higher doses thought to be associated with higher risk.^{19,53} It has been estimated that the overall risk for major birth defects is increased by fourfold to sevenfold after valproate monotherapy, with increased risks for specific cardiovascular, limb, and genital anomalies noted in some reports.²⁷ As with other anticonvulsants, a pattern of minor malformations and growth deficiency has also been identified for valproic acid; it includes midface hypoplasia, epicanthal folds, short nose, broad nasal bridge, thin upper lip, thick lower lip, micrognathia, and subtle limb defects (primarily hyperconvex fingernails).⁵⁴ In addition, there is some evidence that valproic acid monotherapy is associated with reduced cognitive ability and additional educational needs in children prenatally exposed.^{55,56}

Carbamazepine

Similar to valproic acid, carbamazepine has been associated with an increased risk for spina bifida (approximately 1%) with exposure in the early first trimester.¹⁶ It has also been linked to a pattern of minor craniofacial abnormalities, including upslanting palpebral fissures, a long philtrum, and nail hypoplasia, as well as growth deficiency and microcephaly.²⁸ Although some small studies have suggested developmental delay after prenatal exposure to carbamazepine,⁵⁷ others have not.^{58,59}

Other Antiepileptic Drugs

A number of newer antiepileptic medications have been introduced into practice over the past several years, including lamotrigine, gabapentin, and topiramate. Although these agents are currently being studied, insufficient information has been collected to rule out or identify risks similar to those seen with older anticonvulsants. Furthermore, specific risks associated with the use of older- and newer-generation anticonvulsants for other indications, such as treatment of mood disorders, has not been well studied.

Chemotherapeutic and Immunosuppressive Agents

Cyclophosphamide

Eight case reports documenting a unique pattern of malformation in infants prenatally exposed to cyclophosphamide have been published.⁶⁰ Features include growth deficiency, craniofacial anomalies, and absent fingers and toes. In three of these cases, the infant survived and developmental information was available; significant delays were noted in all three. The magnitude of the risk is unknown.

Methotrexate

Both aminopterin and its methyl derivative, methotrexate, have been associated with a specific pattern of malformation that includes prenatal-onset growth deficiency, severe lack of calvarial ossification, hypoplastic supraorbital ridges, small low-set ears, micrognathia, limb abnormalities, and, in some cases, developmental delay.^{61,62} The majority of affected infants have been born to women treated with high-dose methotrexate for psoriasis or neoplastic disease or as an abortifacient. Although the magnitude of the risk is unknown, it has been suggested that the dose necessary to produce the aminopterin/methotrexate syndrome is greater than 10 mg/wk.^{63,64}

Adrenal Corticosteroids

Among four recent case-control studies, three concluded that systemic corticosteroid use in the first trimester appears to be associated with a threefold to sixfold increased risk for cleft lip with or without cleft palate and possibly cleft palate alone.⁶⁵⁻⁶⁸ It is unclear to what extent this association was caused by the various underlying maternal diseases involved in these studies. If only the positive studies are considered, this relative risk translates to a risk of approximately 3 to 6 cases per 1000 pregnancies exposed in the critical period for lip and palate closure. Furthermore, an association has long been recognized between prenatal exposure to corticosteroids and intrauterine growth restriction in humans. The risk appears to be dose-related, suggesting that this concern can be minimized with lower doses.^{69,70}

Antihypertensive Medications

Angiotensin I Converting Enzyme (ACE) Inhibitors and Angiotensin II Receptor Antagonists

Based on case reports and case series, prenatal exposure to an ACE inhibitor (benazepril, captopril, enalapril, enalaprilat, fosinopril, lisinopril, moexipril, quinapril, ramipril) or to an angiotensin II receptor antagonist (losartan, candesartan, valsartan, tasosartan, telmisartan) during the second or third trimester of pregnancy is associated with an increased risk for fetal hypotension, renal failure, and oligohydramnios leading to fetal growth restriction, joint contractures, pulmonary hypoplasia, and stillbirth or neonatal death. Calvarial hypoplasia has also been reported as part of the fetopathy. In children who survive the neonatal period, renal insufficiency often occurs. The magnitude of the risk after second- or third-trimester exposure is not known.^{25,71}

First-trimester exposure to ACE inhibitors or to angiotensin II receptor antagonists has not been well studied. One recent database linkage study suggested an increased risk for cardiovascular defects (risk ratio [RR], 3.72; CI, 1.89 to 7.30) and CNS defects (RR, 4.39; CI, 1.37 to 14.02) in infants born to mothers who had received a prescription for an ACE inhibitor in the first trimester of pregnancy, compared with infants born to women with no exposure to antihypertensive medications during pregnancy. However, these findings have not yet been replicated, and it is possible that they were confounded by inability to completely control for maternal diabetes.⁷²

Psychotherapeutic Medications

Lithium

Early reports from a lithium exposure registry⁷³ included information on 143 infants exposed to lithium in utero; 13 of these were reported to have malformations, 4 of which were Ebstein anomaly (downward displacement of the tricuspid valves within the right ventricle). This finding represented an excess over expected numbers, because the baseline incidence of Ebstein anomaly is approximately 1 in 20,000 births. A subsequent prospective cohort study involving follow-up of 148 women with first-trimester exposure to lithium noted one case of Ebstein anomaly, with no other cardiac malformations identified in the sample.⁷⁴ In contrast, a case-control study published by Zalstein and associates⁷⁵ found no prenatal exposure to lithium among 59 patients with Ebstein anomaly. In summary, the available data suggest that, if there is a risk at all, the use of lithium in the first trimester of pregnancy is associated with a very small increased risk for Ebstein anomaly.

Selective Serotonin Reuptake Inhibitors

Although medications within the selective serotonin reuptake inhibitor (SSRI) class of antidepressants (fluoxetine, paroxetine, sertraline, citalopram, escitalopram, fluvoxamine) have been studied extensively in pregnancy, most investigations have had insufficient sample sizes to rule out increased risks for specific malformations associated with individual medications. Several recent studies have suggested a small increased risk for cardiac defects (approximately twofold) specifically with first-trimester exposure to paroxetine.^{76,77} One recent large, multisite, case-control study did not find an overall increase in cardiac defects but found increased risks for other selected malformations in association with first-trimester use of all SSRIs combined. These specific defects included anencephaly (adjusted OR, 2.4; CI 1.1 to 5.1),

craniosynostosis (adjusted OR, 2.5; CI, 1.5 to 4.0), and omphalocele (adjusted OR, 2.8; CI, 1.3 to 5.7).⁷⁸ A second large, multisite, case-control study did not confirm these findings with respect to craniosynostosis, omphalocele, neural tube defects, or cardiac defects when all SSRIs were evaluated as a group but did find significantly increased risks with specific drugs. With first-trimester sertraline use, the odds were increased for omphalocele (adjusted OR, 5.7; CI, 1.6 to 20.7) and septal defects (adjusted OR, 2.0; CI, 1.2 to 4.0).⁷⁹ With first-trimester paroxetine use, the odds were increased for right ventricular outflow tract obstruction defects (adjusted OR, 3.3; CI, 1.3 to 8.8).

In addition to these findings with respect to structural defects, several other adverse outcomes have been associated with late pregnancy exposure to SSRIs. These include a possible small increased risk for persistent pulmonary hypertension of the newborn⁸⁰ and a well-established increased risk for a neonatal withdrawal or toxicity syndrome consisting primarily of CNS, motor, respiratory, and gastrointestinal signs that are generally mild and resolve by 2 weeks of age.⁸¹

Retinoids

Vitamin A (Retinol)

The teratogenic potential of excessive doses of preformed vitamin A is well described in animal models^{82,83}; however, the threshold dose at which naturally occurring vitamin A might be teratogenic in humans remains controversial. Two studies suggested that preformed vitamin A supplementation at amounts greater than 10,000 IU per day in the first trimester of pregnancy is associated with a small increased risk of selected defects that are consistent with those known to be induced by synthetic retinoids.^{84,85} However, other studies did not confirm these findings or suggested that the elevated risk is concentrated at doses greater than 40,000 IU per day.⁸⁶⁻⁸⁸ The current recommended daily allowance (RDA) for pregnant women carrying a single fetus is 2560 IU of vitamin A. To avoid any of these potential concerns, many prenatal vitamin formulations have replaced retinol with β -carotene.

Isotretinoin and Other Oral Synthetic Retinoids

Consistent with animal data, an increased risk of pregnancy loss and a characteristic pattern of malformations and mental deficiency have been identified after prenatal exposure to isotretinoin. This pattern includes CNS malformations, microtia/anotia, micrognathia, cleft palate, cardiac and great vessel defects, thymic abnormalities, eye anomalies, and, occasionally, limb reduction defects.^{20,89} The estimated risks are at least as high as 22% for spontaneous abortion, 28% for structural defects, and 47% for mild to moderate mental deficiency, even if no structural abnormalities are present.^{20,90,91} Affected children have been reported with exposures to usual therapeutic doses and with treatment for durations shorter than 1 week in the first trimester. There does not appear to be a risk of malformations when the drug is discontinued before conception, which is consistent with the half-life of isotretinoin.^{92,93} Pregnancy prevention among women who are prescribed isotretinoin continues to be a challenge. A third-generation restricted distribution program, iPledge, was implemented in March 2006; it mandates close monitoring of birth control practices and negative pregnancy testing before dispensing of prescriptions for isotretinoin.

Risks for the retinoid embryopathy are also found with other oral synthetic retinoids such as etretinate and its metabolite, acitretin, which are used for the treatment of psoriasis.⁹⁴ The extremely long

half-life of etretinate led to its removal from the U.S. market in 1998. The half-life of acitretin is considerably longer than that of isotretinoin (50 to 60 hours), and it can be converted to etretinate with maternal ingestion of alcohol. Therefore, the drug must be discontinued before pregnancy, and alcohol must be avoided during the entire period of treatment and for at least 2 months after discontinuation of therapy.^{95,96}

Ionizing Radiation

Prenatal exposure to high-dose radiation is associated with an increased risk of microcephaly, mental deficiency, and growth deficiency based on data derived from a small number of pregnant survivors of the atomic bombs in Nagasaki and Hiroshima.⁹⁷ It is estimated that doses of 50 rad (50 cGy) or greater to the uterus are required to produce these effects. The highest risk appears to be associated with exposures between 8 and 15 weeks' gestation, with a higher threshold dose at more advanced gestational ages.⁹⁸ The available data do not support an increase in the risk of mental retardation associated with high-dose radiation exposure beyond 25 weeks or before 8 weeks of gestation.⁹⁷ Based on dose-response calculations, it is not thought that diagnostic procedures involving radiation have the potential to pose a risk to the fetus unless the cumulative dose to the uterus is greater than 10 cGy; conservative guidelines suggest that doses should be kept below 5 cGy to the uterus during pregnancy if radiation exposure is required.⁹⁹

Environmental Agents

Methylmercury

Prenatal exposure to methylmercury has been recognized as a neurodevelopmental teratogen since the experience of environmental contaminations in Japan (Minamata Bay) and Iraq in the mid-20th century.^{100,101} The reported effects, termed *fetal methylmercury syndrome* or *congenital Minamata disease*, include cerebral palsy and a variety of neurologic and functional problems as well as mental deficiency.¹⁰² Although the lower limit of exposure that may pose a risk in prenatal development remains controversial, an independent U.S. National Research Council expert committee concluded that limiting maternal intake to no more than 0.1 $\mu\text{g}/\text{kg}/\text{day}$ was sufficient to protect the fetus.¹⁰³ Currently, consumption of contaminated fish or marine mammals is the major source of methylmercury exposure in most populations. The U.S. Environmental Protection Agency and FDA have advised pregnant women and women of childbearing age who may become pregnant to avoid eating shark, swordfish, king mackerel, and tilefish and to limit their average consumption of other cooked fish to 12 ounces (340 g) per week in order to prevent fetal exposure to excessive amounts of methylmercury.¹⁰⁴ Similarly, limiting tuna consumption to no more than three servings per week is recommended because of methylmercury concerns.

Lead

In utero exposure to very high levels of lead (maternal blood concentrations $>30 \mu\text{g}/\text{dL}$) has been associated with an increase in spontaneous abortion, preterm birth, and mental deficiency.^{105,106} Prenatal exposure to lower levels ($>10 \mu\text{g}/\text{dL}$) may be associated with subtle neurobehavioral effects; however, these effects may not persist into older childhood.¹⁰⁷⁻¹⁰⁹ Occupational and environmental exposures to lead that precede pregnancy may result in fetal exposure due to mobilization of lead stored in maternal bone. These effects may be modified by maternal intake of calcium.¹¹⁰

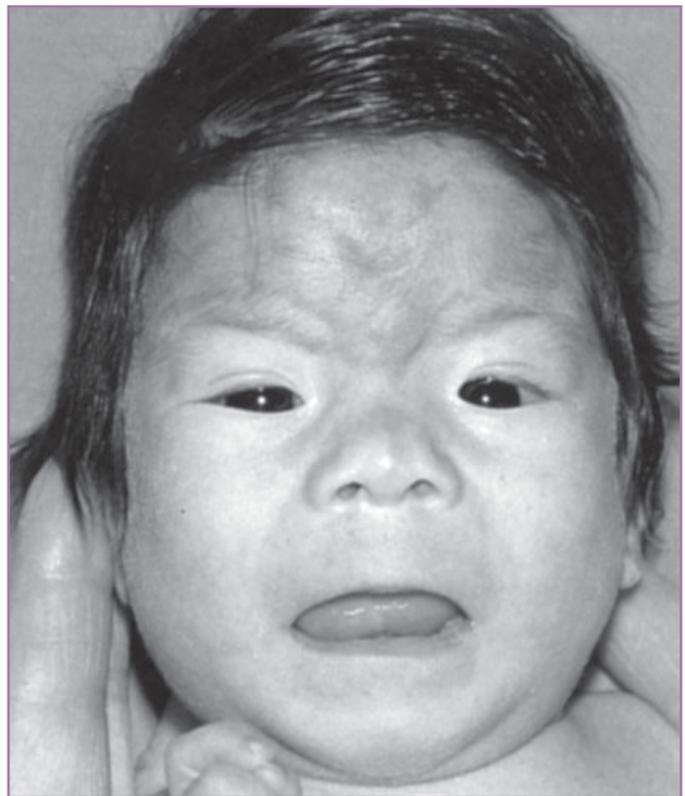

FIGURE 20-1 Nine-month-old infant with fetal alcohol syndrome. (From Streissguth AP, Aase JM, Clarren SK, et al: Fetal alcohol syndrome in adolescents and adults. *JAMA* 265:1961, 1991. Copyright 1991, American Medical Association.)

Social and Illicit Drugs

Alcohol

A pattern of anomalies, known as the *fetal alcohol syndrome (FAS)*, was first described more than 35 years ago in a case series of infants born to alcoholic women.¹¹¹ The characteristic features of this disorder are prenatal and/or postnatal growth retardation, microcephaly or other CNS dysfunction including neurobehavioral deficits and neurologic impairment, and characteristic facial anomalies consisting of short palpebral fissures and a smooth philtrum, with a smooth, thin vermilion border of the upper lip (Fig. 20-1).^{112,113} Although FAS is difficult to diagnose, particularly in the newborn period, estimates of its incidence in selected U.S. and Western European populations are approximately 1 to 4 per 1000 live births.¹¹⁴

Many more children are thought to have alcohol-related neurobehavioral or neurologic impairment with or without some structural features. In addition, congenital heart defects, oral clefts, and abnormalities of the eyes, brain, and kidneys are more common than expected among the children of women who drink moderately to heavily during pregnancy.¹¹⁵⁻¹¹⁸ These children, variably described as having partial FAS, alcohol-related neurodevelopmental abnormalities (ARND), or alcohol-related birth defects (ARBD), are now thought of as representing a continuum known as fetal alcohol spectrum disorders (FASD). Accurate estimates of the prevalence of FASD are lacking; however, one population-based study in the Seattle, Washington, area suggested that the rates may be as high as 1 per 100 children.¹¹⁴ Increased risks for spontaneous abortion, stillbirth, and sudden infant death syn-

drome have also been linked to prenatal alcohol exposure, particularly exposure from alcohol consumed in a heavy episodic or binge pattern.¹¹⁹⁻¹²²

Both animal and human data support a dose-response relation in terms of risk for FAS/FASD. However, because of variabilities in diagnosis and difficulties in obtaining and validating exposure information reported by pregnant women, estimates vary widely regarding the magnitude of the risk. For example, estimates for the full-blown syndrome range from about 4% to 44% of children born to women who drink heavily during pregnancy.^{123,124} The women at highest risk appear to be those who have already had an affected child and who continue to consume alcohol in subsequent pregnancies. Lower levels of maternal alcohol consumption have been associated with less severe neurobehavioral outcomes and persistent growth effects.¹²⁵⁻¹²⁷ However, the exact threshold doses and patterns of consumption for these effects are not well understood. For example, full-blown FAS is typically seen among the children of women who report consuming an average of six or more standard drinks (beer, wine, or spirits) per day during pregnancy. However, some studies have suggested that women who consume more than two standard drinks per day during pregnancy are at increased risk. These risks may be mediated or ameliorated by the pattern of drinking (i.e., binge drinking versus more frequent and lesser quantities), maternal age, nutrition, and genetic susceptibility.^{118,128-130} Furthermore, the duration of exposure is likely to be important, in that CNS development continues throughout gestation.¹³¹

At present, the data are insufficient to assign a risk to certain common patterns of prenatal alcohol exposure, such as alcohol consumption limited to occasional binge episodes before recognition of pregnancy. However, the data do support the notion that reduction or discontinuation of alcohol consumption at any point in pregnancy may be beneficial. A lower threshold of exposure, below which no effects will be seen, has not been defined. Therefore, for those women who are planning pregnancy or who have the potential to become pregnant, the U.S. Surgeon General has recommended that the safest course is to avoid alcohol entirely during pregnancy.¹³²

Tobacco

Maternal cigarette smoking is associated with a variety of harmful effects on the embryo and fetus, including increased risks for specific congenital malformations, spontaneous abortion, placental complications, preterm delivery, reduced birth weight, and sudden infant death syndrome. The structural malformations that have been significantly associated with first-trimester smoking include oral clefts and gastroschisis. A recent meta-analysis of 24 studies estimated the risk for oral clefts to be low: the relative risk for cleft lip with or without cleft palate was 1.34 (CI, 1.25 to 1.44), and for cleft palate alone it was 1.22 (CI, 1.10 to 1.35).¹³³ Some studies have suggested gene-environment interactions in susceptibility for oral clefts when mothers smoke during early pregnancy. Infants who have a null deletion of the detoxifying gene *GSTT1*, or infant genotype at the Taq1 site for transforming growth factor- α and whose mothers smoke are at higher risk for certain oral clefts than infants with either risk factor alone.^{134,135} The elevated risks for gastroschisis after maternal smoking are also estimated to be low.¹³⁶ However, as with oral clefts, there is some evidence for gene-environment interaction between maternal smoking and polymorphisms of fetal genes involved in vascular response.¹³⁷ Other defects reported to occur with increased frequency after pregnancy exposure to tobacco smoke include craniosynostosis and club foot.¹³⁸⁻¹⁴⁰ Most studies with dose information available have suggested a dose-response relation for each of these defects, with the heaviest smokers being at highest risk.

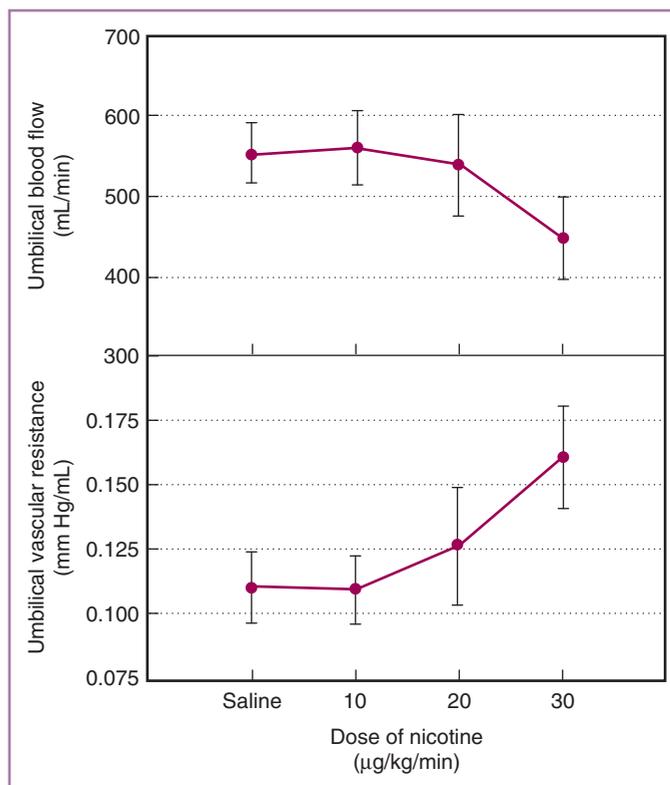

FIGURE 20-2 Umbilical blood flow and umbilical vascular resistance response to maternally administered nicotine. Maternal administration produced a decrease in umbilical blood flow from a baseline of 554 ± 37 to 449 ± 52 mL/min, which was significant only at the $30 \mu\text{g/kg/min}$ dose ($P < .05$). Umbilical vascular resistance increased from a baseline of 0.110 ± 0.013 to 0.161 ± 0.020 mm Hg/mL, which was significant only at the $30 \mu\text{g/kg/min}$ dose ($P < .05$). For the $20 \mu\text{g/kg/min}$ dose, $n = 6$. For saline solution and all other doses, $n = 8$. (From Clark KE, Irion GL: Fetal hemodynamic response to maternal intravenous nicotine administration. *Am J Obstet Gynecol* 167:1624, 1992.)

The deleterious effects of cigarette smoking on other pregnancy outcomes are well documented. Intrauterine growth restriction is the most consistently reported adverse outcome. On average, babies born to women who smoke during pregnancy are 200 g lighter than those born to comparable women who do not smoke, with a clear dose-response gradient.¹⁴¹ This may be a result, in part, of the reduction in uterine blood flow associated with rising levels of plasma nicotine in women who smoke (Fig. 20-2).¹⁴² Lesser reductions in birth weight have also been noted when exposure is limited to environmental or passive smoke.¹⁴³ A strong gene-environment and gene-gene-environment interaction has been demonstrated between the cytochrome P450 isozyme *CYP1A1* and *GSTT1* maternal metabolic genes and infant birth weight in mothers who smoke.¹⁴⁴

Perinatal mortality is also increased with maternal smoking, in part because of the increased risks of placental complications and preterm delivery. In one large study, the combined risk for fetal or infant death for primiparous women who smoked less than one pack per day was estimated to be 25% higher than that for nonsmoking women, and the risk was 56% higher for those who smoked one pack per day or more.¹⁴⁵ However, if smoking is discontinued in the first half of gestation, evidence indicates that the effects on birth weight can be eliminated.¹⁴⁶⁻¹⁴⁸

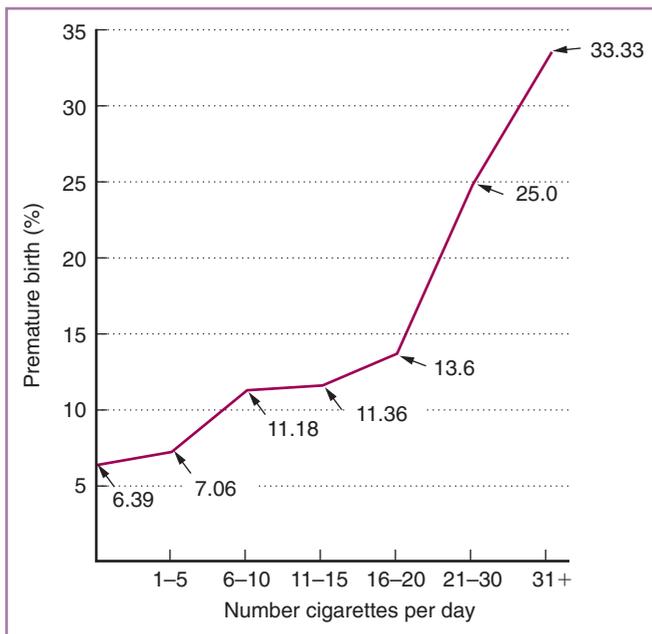

FIGURE 20-3 Dose-response relationship of cigarette smoking and prematurity. (From Simpson WJ: A preliminary report on cigarette smoking and the incidence of prematurity. *Am J Obstet Gynecol* 73:808, 1957.)

Furthermore, based on dose-response data, any reduction in the number of cigarettes smoked may reduce risk for low birth weight, preterm birth, and placental complications (Fig. 20-3).¹⁴⁹⁻¹⁵³

Cocaine

Various structural defects have been reported in newborns prenatally exposed to cocaine and are thought to be the result of intrauterine vascular accidents; they include cavitory CNS lesions, genitourinary anomalies, terminal transverse limb reduction defects, and intestinal atresia/infarction.¹⁵⁴⁻¹⁵⁷ In addition to these structural defects, an increased risk for placental abruption and premature rupture of membranes was documented in a systematic review.¹⁵⁸ However, assessment of the absolute risk for these outcomes after cocaine exposure is complicated by the fact that affected pregnancies often involve use of other drugs, tobacco, and alcohol as well as cocaine; the purity and dose of the drug is often not known, and multiple potential other confounding factors could be involved.

The most consistently reported effects of prenatal cocaine exposure are a small but statistically significant increase in intrauterine growth restriction^{159,160} and abnormalities in neonatal state regulation and motor performance.¹⁶¹ However, based on a synthesis of 36 published studies of children 6 years of age or younger, Frank and colleagues¹⁶² concluded that no consistent negative association existed between prenatal cocaine exposure and postnatal physical growth, developmental test scores, receptive language, or standardized parent and teacher reports of child behavior. An association between prenatal cocaine exposure and decreased emotional expressiveness has been suggested.¹⁶³

Chapter 21

Assessment of Fetal Health

Christopher R. Harman, MD

Defining fetal status clarifies many perinatal decisions. If fetal condition is reassuring and the situation is stable, management is confidently conservative, seeking further intrauterine time for maturation. If fetal status is uncertain, management will depend on gestational age: near term, delivery may be the best option; before then, enhanced surveillance and preparation for delivery is indicated; remote from term, intrauterine therapy might be in order. When fetal compromise is certain, our primary responses are delivery and neonatal management—down to the frontiers of viability. So, what we do is determined by what we think of fetal status.

Just as fetal status indicates management, fetal and maternal conditions modify our approach to surveillance. Risk assignment, and the corresponding acuity of our monitoring, is a process of constant revision. Historical factors are important, but they give way as more specific information becomes available from first- and second-trimester screening and the performance of the individual fetus. Maternal conditions change as well, with advancing gestation, worsening disease, and interaction of maternal treatment all superimposed on changes in placental function and fetal demands. Monitoring must cope with these many complexities.

As the interlocutor between maternal-fetal status and clinical action, assessment of fetal well-being must meet many demands. These requirements, and the complex situations in which they must apply, dictate the prime directive of all fetal assessment: No single parameter can suffice. The aim of this chapter is to describe the integration of multiple components in a comprehensive approach to fetal assessment.

Normal Fetal Behavior

If we can reliably equate normal behavior with normal healthy status, many types of fetal activity provide avenues for evaluation of fetal status. Beginning with pioneering work focused on fetal breathing,^{1,2} it became clear that the absence of specific fetal behaviors could mean serious hypoxemia or acidosis.³⁻⁵ The number of parameters has multiplied, and their application has extended to progressively lower gestational ages, but the general pattern has endured for most variables: present equals normal, and absent equals abnormal.

Basic Functions

Even the most primary functions are subject to marked variability that conditions monitoring techniques and interpretation. Fetal heart rate

(FHR) comes under increasing parasympathetic dominance as pregnancy progresses, resulting in a gradual decrease in heart rate, increase in variability, increasing responsiveness (both accelerations and decelerations), and the emergence of complex relationships with other behaviors.⁶ Variability in basic functions is not restricted to neurologic interactions; as placental and fetal vascular systems mature, so do Doppler resistance characteristics, regionalization of blood flow, and cardiovascular reflexes.⁷ Even at term, changes in cerebral circulation may reflect maturation patterns.⁸ In short, the interpretation of fetal vital functions requires detailed understanding of the fetal environment.

Individual Behaviors

Coordinated activities such as thumbsucking, respiratory movements, and apparently deliberate changes in position begin very early. A large repertoire of fetal activities is already established by 10 to 12 weeks. These individual behaviors change throughout pregnancy, and their distribution may alter dramatically. For example, fetal hiccups are the most dominant form of early diaphragmatic activity, giving way later to rhythmic fetal breathing movement.⁹ Fetal breathing movements, in turn, become much more responsive to maternal glucose levels, the emergence of behavioral states, and circadian rhythms, and they may even show patterns of carbon dioxide responsiveness identical to those of newborn infants as pregnancy progresses.^{10,11} Fetal body movement also demonstrates increasing sophistication with advancing gestation. The wriggling activity seen at 8 to 10 weeks gives way to the total body jumping activity that gradually diminishes as the second trimester begins. By that time, defined kicking, delicate hand movements, fetal breathing, and virtually all the individual behaviors of the term fetus can be demonstrated. The distribution of individual behaviors changes markedly over the remainder of pregnancy, including the often dramatic reduction in fetal kicking at 34 to 38 weeks with the onset of small-amplitude highly coordinated movements typical of infants. Chapter 13 addresses fetal breathing and body movements in greater detail.

Patterned Behavior

As individual behaviors change, so do their relationships with one another. In the first trimester, individual behaviors are present, often to the virtual exclusion of others (e.g., the fetus almost never hiccups while moving). By 18 to 20 weeks, there are periods of high and low activity, during which many behaviors may appear simultaneously.

Beginning at this time, diurnal patterns are evident in fetal urine production, adrenal steroid production, heart rate, Doppler arterial velocities, and virtually all complex behaviors.¹²⁻¹⁴

Fetal Behavioral States

By the beginning of the third trimester, behavioral states 1F to 4F can be defined,^{4,9,15} and they are directly analogous to the neonatal behavioral states originally described by Prechtl.¹⁶ Two patterns dominate—quiet sleep and active sleep. In quiet sleep, state 1F, rapid eye movements and repetitive mouthing movements are present, but almost all other movements are absent. As term approaches, this level of inactivity extends, from a mean of about 220 seconds in mid-trimester, to as long as 110 minutes by 40 weeks.^{9,17} During state 2F, active sleep, movements are grouped, providing efficient monitoring, because multiple activities overlap. In state 4F (active awake), the “jogging fetus” illustrates a high level of voluntary activity and also a sustained high heart rate where return to baseline may be interpreted as decelerations. As with its neonatal equivalent, state 3F (quiet awake) is unusual and short and is seldom present before term. Clearly, fetal assessment using any or all of these variables must account for their complex presentation and for their influence on basic functions, such as Doppler characteristics.^{18,19}

Coupled Behaviors

Several behavioral characteristics provide advantages for monitoring because they are coupled. The classic association of FHR accelerations with fetal movement, the basis of the nonstress test (NST), is so reliable that an acceleration of significant amplitude can be inferred to prove fetal activity.²⁰ Fetal breathing movements and maternal glucose levels are reliably connected, so that fetal assessment units operate most efficiently in the 2 to 3 hours after each mealtime.²¹ Of course, fetal breathing movements produce effects in many other individual parameters (Fig. 21-1). Over the longer term, the pairing of sleep and wake cycles may be the most reliable evidence available of normal fetal oxygen status.²²

Fetal-to-Neonatal Transition

True “infant” behavior in term fetuses is seen in many systems. Sometimes this responsiveness is problematic; even earlier than term, the

fetal ductus arteriosus may begin to close with indomethacin exposure.²³ During behavioral state 4F, in addition to unusually vigorous activity, the “jogging fetus” coordinates combined facial and chest movements that can be seen clearly as “crying.” During these short periods at term, it appears the fetus is actually awake. Finally, the fetus exposed to high concentrations of oxygen will initiate carbon dioxide-dependent breathing activity that includes deep inhalation and expiration movements, moving much more pulmonary fluid than in normal fetal breathing movement activity.¹¹ This “true breathing” includes a series of cardiovascular changes similar to those of infancy, all of which may be reversed by allowing fetal oxygen levels to decline back to normal. These levels of responsiveness, including Doppler evaluation of flow changes, may provide detailed information about fetal maturity.²³

Fetal Responses to Hypoxemia

Fetal evaluation relies on inference: alterations in fetal behavior imply alteration in fetal status. For many reasons, such inference must be cautious. First, oxygen in the fetal environment is not easily measured: with oxygen partial pressure seldom exceeding 60 mm Hg throughout pregnancy, simply measuring PO₂ is imprecise; exacting methodology measuring oxygen content is more accurate. Second, PO₂ normally declines throughout gestation, provoking many normal adaptations. Next, responses to abnormal drops in oxygen may be only temporary responses to a variety of acute, chronic, or acute-superimposed-on-chronic insults,²⁴ so the mechanisms of compensation are highly individualized.^{25,26} For discussion, fetal compensatory responses can be grouped into three phases:

1. *Increase oxygen supply.* Several temporary responses will increase oxygen availability. Although these produce the marginal increments necessary to respond to most incidental issues, they are unlikely to suffice in the case of placental insufficiency or marginal fetal status subject to the onset of labor. These include increase in baseline heart rate, increase in hemoglobin concentration, improved cardiac contractility or efficiency, and increased oxygen extraction.^{24,27} These steps are limited in capacity. Whereas mild intrauterine growth restriction (IUGR) features increased nucleated red cell liberation and a tendency toward polycythemia, more severe IUGR features even higher libera-

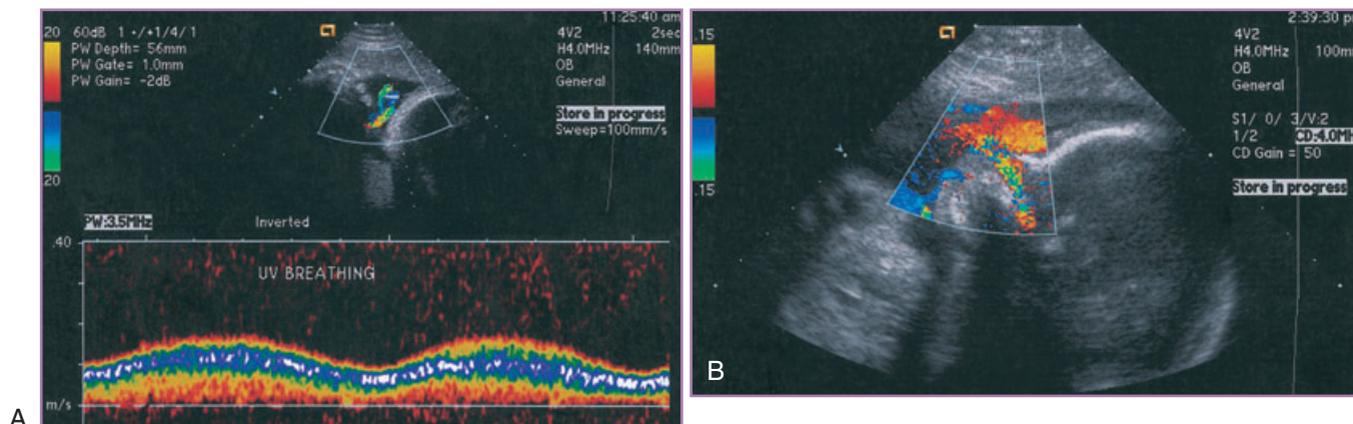

FIGURE 21-1 Fetal breathing movement. **A**, Umbilical venous fluctuations accompanying diaphragmatic excursion during fetal breathing movements. **B**, Nasal flaring of expelled lung fluid during fetal breathing movement.

tion of premature red cell forms but worsening anemia.²⁸ On the other hand, during “normal” situations of decreased oxygen (e.g., during contractions in term labor), increased oxygen extraction may contribute up to 14% additional oxygen on a virtually instantaneous basis.²⁹ Even these initial responses may be complex—rising placental resistance may be met by increased fetal blood pressure, with the result that changes in cardiac function and cerebral perfusion, once thought to be caused by hypoxemia, may in fact be part of the fetal hypertensive state.³⁰

2. Control oxygen distribution. The distribution of blood flow results in preservation of oxygenation in vital centers of the brain, heart, adrenals, and placenta, with corresponding reduction to mesenteric, renal, and distal aortic outflow tracts (see Chapter 14).^{31,32} The resulting differences in perfusion will lead to differential growth rates and asymmetrical IUGR and will have long-term implications far beyond fetal and neonatal health. Many of these hemodynamic adaptations can be depicted on serial Doppler evaluation of placental and fetal systemic circulations (see later), which occur before acute changes in other fetal behaviors. Initial steps may be subtle—changes in the proportion of resistance in the cerebral and placental circulations may be the first signs of beneficial diversion of flow toward the brain.³³ Later, overt increases in brain blood flow depicted in the middle cerebral artery with Doppler, most likely represent interaction of increases in perfusion resulting from systemic hypertension, and decreases in regional resistance resulting from hypoxemic vasodilation. Such changes occur in many organs, including the brain, liver, and adrenal glands, with corresponding shunting away from organs less critical to fetal survival. Thus, “brain-sparing” depiction of increased brain flow in the face of rising placental vascular resistance may signal shunting of blood away from somatic arterial beds.³⁴ “Heart-sparing” dilation of the fetal coronary arteries appears to be a much later hemodynamic change, associated with marked placental insufficiency.³⁵ The onset of these hemodynamic responses may be very subtle, including minor shifts in the cortical proportion of renal blood flow or slight reductions in gut perfusion. Progressive redistribution, up until cardiac decompensation, is an effective means of rationing the limited or declining oxygen supply.⁴ Most fetuses experiencing chronic limitations in oxygen can maintain normal pH, neurologic function, and cardiac efficiency through a range of very low umbilical venous PO_2 .^{26,36}

3. Reduce oxygen consumption. This sophisticated mechanism of fetal adaptation to oxygen limits should not be confused with the obtundation induced by severe absolute cerebral hypoxemia. Most fetal responses that decrease oxygen consumption are voluntary and can be rapidly turned on and off.³⁷ These are initiated with minor increases in time between activity cycles and may extend all the way to complete abolition of fetal activity, rapidly reversible mere minutes after delivery. Fetal oxygen consumption may fall more than 15% during inactivity, and when this is coupled with redistribution and extraction, there may even be significant increases in oxygen supply to critical organs.³⁸ Different elements of fetal behavior may illustrate different sensitivities to declining oxygen levels. Heart rate reactivity tends to disappear before fetal breathing movements, which are almost always absent before fetal movements disappear (Fig. 21-2).³⁹

These pathways of response are sequential, overlapping, and potentially reversible.⁴⁰ The IUGR fetus, for example, may deal effectively with increasing placental insufficiency with a combination of increasing oxygen extraction, increased hemoglobin concentration, and diversion of flow, such that temporary reduction in fetal activity may be restored and amniotic fluid volume maintained.⁴¹ The extent to which these changes are reversible in utero will vary, but they include increased

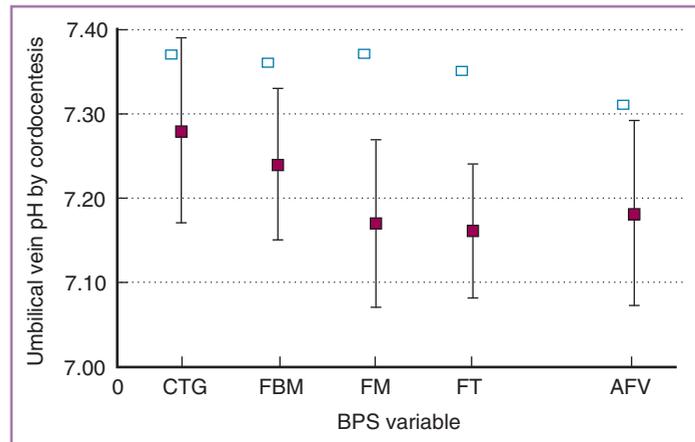

FIGURE 21-2 Changes in fetal behavior with declining pH. As umbilical venous pH falls, various behaviors become less frequent and eventually disappear. The graph summarizes cordocentesis data relating antepartum pH to individual biophysical profile score (BPS) variables. *Open squares*, mean pH when the variable was present (normal); *Filled squares*, mean pH \pm 1 standard deviation when the variable was absent (abnormal). Data suggest that loss of individual variables is sequential. AFV, amniotic fluid volume; CTG, cardiotocogram; FBM, fetal breathing movement; FM, fetal movement; FT, fetal tone.

fetal activity with maternal supplemental oxygen and improved Doppler resistance patterns when oligohydramnios is restored by amnioinfusion.

Fetal Compromise

As compensatory mechanisms reach their limits, metabolic consequences of hypoxemia arise—lactic acidemia, cardiac dysfunction, and progressive acidosis. Identification of these end points has become a critical role of fetal monitoring in the markedly premature. Even when venous Doppler indices have deteriorated, suggesting cardiac decompensation, acute fetal monitoring may still be used to coax a few more days of gestation, as well as to allow administration of antenatal steroids, with resulting improvement in long-term outcome.⁴² Understanding the interaction between arterial and venous Doppler tracings and biophysical fetal behavior becomes critical in this situation.

Absent Fetal Behavior: How Long Is too Long?

Fetal behavioral state 1F is known as quiet sleep. The fetal electroencephalogram features low-frequency, high-voltage patterns, occasional twitches but few voluntary movements, individual breathing movements without sustained episodes, marked diminution in heart rate variability, odd mouthing movements, and absence of acceleration-movement coupling.⁴³

Near term, such profound inactivity, illustrated by the nonreactive NST (Fig. 21-3), is readily confused with fetal compromise. This confusion led to many inappropriate interventions during the initial development of FHR monitoring. Although state 1F and the nonreactive NST seldom persist longer than 40 minutes, intervals approaching 2 hours are still most likely normal.⁴⁴ The definition of these abnormal periods depends very much on the modality of testing. Multitransducer real-time observation of fetal activity often discloses frequent

FIGURE 21-3 Eighteen-minute sleep-wake cycle in the term fetus. Virtually no activity (one kick, one acceleration) in the first 9 minutes, with low-variability fetal heart rate, behavioral state 1F. In the next 9 minutes, 60 discrete fetal movements on real-time ultrasound, multiple accelerations, increased variation between accelerations (2F).

small movements of hands, mouth, and trunk when less rigorous assessment describes complete inactivity. Clearly, any fetal testing modality must address this critical distinction: nearly dead or just napping.

Principles of Monitoring

To account for all these potential variables, the ideal monitoring system would gather a wide range of information, with versatility for all maternal and fetal conditions and flexibility for all gestational ages, allowing for varying degrees of onset, severity, and duration of intrauterine challenges.³⁹ In meeting these objectives, an ideal antenatal monitoring system would do the following:

1. Detect fetal peril with specificity, sensitivity, and timeliness to allow preventive intervention. Achieving these qualities entails the following:
 - Correlation with measurable standards of fetal compromise (antepartum pH; postdelivery outcome such as blood gases, Apgar scores, and neonatal performance)
 - Proportionality between test results and outcome (the worst score equals the highest risk of permanent handicap or perinatal mortality)
 - A low false-alarm rate, especially as prematurity deepens
 - Application to all ranges of perinatal morbidity as well as basic perinatal mortality
 - A reliable relationship to compromise that yields intervention early enough to prevent permanent damage but late enough to be certain of the need for intervention and to minimize the risks of prematurity
2. Reliably exclude stillbirth or permanent injury over a significant period of time. However, allowing for the possibility of acute change such as placental abruption, a normal test must exclude abnormal outcomes for a clinically important length of time, most commonly 7 days.
3. Exclude lethal congenital anomalies. This mandates at least one high-resolution comprehensive fetal examination but does not dictate that this must be repeated at every testing opportunity.
4. Incorporate multiple variables. This principle reflects the only way in which a monitoring system can address both the complexity of normal fetal behavior and the individual nature of fetal compensation.

5. Apply to fetal compromise from a variety of basic sources, including asphyxia, poisoning, metabolic abnormalities, anemia, and chance obstetric factors such as cord accident, to address the many origins of adverse outcome. These should be applicable in outpatient settings, with readily available equipment, accessible technicality, and high reproducibility.
6. Have measurable benefits to high-risk populations, in reduction of perinatal mortality and perinatal morbidity, at least in part by safely extending intrauterine time. Meeting these objectives simultaneously will, by definition, be cost effective.

In the context of the great variability in normal behavior and the complex cascades of responses to abnormal conditions, no single parameter could satisfy all these objectives. In balancing the risks of stillbirth from intrauterine decompensation against the likelihood of neonatal death from prematurity, single-modality tests have an impressive record of failure. The recent perinatal literature is full of such examples, including the use of the biparietal diameter as the unequivocal measurement for definition of IUGR,⁴⁵ nonstress testing as the single parameter to determine obstetric management,⁴⁶ or a series of Doppler parameters (absent diastolic velocities, cerebralization of blood flow, umbilical-venous pulsations, in that historical order) where knee-jerk responses, in the form of delivery as soon as the observation was made, have resulted in a litany of iatrogenic problems.⁴⁷

Tests of Fetal Health: Monitoring Methods

Biophysical Profile Scoring

The biophysical profile score (BPS) presumes that multiple parameters of well-being are better predictors of outcome than single parameters.⁴⁸ Figure 21-4 shows one example of the detailed evaluation of outcome variables performed during development.^{49,50} The traditional BPS study includes five variables (Table 21-1), with a total possible score of 10, but several variations have been proposed. Vintzileos and colleagues⁵¹ added placental grading, for a total possible score of 12. Several authors proposed a modified biophysical profile that usually includes heart rate monitoring and amniotic fluid evaluation.^{52,53} There may be modest differences in these approaches, but all emphasize the principle of multivariable fetal assessment.

Biophysical Profile Score Variables
AMNIOTIC FLUID MEASUREMENT

With the transducer vertical to the maternal abdomen, the maximum vertical depth of a clear amniotic fluid pocket is recorded. The transducer is then rotated 90 degrees in the same vertical axis,

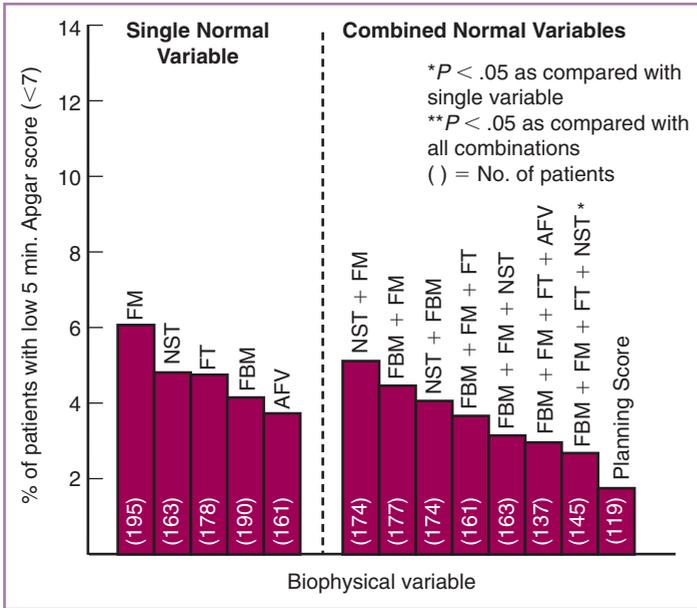

FIGURE 21-4 Prediction of outcome by individual biophysical profile score variables (*left*) or combinations of variables (*right*). In this example, a 5-minute Apgar score less than 7 was best predicted by a combination of all five variables. (The Planning Score, named for Platt and Manning, was the first full biophysical profile score.) AFV, amniotic fluid volume; FBM, fetal breathing movement; FM, fetal movement; FT, fetal tone; NST, nonstress test.

confirming that the measured pocket has true biplanar dimensions. The phrase 2×2 pocket does not mean the pocket is 2 cm deep and 2 cm wide; it refers to the documentation that the pocket is 2 cm deep in at least two intersecting ultrasound planes, avoiding the possibility that a “sliver” of amniotic fluid is misconstrued as a true three-dimensional pocket. Amniotic fluid is measured in real time, and when there is doubt about a true clear pocket, it is confirmed by pulsed Doppler. Continuous color imaging may lead to the false impression of oligohydramnios (Fig. 21-5).⁵⁴ This method reflects the relative amount of amniotic fluid and was not meant as an absolute physiologic parameter.⁵⁵

Amniotic Fluid Volume. Maximum amniotic fluid pocket depth less than 2 cm or more than 8 cm mandates a detailed fetal evaluation to exclude anatomic and anomalous explanations.^{56,57} For moderately increased fluid (maximum vertical pocket depth, 8 to 12 cm), the most common explanations are structural abnormalities, fetal macrosomia resulting from maternal diabetes, and idiopathic polyhydramnios, and fetal testing is likely to reflect fetal neurologic status accurately.⁵⁸ For pockets deeper than 12 cm in singleton pregnancies, neurologic issues and structural defects associated with aneuploidy are more likely and the BPS may not be valid.⁵⁹ Through the normal range (maximum vertical pocket depth, 3 to 8 cm), the maximum vertical depth assigns “normal” status accurately, although it may not correlate precisely with absolute volumes. As amniotic fluid volume decreases, the statistical value of the maximum vertical pocket method improves.

Subjectively Reduced Amniotic Fluid. In this situation, the minimum criterion of a 2-cm pocket depth is met, but there is no cord-free pocket greater than 3 cm. This suggests that fluid is significantly less than average, and subjective findings often include restricted extension of fetal movement, the uterus or the placenta molding to the contours of the fetus (or both), FHR decelerations with transducer pressure, spontaneous decelerations associated with fetal movement, and maternal reports of decreased fetal movement.³⁹

Oligohydramnios. The original criterion for this diagnosis was a maximum vertical pocket of only 1 cm. Although this finding is highly

TABLE 21-1 INTERPRETATION OF BIOPHYSICAL PROFILE SCORE (BPS) VARIABLES

Fetal Variable	Normal Behavior (score = 2)	Abnormal Behavior (score = 0)
Fetal breathing movements (FBM)	Intermittent, multiple episodes of more than 30-sec duration, within 30-min BPS time frame. Hiccups count. Continuous FBM for 30 min, rule out fetal acidosis.	Continuous breathing without cessation. Completely absent breathing or no sustained episodes.
Body or limb movements	At least four discrete body movements in 30 min. Continuous active movement episodes = single movement. Includes fine motor movements, rolling movements, and so on, but not rapid eye movements or mouthing movements.	Three or fewer body or limb movements in a 30-min observation period.
Fetal tone/posture	Demonstration of active extension with rapid return to flexion of fetal limbs and brisk repositioning or trunk rotation. Opening and closing of hand or mouth, kicking, and so on.	Low-velocity movement only. Incomplete flexion, flaccid extremity positions, abnormal fetal posture. Must score 0 when fetal movement (FM) is completely absent.
Cardiotocogram (CTG)	Normal mean variation (computerized fetal heart rate interpretation), accelerations associated with maternal palpation FM (accelerations graded for gestation), 20-min CTG.	FM and accelerations not coupled. Insufficient accelerations, absent accelerations, or decelerative trace. Mean variation <20 or short-term variation <4.5 msec on numerical analysis of CTG.
Amniotic fluid evaluation	At least one pocket >2 cm with no umbilical cord. See text regarding subjectively decreased fluid.	No cord-free pocket >2 cm, or multiple definite elements of subjectively reduced amniotic fluid volume.

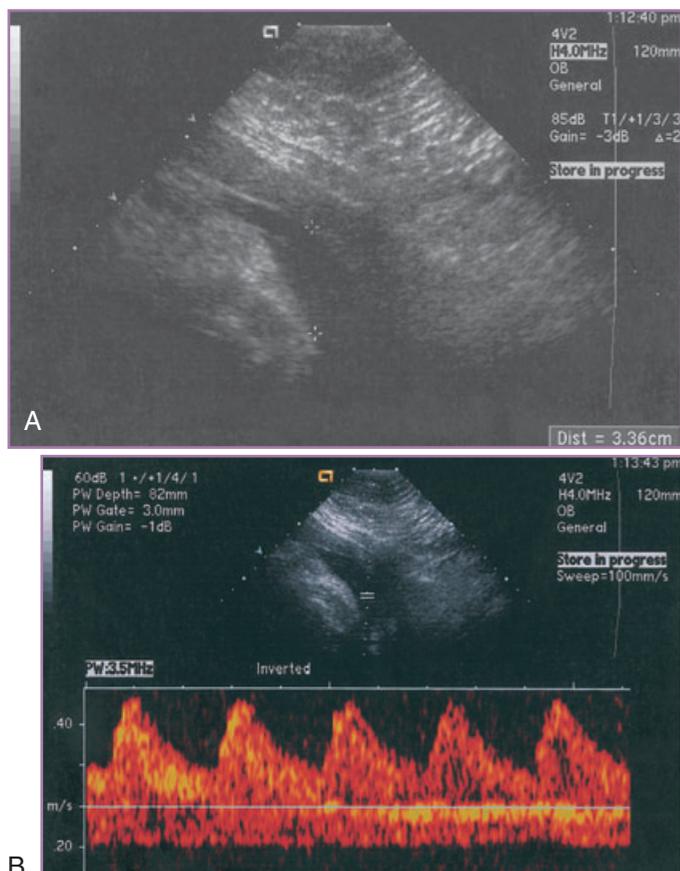

FIGURE 21-5 Fluid pocket verification. **A**, Amniotic fluid apparently meets vertical pocket criteria of the biophysical profile score. **B**, Pulsed Doppler demonstrates that this is a vertical pocket of umbilical cord, with no measurable amniotic fluid.

correlated with IUGR, it is so rare as to be clinically insignificant. The 2-cm standard for oligohydramnios has good reliability as a test for potential fetal compromise, as a correlate of IUGR and as a correlate of repetitive decelerations in labor, leading to a decision for cesarean delivery. Because of its reduced likelihood of false-alarm diagnosis, reduced intervention, and the corresponding reduced maternal morbidity despite identical outcome predictions, the maximum vertical pocket method is superior to the four-quadrant amniotic fluid index (AFI).^{60,61} The use of maximum vertical pocket depth, and not the four-quadrant AFI, in traditional BPS is validated by current research.⁶² The underlying principle, fetal oliguria, is a component of redistribution of fetal blood flow and segmental renal hemodynamics,⁶³ reflected in abnormal placental Doppler indices. For predicting adverse fetal outcome, there is an excellent complementary association between oligohydramnios and worsening placental function.⁶⁴

FETAL BREATHING MOVEMENTS

Either rhythmic fetal diaphragm contractions or hiccups lasting more than 30 seconds meet normal criteria. This fetal behavior is the one most easily suppressed by hypoxemia, but it is also the most episodic in normal fetuses. Because the amplitude of fetal breathing depends on gestational age, maternal glucose, exposure to increased oxygen concentrations, and many medications (e.g., xanthenes), careful evaluation of all parameters is necessary before intervention is

precipitated.⁶⁵ The unusual presence of continuous monotonous fetal breathing, or fetal gasping, with complete absence of all other behavior for an extended period, may indicate acidosis, especially in the fetus of a diabetic mother.⁶⁶⁻⁶⁸

FETAL MOVEMENT AND TONE

One of the interpretive pitfalls of BPS is that at least some movement must be present to evaluate tone.³⁹ Tone is not simply the flexed posture of a normal fetus. The evaluation of tone is indeed subjective, but absent tone is strongly correlated with fetal acidosis.

Fine motor movement of the face and hands, purposeful movement such as swallowing, facial expressions, sucking, yawning, large kicks, small kicks, rolling motions, and so on may all be included as movements. When a fetus does not move for a period of 30 minutes, extended testing is required,⁶⁹ and completion of heart rate testing is also performed to extend the time of continuous observation. In practice, fetal movement is referenced to previous BPS experience with this fetus, maternal reports, and gestational age. The markedly preterm fetus moves virtually all the time, and a movement frequency of only five to eight movements per hour would call for increased testing, even though minimal criteria are met.

CARDIOTOCOGRAM

An experienced observer can derive much information from the systematic recording of the FHR with simultaneous documentation of uterine activity, which comprises the cardiotocogram (CTG) (Fig. 21-6).⁷⁰ When fetal heart rate and uterine activity are recorded passively, relating fetal movement to standardized interpretation of FHR accelerations, a nonstress test is defined as reactive (a score of 2 meets criteria for accelerations associated with fetal movement) or nonreactive (a score of 0 means acceleration criteria are not met).⁷¹ These data can be acquired digitally by a computerized system that not only interprets accelerations and decelerations but also numerically analyzes FHR variability within gestational-age-normalized paradigms.^{72,73} This significantly reduces the impact of gestational age on FHR testing, making it more interpretable at gestational ages progressively less than 32 weeks.

A valuable component of the CTG is elicited uterine activity. Contraction patterns may suggest uterine irritability, such as in preterm labor, with uterine infection, or with impending abruption placentae. The minimal deceleration pattern illustrated in Figure 21-7 suggests oligohydramnios. Fetal breathing often produces characteristic deflections of the tocodynamometer, as well as irregularities in FHR (Fig. 21-8).⁷⁴ Normal variability with a monotonous repetitive (sawtooth) pattern for more than 40 minutes may indicate fetal anemia, whereas overt sinusoidal heart rate is indicative of more severe fetal compromise, including hydropic anemia, drug intoxication (e.g., narcotics), or abnormalities of the central nervous system with decorticate behavior.^{75,76}

CTG is never used alone in biophysical profile scoring.^{77,78} Any of the patterns just mentioned would immediately call for performance of all ultrasound parameters in the BPS. The CTG must be interpreted within the context of gestational age.⁷⁹ Modification of the interpretation of the NST is shown in Table 21-1 and reflects the potential benefits of computerized CTG in the preterm fetus.^{80,81}

Biophysical Profile Score Technique

Table 21-2 shows how the BPS is systematically interpreted and applied to management. More detailed instructions on the application of BPS are available elsewhere,^{39,82} but some technical points deserve emphasis.

FIGURE 21-6 Reactive nonstress test. Prominent fetal heart rate accelerations associated with palpated fetal movements (also documented by this type of monitor, *second tracing from bottom*). Between large accelerations, normal variability, classified as moderate by the National Institute of Child Health and Human Development criteria. No detectable uterine contractions (*bottom tracing*).

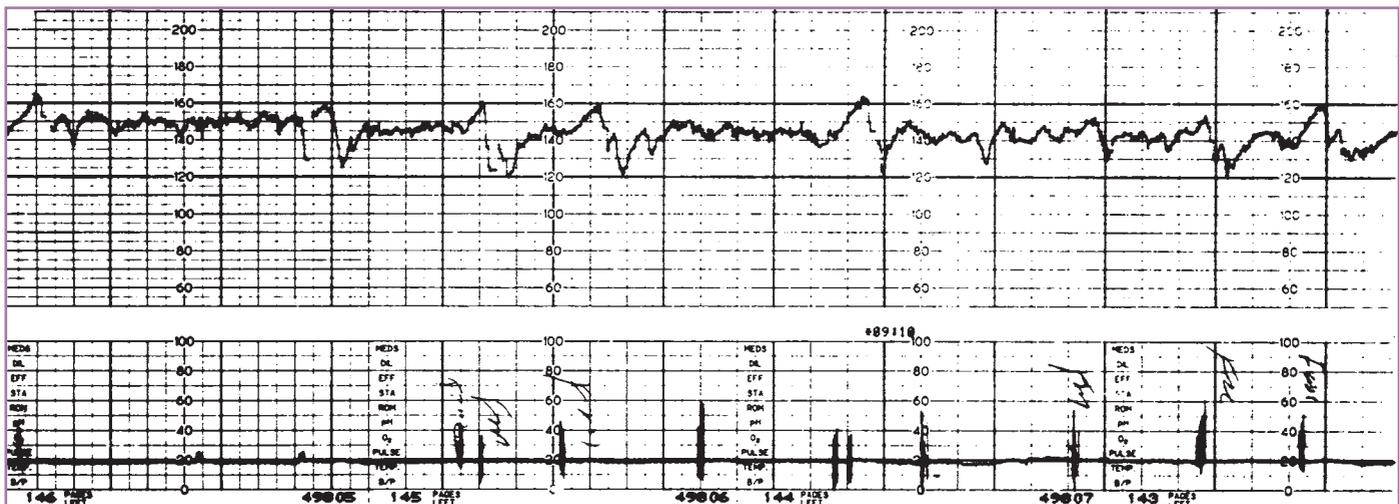

FIGURE 21-7 “Minimal variable” FHR pattern. Numerous fetal movements (marked FM on *lower tracing*), were associated with small decelerations caused by cord compression. Biophysical profile score was 6/10, with equivocal nonstress test and no amniotic fluid pocket more than 2.0 cm. Fetus failed induction because of repetitive decelerations despite amnioinfusion in labor.

Score of 10. A score of “6/8” is not a BPS. When the four ultrasound variables are performed first, but at least one of them is absent, the CTG must be performed before the BPS is complete, and the score will then be reported as 6 or 8/10. The only score that is allowed to stand after only the ultrasound variables have been evaluated is 8/8. In that case, the CTG is not required. Based on randomized controlled trial data, the NST is used selectively after ultrasound variables have been performed. When this protocol is followed, the NST is required in only about 10% of cases.^{39,78} Exceptions to this design include high-risk fetuses with hemodynamic abnormalities; the presence of multiple medical disorders (especially active lupus, thrombophilia, and the combination of hypertension and diabetes); volatile situations such as chronic abruption, fetal infection and arrhythmias; and in recognition of prior adverse outcome. Fetuses who always require a five-variable BPS (a score “out of 10”) are those with Doppler-defined placental insufficiency, including absent or reversed end-diastolic velocities (REDV) or venous Doppler abnormalities (see later).

8/10-Oligohydramnios. The recommendation to proceed with delivery when there is no pocket of 2 cm or greater is based on the close association with adverse outcome⁸³—that is, on a high perinatal mortality (up to 560 per 1000 in fetuses with no amniotic fluid pocket greater than 1 cm). At term, the recommendation is to proceed with a trial of labor, noting that up to 45% of the time, cesarean delivery is required for repetitive FHR decelerations. For preterm gestations, if the remainder of fetal behavior is within normal limits, additional time may be taken to administer antenatal steroids, transfer to a tertiary center, and prepare the maternal cervix, provided close monitoring continues. Extending this rationale to less severe oligohydramnios (e.g., when using an AFI of 5 cm) has caused confusion on this point. Using maximum vertical pocket depth will avoid undue interference in most cases. Remote from term, diagnostic amnioinfusion reveals occult rupture of membranes in up to 19%.⁸⁴ The role of chronic amnioinfusion to preserve fluid volume has not been substantiated in randomized control trials.

FIGURE 21-8 Active fetus with “respiratory arrhythmia.” Simultaneous real-time ultrasound showed episodic fetal breathing for most of this tracing after the first large acceleration. *Upper tracing* shows increased short-term variability; *lower tracing* shows maternal abdomen moving in small-amplitude waves (20 to 30/min) caused by fetal chest movement.

TABLE 21-2 SYSTEMATIC APPLICATION OF BIOPHYSICAL PROFILE SCORING (BPS)

BPS	Interpretation	Predicted PNM/1000*	Recommended Management
10/10 8/8 8/10 (AFV normal)	No evidence of fetal asphyxia present.	Less than 1/1000	No acute intervention on fetal basis. Serial testing indicated by disorder-specific protocols.
8/10-oligohydramnios	Chronic fetal compromise likely (unless ROM is proven)	89/1000	For absolute oligohydramnios, prove normal urinary tract, disprove undiagnosed ROM, consider antenatal steroids, then deliver.
6/10 (AFV normal)	Equivocal test, fetal asphyxia is not excluded	Depends on progression (61/1000 on average)	Repeat testing immediately, before assigning final value. If score is 6/10, then 10/10, in two continuous 30-min periods, manage as 10/10. For persistent 6/10, deliver the mature fetus, repeat within 24 hours in the immature fetus, then deliver if less than 6/10.
4/10	Acute fetal asphyxia likely. If AFV-oligo, acute on chronic asphyxia very likely.	91/1000	Deliver by obstetrically appropriate method, with continuous monitoring.
