Brow presentation, in contrast, was associated with abnormalities of descent and longer second stage of labor compared with vertex presentation in matched controls. This is not surprising, because in brow presentation the largest dimension of the head, the mento-occipital diameter, must negotiate the inlet of the pelvis. Consequently, successful descent, rotation, and delivery of a brow presentation in the term infant depend on conversion to either a face or a vertex presentation. Moreover, it is often the delay in labor associated with this conversion that results in a more careful assessment of fetal position and the recognition of a brow presentation. Perinatal mortality rates for brow

and face presentations are higher than for vertex presentations, but the differences can be accounted for by fetal anomalies (anencephaly), prematurity, and asphyxia and trauma associated with manipulation during vaginal delivery.

Management begins with recognition of the abnormality. Awareness and diagnosis of deflection problems are enhanced by an emphasis on careful vaginal examination and a description of the position and characteristics of the presenting fetal part as an essential element in labor monitoring. If, on vaginal examination, the lambdoid sutures and posterior fontanelle cannot easily be identified as occupying a central position in the pelvis, an abnormal presentation or deflection of a cephalic presentation must be suspected. Palpation of the anterior fontanelle or one of the orbits clearly identifies a deflection problem. Furthermore, in cases of abnormal descent or prolonged second stage of labor, deflection of the fetal head should be considered one of the possible causes, and the patient should be reevaluated with this in mind.

If deflection of the fetal head is identified in association with abnormal progression of labor, CPD must be suspected. Friedman³ found that 10.9% of patients with brow presentation had clinical and radiographic evidence of CPD, compared with 2.7% of controls with vertex presentations. If progress of labor is arrested and CPD is suspected, cesarean delivery is indicated. If labor progresses and there is evidence of resolution of a brow presentation to either a face or vertex presentation, labor should be managed with the expectation of vaginal delivery. If labor is arrested and there are poor uterine contractions in the absence of CPD, the use of a carefully monitored course of oxytocin augmentation may be warranted. Seeds and Cefalo¹⁹⁹ suggested that radiographic pelvimetry be considered in these situations to exclude CPD.

Most brow presentations convert spontaneously to either a face or a vertex presentation, and 70% to 90% of face presentations result in spontaneous delivery. If the brow presentation fails to convert or the face presentation rotates to a persistent mentum posterior, cesarean delivery is required. If uncorrectable fetal distress occurs, labor should be terminated by abdominal delivery. It is generally agreed that rotating the fetal head or converting its deflection position either manually or with forceps is excessively dangerous to fetus and mother.

Compound Presentation

A compound presentation exists if an extremity is adjacent to the presenting part. This complication of labor occurs in approximately 1 of every 1000 deliveries and is associated with high rates of prematurity (31% to 61%) and fetal mortality (16% to 22%).^{200,204,205} Cord prolapse, which occurs in 11% to 20% of cases, is the most common intrapartum complication.¹⁹⁹ The vertex-arm combination is the most frequent compound presentation and has the best prognosis.

Management includes early diagnosis and fetal monitoring, with retraction of the presenting extremity and normal vaginal delivery occurring in most cases. If fetal distress or cord prolapse occurs or labor progress ceases, abdominal delivery should be accomplished promptly. Stimulation or manipulation of the presenting extremity to encourage retraction within the uterus is controversial.

Cruikshank and White²⁰⁰ reported that, of 32 compound presentations, the presenting extremity could be manually replaced in 16 cases, resulting in uneventful vaginal delivery in 15 of the patients. On the other hand, Seeds and Cefalo,¹⁹⁹ in their review of the literature regarding compound presentation, advised against manipulation of the prolapsed part. Indeed, spontaneous retraction of the extremity occurs so frequently that attempts to replace it may not be necessary and, in certain cases, may encourage prolapse of the umbilical cord.

Operative Delivery

Cesarean Delivery

The evolution of cesarean delivery as a safe procedure with extraordinarily low maternal and fetal mortality rates is one of the most important developments in modern perinatal medicine. Maternal mortality rates from cesarean operations in the 19th century were 85% or greater, with the operation being performed only in the most extraordinary circumstances to save the life of the mother.²⁰⁶ By the early decades of the 20th century, several important innovations in surgical care had occurred, including aseptic technique, reliable anesthesia, and the control of hemorrhage by proper suturing of tissue planes as well as ligation of severed blood vessels. Specifically for the cesarean operation, introduction of the low-segment incision, which allows exclusion of the uterine wound from the peritoneal cavity, dramatically decreased the risk of postoperative peritonitis as a complication of puerperal endometritis.²⁰⁷

The later additions of blood transfusion and antibiotic therapy further reduced the morbidity and mortality of cesarean delivery, to the extent that, in 1950, D'Esopo published a remarkable study reporting 1000 consecutive cesarean deliveries without a single maternal death.²⁰⁸ The decrease in maternal morbidity of cesarean delivery made the operation a reasonable alternative for delivery of the fetus at increased risk for asphyxia or trauma from labor and vaginal delivery. This decrease, together with more sophisticated methods of detecting chronic and acute fetal distress (e.g., ultrasonography, continuous fetal heart monitoring, fetal scalp blood sampling) changed the indications for and frequency of cesarean section for delivery.

Before 1960, cesarean deliveries comprised fewer than 5% of births and were performed primarily for maternal indications such as placenta previa, radiographically documented CPD, failure of induction of labor in severe preeclampsia, and repeat cesarean delivery.²⁰⁹ After 1960, with the emergence of fetal diagnostic and monitoring techniques, cesarean delivery rates gradually increased worldwide and were more commonly performed for fetal indications.^{210,211} The rate and duration of the increase varied; in the United States, the rate of cesarean delivery reached a peak of 23.5% in 1988.²¹² Four indications were found to account for 90% of the increase in the United States: dystocia, repeat cesarean delivery, breech presentation, and "fetal distress."²¹³ Although new indications for cesarean delivery, such as fetal spinal or abdominal wall abnormalities and prevention of vertical transmission of certain infectious diseases, played a small role in this increase, a more important effect was a lowered threshold for the standard indications.²¹⁴ Fear of litigation also played a role in the rise in cesarean delivery rates, not only in the United States but also in the United Kingdom.²¹⁵ Although it has been suggested that the rate of cesarean delivery is linked to physician reimbursement, the increase in cesarean delivery rates in countries that have global obstetric fees (e.g., Australia) suggests that financial incentive alone cannot account for the rise in cesarean delivery rates.²¹⁶

In some countries, such as Brazil and Chile, the increase in the cesarean delivery rate has been well beyond that which could be accounted for by obstetric or medical indications.^{217,218} In these countries, the increase has occurred largely as a result of an increase in prelabor elective cesarean delivery, presumably for the convenience of patients or doctors. This phenomenon has occurred primarily, though not exclusively, among women in upper income levels. There is debate as to whether this has resulted from a patient population that is well educated in the risks and benefits of vaginal versus cesarean delivery

and exercising their right of patient autonomy or a patient population that has been overly influenced and biased by health care providers to choose cesarean delivery.²¹⁹

In the 1990s, interest emerged in the role of cesarean delivery to prevent pelvic floor dysfunction that has been attributed to vaginal birth. The risk of urinary incontinence at 6 months after delivery is twofold greater for women who have a spontaneous vaginal delivery than for those who have a cesarean delivery.²²⁰ In a large, multicenter, prospective, randomized, controlled trial of planned prelabor cesarean delivery compared with planned vaginal delivery in women with a term breech presentation, urinary incontinence was less common at 3 months after cesarean delivery (relative risk, 0.62; 95% confidence interval [CI], 0.41 to 0.93).²²¹ The long-term effects of vaginal delivery on urinary continence are less clear-cut. Buchsbaum and colleagues²²² found no significant difference in the incidence of urinary incontinence in nulliparous versus parous postmenopausal women. In a large, population-based study in Australia, MacLennan and associates²²³ found that the incidence of long-term pelvic floor dysfunction, including urinary incontinence, was greater in women who had operative vaginal deliveries than in those who had cesarean deliveries. However, there was no difference in incidence of pelvic floor dysfunction with cesarean versus spontaneous vaginal delivery.

Sultan and colleagues²²⁴ found that forceps delivery and episiotomy were risk factors for anal sphincter lacerations, whereas vacuum-assisted delivery and cesarean delivery were protective.²²⁴ Other studies found that cesarean delivery was associated with a reduced incidence of fecal incontinence if it was performed before onset of the second stage of labor.²²⁵ Associations between the method of delivery and long-term anal sphincter function are less clear. Nygaard and associates,²²⁶ in a 30-year follow-up study of anal incompetence, found that the aging process was as important as obstetric events.

Notwithstanding the mounting evidence of an untoward effect of vaginal delivery (especially forceps delivery) on postpartum pelvic floor dysfunction, prospective randomized trials with adequate follow-up are necessary to adequately evaluate the effect of various methods of delivery on long-term pelvic floor function. There is currently insufficient evidence to recommend elective cesarean delivery to prevent long-term urinary or anal incontinence.

Finally, a number of the common risk factors for cesarean delivery—fetal macrosomia, advanced maternal age, increased maternal body mass index, gestational diabetes, multiple pregnancy, and dystocia in nulliparous women—are increasing in frequency, especially in developed countries.

Cesarean delivery rates vary widely worldwide, from as low as 5% in Bolivia to as high as 40% in Chile.²¹⁶ In the United States, the rate of cesarean deliveries declined 8% between 1991 and 1996 but has steadily increased thereafter, primarily because of a decline in vaginal births after previous cesarean deliveries,²²⁷ reaching 29.1% of all births in 2004 (National Center for Health Statistics preliminary birth data for 2004, available at <http://www.cdc.gov/nchs/births.htm> [accessed February 8, 2008]).

It seems unlikely that the cesarean delivery rate in the United States or in most developed countries will ever be as low as 15%, which is the goal of the World Health Organization.²²⁸ The cesarean delivery rate will not reach this level and is likely to increase gradually for the following reasons:

- There is a heightened sensitivity to, and lowered threshold for, using cesarean delivery for the traditional indications.
- There is an increased proportion of pregnant women whose pregnancies are complicated by the conditions for which cesarean delivery is necessary.

- There are evolving new indications for cesarean delivery, albeit indications that are variously supported by reliable evidence.
- Emphasis on patient autonomy in making decisions about method of delivery will result in women's vulnerability to bias and non-evidence-based information about the relative risks and benefits of cesarean delivery.
- The benefits of a trial of labor for women with a previous cesarean delivery are equivocal.
- Fear of litigation will persist in the absence of tort reform.

Visco and colleagues from the University of North Carolina conducted a systematic evidence review on the topic of cesarean delivery on maternal request.²²⁹ After a review of 1406 articles, they concluded that the evidence about this approach to childbirth is "significantly limited" and that the literature confounded by having studied *actual* route of delivery rather than *planned* route. They could make no conclusions on the effectiveness and safety of cesarean delivery on maternal request and called for the establishment of a CRT code that could document this indication. A 2006 NIH consensus conference came to similar conclusions (the final statement and video from that event are available at <http://consensus.nih.gov> [accessed February 8, 2008]).

Another factor that tends to increase the rate of cesarean delivery is the waning enthusiasm for a trial of labor in women who have had a previous cesarean delivery. This has occurred as a result of an increase in the number, if not the incidence, of untoward fetal and maternal consequences of uterine rupture. In the 1980s, the incidence of vaginal birth after a previous cesarean (VBAC) increased in response to initiatives to control the rising cesarean delivery rate. Consequently, more physicians experienced one or more cases of uterine rupture, even though the incidence of symptomatic scar separation remained constant at about 0.5%. Relatively large population-based, retrospective studies have found the overall risk of serious maternal complications (e.g., uterine rupture, hysterectomy) to be twofold to threefold higher for a trial of labor after a previous cesarean compared with a repeat elective cesarean delivery.^{230,231} In a large, population-based study from Scotland comparing perinatal outcomes (not related to congenital abnormalities) for women who had a trial of labor after a previous cesarean delivery, compared with those who had an elective repeat cesarean delivery, the risk of delivery-related perinatal death in the former group (12.9/10,000) was 11 times greater than with repeat cesarean.²³²

Complications of Cesarean Delivery

MATERNAL COMPLICATIONS

Although cesarean delivery is a reasonably safe surgical procedure, it is generally regarded as being associated with higher risks of morbidity and mortality than vaginal delivery. Data from the Professional Activities Survey of the Commission of Professional and Hospital Activities for the year 1978, which included about 1 million births and 100,000 cesarean deliveries, showed the rates of maternal death per 100,000 births to be 9.8 for vaginal deliveries, 40.0 for all cesarean deliveries, and 18.4 for "repeat" cesarean deliveries.²¹³ Others have documented lower risks for cesarean delivery. Sachs and colleagues,²³³ reviewing cesarean delivery-related mortality in Massachusetts in the period 1954 to 1985, found that the rate of death directly related to cesarean birth was 5.8 per 100,000 procedures. Frigoletto and coworkers²³⁴ reported on 10,231 consecutive cesarean deliveries at Boston Hospital for Women between 1968 and 1978 without a single maternal death. Varying definitions of maternal mortality and failure to control for the confounding influences of parity, maternal age, and medical and obstetric complications account for some of the differences in

maternal mortality rates associated with cesarean delivery. In a study of 250,000 deliveries, Lilford and associates²³⁵ found a sevenfold relative risk of death associated with cesarean compared with vaginal delivery when preexisting medical conditions were excluded. The same authors found that the relative risk of dying from a nonelective cesarean birth compared with an elective cesarean birth when preexisting medical conditions were excluded was 1.5. A population-based study in Washington State (1987-1997) that controlled for parity, maternal age, severe preeclampsia, and deaths unrelated to pregnancy found no significant increase in maternal mortality related to cesarean delivery.²³⁶

It is apparent that the risks of morbidity and mortality of cesarean delivery are influenced by the associated medical complications in the patient requiring abdominal delivery and the skill of the medical team performing the procedure. Serious intraoperative complications occur in approximately 2% of cesarean deliveries and include anesthesia accidents (e.g., problems with intubation, drug reactions, aspiration pneumonitis), hemorrhage, bowel or bladder injury, amniotic fluid embolism, and air embolism.²³⁷

Frequently, cesarean delivery must be performed under emergency conditions soon after the patient is admitted to the hospital. Patient anxiety, obesity, an incompletely emptied stomach, acute hemorrhage from a placental accident, low blood volume and constricted vascular space in association with pregnancy-induced hypertension, and hypotension secondary to vena caval and aortic compression by the pregnant uterus are just a few of the problems frequently encountered in patients requiring emergency cesarean delivery. These problems challenge even the most skilled anesthesiologist. On some occasions, an emergency cesarean delivery must be performed with such haste that sterile and surgical techniques are compromised. Urinary tract injuries, which occur in 1 or 2 per 1000 deliveries, are 10 times more common in cesarean deliveries than in operative vaginal deliveries.²³⁸ Most of the injuries that occur with cesarean delivery are simple bladder lacerations that are promptly identified and repaired without sequelae. Bowel injuries are often associated with intra-abdominal adhesions from previous cesarean deliveries or other abdominal surgeries. Some intraoperative complications, such as amniotic fluid embolus syndrome and air embolus, are extremely rare and usually not preventable.

The following are postpartum maternal complications associated with cesarean delivery:

- Atelectasis
- Endomyometritis
- Urinary tract infection
- Abdominal wound hematoma formation, dehiscence, infection, or necrotizing fasciitis
- Thromboembolic disease
- Bowel dysfunction—adynamic ileus, pseudo-obstruction of the cecum (Ogilvie syndrome), and sigmoid volvulus

Duff²³⁹ found that, with the use of prophylactic antibiotics, the rate of febrile puerperal complications for cesarean delivery was 5% to 10% in a university obstetric service (see Chapter 38). Watson and colleagues²⁴⁰ found that febrile morbidity occurred in only 2.3% of high-risk private patients who underwent cesarean delivery. The rate of febrile morbidity in patients undergoing cesarean delivery without labor was only 0.5%. These studies emphasized the fact that low socioeconomic status and labor are important risk factors for postpartum febrile morbidity after cesarean delivery.

Postcesarean endomyometritis is a polymicrobial infection characterized by abdominal pain, malaise, anorexia, fever, uterine tenderness, and malodorous lochia. Prompt diagnosis and proper selection of

antibiotic therapy for patients who become symptomatic with endomyometritis is important. In a systematic review of 47 trials comparing various antibiotic regimens for treatment of puerperal endometritis, French and Smaill²⁴¹ found that the combination of clindamycin and gentamicin administered intravenously was more effective than other regimens. Regimens with activity against penicillin-resistant anaerobic bacteria were superior to those without this coverage. Furthermore, they found that oral follow-up treatment was not necessary once the clinical signs indicated improvement.

Postcesarean bacteriuria occurs in approximately 11% of patients and is related largely to routine urethral catheterization.²⁴² Studies have shown that the risk of urinary tract infection after cesarean delivery can be reduced substantially by eliminating catheterization or by using intermittent rather than indwelling catheterization.^{243,244}

Wound hematomas are usually caused by faulty hemostasis and respond to drainage of the hematoma. The use of prophylactic antibiotics has substantially decreased the incidence of postcesarean abdominal wound infections, which now occur in 3% or less of cesarean deliveries.^{245,246} Cesarean deliveries performed in the second stage of labor carry greater risk for wound infection; and obesity and the use of suprafascial drains are also risk factors. Obese women are at increased risk for development of necrotizing fasciitis, one of the most serious and potentially fatal consequences of wound infection.²⁴⁷ Between 25% and 30% of wound infections are caused by *Staphylococcus aureus*; these infections do not usually originate from wound contamination from the endometrium. For this reason, attention to sterile technique and proper wound care are essential for patients undergoing cesarean delivery.

Puerperal deep venous thrombosis occurs in 1% to 2% of patients delivered by cesarean section.²⁴⁸ Although pulmonary embolism is rare, it is one of the major causes of maternal mortality. Obesity, prolonged operative procedures, endometritis, and any inherited thrombophilia are risk factors. Treatment is intravenous heparinization followed by treatment with oral anticoagulants, the duration of which depends on the severity of the disease and whether the patient is found to have an inherited thrombophilia. Postoperative pelvic thrombophlebitis is a diagnosis made by exclusion when puerperal fever does not respond to antibiotic therapy but resolves with heparin treatment. Ovarian vein thrombosis can be recognized in patients with postoperative abdominal pain and a palpable tender mass extending from the lower quadrant into the flank, usually on the right side. Prophylactic heparinization is commonly used in the United Kingdom and Europe for both elective and emergency cesarean deliveries, but in the United States it is used only in patients at high risk for thromboembolism.^{249,250} There is no consensus as to whether an evaluation for inherited thrombophilia should be recommended for all patients with postcesarean deep venous thrombosis or pulmonary embolism. Clearly, such testing is in order if there is a family history of thromboembolism.

Postoperative adynamic ileus is not uncommon after cesarean section, especially if the bowel has been manipulated during the surgery. Kammen and colleagues,²⁵¹ in a study of 21 patients who had abdominal radiographs because of obstructive symptoms after cesarean delivery, found radiographic signs of distal colonic obstruction in 15. All 21 patients had rapid clinical and radiographic improvement on conservative management, confirming the eventual diagnosis of transient postoperative ileus. A more serious problem is postcesarean pseudocolonic obstruction with marked dilation of the cecum (Ogilvie syndrome). Although the etiology and pathogenesis of this syndrome is not clear, early recognition and surgical decompression are necessary to avoid rupture of the cecum.²⁵²

Prophylactic antibiotics, regional anesthesia, early ambulation, and intermittent rather than indwelling urethral catheterization all have

contributed to reducing the incidence of postcesarean febrile complications.

The incidence of long-term complications of cesarean delivery is more difficult to document. These complications include the following:

- Cesarean delivery in a subsequent pregnancy
- Uterine rupture in a subsequent pregnancy
- Placenta previa or placenta accreta in a subsequent pregnancy
- Ectopic pregnancy
- Infertility
- Bowel obstruction resulting from intra-abdominal adhesions
- Decision to limit family size
- Fewer subsequent pregnancies

In the United States, the incidence of repeat cesarean delivery is greater than 75%. Among women who have a trial of labor after a previous cesarean delivery in which a low-transverse uterine incision was used, the risk of uterine rupture is 0.5% to 1.0%.²⁵³ This risk has remained remarkably constant for decades. The risk is substantially increased after the classic (i.e., fundal) cesarean incision. Ananth and associates,²⁵⁴ in a systematic review of 36 studies published from 1950 through 1996, found that women who had a cesarean delivery were at twofold to threefold greater risk for placenta previa in the subsequent pregnancy compared with women who had a vaginal delivery, and the risk increased with the number of prior cesarean deliveries (see Chapter 37). A more recent, population-based, retrospective study of births in the state of Washington found a somewhat lower but statistically significant risk of placenta previa (odds ratio [OR], 1.4; CI, 1.1 to 1.6) for the next pregnancy after a first-birth cesarean.²⁵⁵ Some authors also have found an association between previous cesarean delivery and placenta accreta in subsequent pregnancies, but this association is more difficult to document because of the rarity of placenta accreta²⁵⁶ (see Chapter 37). Although there is controversy as to whether there is an increased risk of ectopic pregnancy after cesarean delivery, there are a number of reports of ectopic pregnancies occurring in the uterine incision.²⁵⁷⁻²⁵⁹ Somewhat less controversial is the increased risk of infertility for patients delivered by cesarean.²⁶⁰ Postcesarean infertility is not explained by increased maternal age or by voluntary infertility, but it may be related to fallopian tube damage from postpartum infection.

NEONATAL COMPLICATIONS

It appears that the safest, most atraumatic method of delivery for an infant is by cesarean section, and the increase in cesarean delivery rates after 1960 undoubtedly was fueled, in part, by concerns about the dangers to the fetus of labor and vaginal delivery in certain situations. Nevertheless, abdominal delivery is also associated with uncommon but significant dangers to the infant, including the following:

- Fetal asphyxia resulting from uteroplacental hypoperfusion induced by conduction anesthesia or maternal position
- Neonatal respiratory morbidity
- Scalpel lacerations

Maternal hypotension and its deleterious effect on uteroplacental perfusion are well-known dangers of the supine position. Conduction anesthesia, by blocking vasoconstriction in the lower extremities through the sympathetic nervous system, can further reduce cardiac output and further compromise uterine blood flow. Corke and associates²⁶¹ demonstrated that even brief (2-minute) episodes of hypoten-

sion result in umbilical blood gas values consistent with metabolic acidosis.

Cesarean delivery has long been recognized to be associated with an increase in neonatal respiratory morbidity at all gestational ages.²⁶²⁻²⁶⁴ The frequency of this complication, its specific etiology and pathophysiology, and the mortality rate associated with it are all matters of dispute. The incidence of severe respiratory morbidity in infants born by elective cesarean delivery near term is inversely related to gestational age. Wax and colleagues¹⁴⁶ found that infants born by elective cesarean delivery at 37 and 38 weeks' gestation had greatly increased risks, of severe respiratory morbidity requiring mechanical ventilation (38-fold and 13-fold, respectively), compared with those born at 39 or 40 weeks' gestation. This syndrome could be related to a number of problems, without a clear-cut and similar pathophysiology in each case, but the common denominator is cesarean delivery, especially when it is performed in the absence of labor. Morrison and coauthors,²⁶⁵ in a study of 33,289 deliveries at or after 37 weeks of gestation, found that the incidence of neonatal respiratory morbidity was significantly higher for the group delivered by cesarean section before labor (35.5/1000) compared with cesarean section during labor (12.2/1000) (OR, 2.9; CI, 1.9 to 4.4).

Some cases of respiratory morbidity after cesarean delivery are due to true iatrogenic prematurity, in which inaccurate gestational dates result unexpectedly in a premature infant. Even careful attention to the duration of pregnancy and the use of amniotic fluid tests of fetal lung maturity have not completely eliminated this problem. Schreiner and colleagues²⁶⁶ and Heritage and Cunningham²⁶⁷ suggested that neonatal respiratory disease after elective repeat cesarean delivery—usually manifested as mild transient tachypnea of the newborn (wet lung syndrome)—is, in its most severe form, persistence of the fetal circulation. These observations, together with the studies of Boon and associates²⁶⁸ demonstrating the reduced air volume in the lungs of infants delivered by cesarean section compared with those delivered vaginally, suggest that the neonatal respiratory disease after cesarean delivery is caused by incomplete adaptation of the fetal lung to extrauterine respiration. The specific sequence and timing for this adaptation to extrauterine cardiorespiratory status are unknown; nor is it known whether the physiologic and mechanical events of labor and delivery are necessary to complete pulmonary adaptation. The higher incidence of neonatal respiratory morbidity associated with repeat cesarean delivery in patients not in labor compared with those who are in labor suggests that labor is the signal that crucial physiologic changes have occurred to prepare a fetus for extrauterine life.

Accidental lacerations of the fetus occur in 1% to 2% of cesarean deliveries.^{269,270} The frequency of these accidents appears to be related to the experience of the surgeon, the most common situation being a well-thinned-out lower uterine segment in a patient who has ruptured membranes; in such cases, the uterus at the incision site may be only 2 or 3 mm thick. Usually, these inadvertent scalpel lacerations of the fetus are of only cosmetic importance, but we know of one infant who died as a result of a thrombosis of the sagittal sinus secondary to a scalpel incision incurred during cesarean delivery.

Cesarean delivery also imparts added risks for infants of future pregnancies, including fetal death resulting from antepartum rupture of uterine incisions and neonatal respiratory disease associated with subsequent elective cesarean delivery.²²⁹

Indications for Cesarean Delivery

Reducing the frequency of maternal and neonatal complications of cesarean delivery begins with a proper respect for the dangers of the procedure and careful selection of patients to be delivered in this

manner. In general, cesarean delivery is indicated any time delivery must be accomplished and induction of labor, a trial of labor, additional labor, or vaginal delivery of the fetus is deemed to be of greater risk to the mother or the fetus than abdominal delivery. This straightforward generalization, although constituting a more rational approach than a simple list of absolute indications for the operation, does not do justice to the complexities of the decision in each case.

As the fetal indications for cesarean delivery have multiplied, so have the dilemmas of balancing the benefits and risks of operation for the mother and the fetus. For example, in placenta previa, vaginal delivery subjects both mother and fetus to unacceptable risks of exsanguination, and cesarean delivery is clearly in the best interests of both patients. In the case of a difficult mid-forceps delivery for fetal distress or failure of progress in the second stage of labor, the fetus will most certainly benefit from an expeditious abdominal delivery, but the mother's risks from cesarean versus vaginal delivery are a matter of serious debate. At the other end of the spectrum is the case of a footling breech presentation or genital herpes simplex infection, in which the operation is performed entirely for the benefit of the fetus, with no advantages to the mother apart from the reassurance that it may help her infant. Countless other situations could be used as examples of the difficult decision that faces both physician and patient when evaluating the proper method of delivery. One of the most recent examples, ironically, is the interest in nulliparous patients being considered as candidates for elective cesarean delivery in the absence of the usual indications for abdominal delivery. Studies that have linked postpartum urinary and anal incontinence to vaginal delivery have encouraged some women, especially nulliparas, and their obstetricians to consider elective cesarean delivery at term to reduce the risk of pelvic floor dysfunction. Harer²⁷¹ summarized the arguments in support of such a practice. As noted earlier in this chapter, however, there is insufficient evidence from adequate prospective trials to determine the long-term consequences of alternative methods of delivery on pelvic floor function or to support a recommendation for elective cesarean section to reduce the risks of urinary and anal sphincter incontinence.

The Consensus Development Statement on Cesarean Childbirth²¹³ did much to clarify the indications for cesarean delivery and to draw attention to specific situations in which the need for cesarean delivery can be reduced by thorough evaluation of the patient and the facility.

The problem of dystocia, which includes both proven CPD and the less well-defined problem of "failure of labor to progress," was found to account for 30% of the increase in cesarean delivery rates in the United States. Studies by Silbar²⁷² and by Seitchik and colleagues²⁷³ found that the increase in cesarean birth rate for dystocia resulted, in part, from an increased incidence of large infants and a consequent absolute increase in fetal-pelvic disproportion. Continuous electronic fetal heart rate monitoring contributed to the increase in cesarean delivery for "dystocia." Haverkamp and associates,²⁷⁴ in a prospective, controlled study, found that cesarean delivery was more often performed for dystocia when continuous labor and fetal monitoring data were available, compared with documentation of uterine contractions and fetal heart rate data via palpation and auscultation by a nurse at the bedside. In the absence of data about absolute intrauterine pressure values and subtle fetal heart rate decelerations, it is tempting to speculate that there is longer and more vigorous oxytocin augmentation of desultory labors before cesarean section is considered in the group monitored by a bedside nurse. Or perhaps the nurse at the bedside allays anxiety and thereby contributes to a normal labor pattern and less fetal distress.

The diagnosis of fetal distress, which accounted for 10% to 15% of the increase in cesarean delivery rate in the studies described, is often made in the context of a labor that is not progressing normally. Zalar and Quilligan²⁷⁵ found that the use of fetal scalp blood sampling substantially reduced the number of cesarean deliveries performed for presumed fetal distress. Moreover, as experience is gained with reading fetal monitoring tracings, one is less likely to perform operative deliveries for abnormal but not necessarily ominous fetal heart rate changes. Consequently, judicious interpretation of continuous fetal heart rate monitoring data and persistent attention to factors that will improve the fetal environment often allow the additional time needed for successful labor and vaginal delivery. Garite and colleagues²⁷⁶ found that continuous fetal pulse oximetry in labor resulted in a 50% reduction in the number of cesarean deliveries for nonreassuring fetal status, compared with continuous electronic fetal heart rate monitoring in control subjects, but the overall rate of cesarean section was not reduced, because the number of abdominal deliveries for dystocia increased.

Bloom and coworkers²⁷⁷ randomly assigned 5341 nulliparous women in labor to either "open" or "masked" fetal pulse oximetry. Clinicians had access to oximetry data in the "open" arm and did not in the "masked" arm. There were no differences in the overall rate of cesarean delivery, nor in the rates of abdominal delivery for dystocia or fetal distress; a planned subanalysis of cases with nonreassuring fetal heart rate tracings also demonstrated no differences. This trial called into question the value of fetal pulse oximetry in helping patients forego abdominal delivery or improving the health of newborns.

The waning enthusiasm for midpelvic forceps deliveries has contributed to the increased number of cesarean deliveries in the "dystocia" category.

Vaginal Birth after Cesarean Section

Before 1980, abdominal delivery after a previous cesarean section accounted for 25% to 30% of the increase in cesarean delivery rate.²¹³ However, previous cesarean delivery performed through a low transverse uterine incision for a nonrecurring indication (presumed CPD not included) need not be an indication for a subsequent cesarean delivery. In hospitals with appropriate facilities (i.e., services and staff available for prompt emergency cesarean birth), a patient who has undergone previous cesarean delivery can be allowed a trial of labor.

In a meta-analysis of 31 studies that included 11,417 patients with a trial of labor after a previous low-transverse cesarean delivery, Rosen and associates²⁷⁸ found that maternal febrile morbidity was significantly lower after a trial of labor than after an elective repeat cesarean. Although the combined rate of rupture or dehiscence of the uterine wound was the same in the two groups, the odds ratio for perinatal death in all patients with a trial of labor, compared with those who had undergone elective cesarean delivery, was 2.1 (CI, 1.3 to 3.4). The intended route of delivery, the presence of an unknown type of scar, and the use of oxytocin made no difference in the rate of uterine wound dehiscence.

In a study of 6138 patients with one previous low-transverse cesarean birth, McMahon and colleagues²³⁰ found that major maternal complications (defined as need for hysterectomy, uterine rupture, or serious operative injury) occurred more often in women with a trial of labor than in those who delivered by repeat elective cesarean (OR, 1.8; CI, 1.1 to 3.0). All of the major complications occurred in women with unsuccessful vaginal birth.

Consequently, the overall risk associated with a trial of labor after a previous cesarean delivery will be decreased by selecting women who

have a high probability (>80%) of successful vaginal delivery. Women likely to have a successful VBAC are those who are younger than 35 years of age, whose fetus weighs less than 4000 g, and whose previous cesarean delivery was performed for a reason other than failure of descent in the second stage of labor.

Small series have addressed the question of the safety of VBAC in patients with breech presentation,²⁷⁹ twin gestation,²⁸⁰ or post-term pregnancy.²⁸¹ Although each of these reports noted no greater incidence of complications in those circumstances than for VBAC in singleton pregnancies with a vertex, term presentation, the small number of patients in each series demands continued caution in recommending VBAC for such patients.

Intrapartum rupture of a low-transverse uterine scar, which occurs in 0.5% to 1% of women who undertake a trial of labor after a cesarean delivery, is a serious emergency and can result in perinatal death.²⁸² Furthermore, serious puerperal morbidity is more common in women who undergo cesarean delivery after a trial of labor than in those who undergo a repeat elective abdominal delivery.²³⁰ After being fully informed about the risks and benefits of a trial of labor and VBAC, women are not universally enthusiastic. More than 25% choose to undergo another elective cesarean delivery if given the chance.²⁸³

Landon and associates²⁸⁴ reported on a cohort study of more than 30,000 women in which women with one prior cesarean delivery underwent either elective repeat cesarean delivery or a trial of labor. The prevalence of symptomatic uterine rupture was 0.7%. No infant in the repeat cesarean group but 12 of the infants in the trial of labor group suffered encephalopathy, and 7 of those 12 cases were associated with uterine rupture (for a rate of 0.46 per 1000 trials of labor). The rates of endometritis and of transfusion were higher in the trial of labor group, but there were no differences in the rates of hysterectomy or maternal death. This contemporary cohort is useful in counseling patients and demonstrates the low absolute risks associated with either approach.

Reducing Morbidity of Cesarean Delivery

When cesarean delivery must be performed, the following measures ensure the lowest morbidity and mortality risks for mother and infant:

- Anesthesia administered by a skilled anesthesiologist
- Attention to maternal position and blood volume in the peripartum period
- Prophylactic antibiotics
- Use of a transverse uterine incision whenever possible
- Awaiting the onset of labor whenever possible in cases of repeat cesarean delivery
- Presence of a person skilled in newborn resuscitation

Equally good neonatal and maternal outcomes from cesarean delivery can be obtained with spinal, epidural, or general anesthesia or with local infiltration, provided that it is administered by a skilled person who is fully aware of the unique physiologic problems of the pregnant patient and her fetus.²⁸⁵⁻²⁸⁷ There are, however, maternal and fetal risks associated with each method of anesthesia.

SPINAL ANESTHESIA

Spinal anesthesia is associated with the highest incidence of hypotension and should always be accompanied by uterine displacement, maternal prehydration, and (more controversially) prophylactic ephedrine administration. Lindblad and associates²⁸⁸ used Doppler ultra-

sound to estimate fetal aortic and umbilical blood flow in women during cesarean delivery with intrathecal anesthesia. They found that, if maternal blood pressure was maintained within the normal range with preload infusion of lactated Ringer solution and ephedrine, fetal blood flow was unaffected for 30 minutes after induction. After this time, the pulsatility index in the fetal vessels decreased. Most important for the obstetrician is the awareness that, with spinal anesthesia, the time from onset of anesthesia to delivery of the infant is directly related to the degree of fetal metabolic acidosis resulting from uteroplacental hypoperfusion.²⁸⁹ Simply because the patient is alert is no reason to procrastinate in delivering the infant. There is perhaps as much, if not more, need for prompt delivery of the infant after spinal anesthesia as there is with general anesthesia.

EPIDURAL ANESTHESIA

Epidural anesthesia is associated with maternal hypotension less often than is spinal anesthesia. Jouppila and colleagues,²⁹⁰ however, found that epidural anesthesia was associated with a decreased clearance of xenon 133 (presumed to reflect decreased uteroplacental perfusion), especially when hypotension occurs. One major disadvantage of epidural block for cesarean delivery is the time required for the onset of operative anesthesia, which could preclude its use in many emergency situations. Quinn and Kilpatrick's study²⁹¹ of fetal outcomes in 212 consecutive cesarean deliveries demonstrated that regional anesthesia is satisfactory for urgent cesarean deliveries provided that delivery is not required within 20 minutes. Inhalation anesthesia was needed if the time interval from decision to delivery was less than 20 minutes.

GENERAL ANESTHESIA

General anesthesia, which has the advantage of rapid onset, is also associated with decreased uteroplacental perfusion during induction of the anesthesia.²⁹² Pulmonary aspiration of gastric contents (Mendelson syndrome) is always a major threat with general anesthesia, and this risk is accentuated by the delayed gastric emptying in patients in labor; Cohen²⁹³ reviewed this subject. There is evidence that the particulate antacids, which are commonly used preoperatively to neutralize gastric acidity, may themselves cause pulmonary damage if aspirated, and their use has not eliminated Mendelson syndrome. A nonparticulate antacid such as sodium citrate, given 10 to 45 minutes before anesthesia, alone or in combination with a histamine₂ (H₂) receptor blocker such as ranitidine, should significantly decrease the risk of aspiration without contributing added hazard.²⁹⁴ Perhaps the most important safeguard against the aspiration syndrome is skillful intubation while cricoid pressure is applied.

In patients given general anesthesia, as well as those given conduction anesthesia, prompt delivery of the infant is important, the crucial time being that from incision of the uterus to delivery.²⁹⁵ Delivery of the infant within 90 seconds of making the uterine incision reduces the risk of fetal hypoxemia from altered uteroplacental and umbilical blood flow.

If regional anesthesia is used, adequate volume replacement is important in preventing hypotension. Prehydration with 1000 mL of saline or injection of lactated Ringer solution frequently compensates for vasodilation after onset of anesthesia. The supine position is a well known but frequently neglected danger in all pregnant women in the third trimester.²⁹⁶ Often, during preparation for surgery and administration of the anesthetic agent, the patient is placed flat on her back. Appropriate wedges, left lateral tilt of the table, and even operating with the patient in the lateral position have been shown to prevent supine hypotension and reduce fetal asphyxia.

Bloom and colleagues,²⁹⁷ using the previously described registry,²⁸⁴ demonstrated that more than 93% of abdominal deliveries could be accomplished with a regional technique, with a low failure rate (3.0%). Risk factors for needing general anesthesia included maternal size, increasing preoperative risk scores, and short interval from decision to incision. One maternal death was caused by an anesthetic complication (fluid intubation). This large series attests to the preferability and safety of regional anesthesia in contemporary obstetrics.

In addition to the use of regional anesthesia and early ambulation, the widespread use of prophylactic antibiotics for patients undergoing a cesarean delivery has reduced the risk of puerperal morbidity (see Chapter 38). The use of prophylactic antibiotics for cesarean delivery was the subject of two extensive systematic reviews. Smail and Hofmeyr²⁹⁸ reviewed 81 trials and found a significant reduction of puerperal endometritis and wound infection among women treated with prophylactic antibiotics for cesarean delivery, compared with women who did not receive such treatment. Hopkins and Smail²⁹⁹ reviewed 47 trials comparing various antibiotic regimens used as prophylaxis for cesarean delivery. Ampicillin and first-generation cephalosporins were equally effective in reducing puerperal endometritis. Multiple-dose regimens were of no greater efficacy than single-dose treatments, and there was no significant difference in outcome with systemic versus lavage administration. Also, there was no advantage for the use of antibiotics with a broader range of activity. Although there is no conclusive evidence regarding optimal timing of administration, most obstetricians administer the medication after the umbilical cord is clamped, in the interest of avoiding unnecessary exposure of the infant to an antibiotic. Finally, antibiotic prophylaxis reduces morbidity in elective cesarean delivery as well as in cesarean delivery performed during labor.

In the past, the extraperitoneal approach to cesarean delivery was used if chorioamnionitis was suspected.^{300,301} It appears that this operative technique is no longer widely taught or used, and the risks and benefits of this approach, compared with the standard intraperitoneal approach, have not been delineated.

The advantages of the transverse compared with the vertical uterine incision for cesarean delivery were first recognized by Kerr,³⁰² who showed that low vertical incisions almost always extended into the thicker muscle layers of the fundus and were more frequently complicated by improper healing and subsequent rupture. Also, if the entire uterine incision could be covered by bladder peritoneum, the risk of postoperative ileus, peritonitis, and subsequent adhesions and bowel obstruction was reduced.

The advantages of awaiting onset of labor before performing a subsequent cesarean delivery are the elimination of iatrogenic prematurity and reduction of the risk of neonatal respiratory illness. Awaiting the onset of labor also results in thinning of the lower uterine segment, which decreases blood loss and facilitates development of the bladder flap during the procedure.

Finally, the presence of a professional skilled in neonatal resuscitation is essential, especially when cesarean delivery is performed for fetal distress. It is not only courteous but also often vitally important to inform the pediatrician or nursery personnel as early as possible of an impending cesarean delivery. Special equipment, drugs, and blood products may need to be assembled for a sick neonate. It is a disservice to the mother to perform a major operation in the interest of fetal well-being and not follow up with the most expert care of the newborn.

Cesarean hysterectomy is occasionally lifesaving, especially in cases of uncontrolled hemorrhage from the site of a placenta previa, placenta

accreta, or ruptured uterus. Cesarean hysterectomy could also be the treatment of choice in the woman with chorioamnionitis who desires sterilization and in whom cesarean delivery is indicated. For other indications, such as cervical intraepithelial neoplasia and a request for sterilization with a subsequent cesarean delivery, the operation is associated with sufficient morbidity to make its usefulness in these situations doubtful.

In a review of cesarean hysterectomy including 3913 operations, Park and Duff³⁰³ found the following complication rates: maternal mortality, 0.71%; bladder injury, 3%; vesicovaginal fistula, 0.4%; ureteral injury, 0.25%; and intraperitoneal bleeding requiring reoperation, 0.97%. Supracervical cesarean hysterectomy is justified in cases of life-threatening hemorrhage if the patient's vital signs are unstable. Complete removal of the cervix is one of the most difficult and time-consuming aspects of the cesarean hysterectomy procedure, especially if there has been substantial effacement and dilation of the cervix.

Obstetric Forceps Delivery

Obstetric forceps were first used by members of the Chamberlen family in the 17th century but were not widely accepted until 100 years later.³⁰⁴ William Smellie was the first to systematically teach the principles of forceps deliveries. It is clear that he also was fully aware of the potential dangers of the instruments; in the introduction to Volume II of *Treatise on the Theory and Practice of Midwifery*,³⁰⁵ he wrote, "If these expedients (forceps) are used prematurely when the nature of the case does not absolutely require such assistance, the mischief that may ensue will often over balance the service for which they were intended and this consideration is one of my principal motives for publishing this second volume."

In 1988, the American College of Obstetricians and Gynecologists (ACOG)³⁰⁶ issued a Committee Opinion establishing new definitions for obstetric forceps. These definitions, which were incorporated in the 1991 ACOG Technical Bulletin entitled Operative Vaginal Delivery,³⁰⁷ were divided into three categories:

1. Outlet forceps
 - a. Scalp is visible at the introitus without separating labia
 - b. Fetal skull has reached pelvic floor
 - c. Sagittal suture is in anteroposterior diameter or right or left occiput anterior or posterior position
 - d. Fetal head is at or on perineum
 - e. Rotation does not exceed 45 degrees
2. Low forceps
 - a. Leading point of fetal skull is at station at +2 cm or lower and not on the pelvic floor
 - b. Rotation is less than or equal to 45 degrees (left or right occiput anterior to occiput anterior or left or right occiput posterior to occiput posterior)
 - c. Rotation is greater than 45 degrees
3. Mid-forceps
 - a. Station is above +2 cm but head is engaged

This classification reflects what has been widely recognized among practicing obstetricians, that there are two types of forceps deliveries: low forceps deliveries, which are usually simple and uncomplicated for both mother and infant, and mid-forceps deliveries, which sometimes are difficult and can cause substantial trauma to either patient.

Hagadorn-Freathy and colleagues³⁰⁸ prospectively evaluated forceps deliveries, comparing outcomes as designated by the ACOG criteria

published in 1965.³⁰⁹ When the older classification was used, there was no difference in outcome between outlet forceps and mid-forceps deliveries. When the deliveries were reclassified according to the more recent criteria, however, mid-forceps deliveries were associated with lower cord pH values and a higher incidence of fetal injury, compared with outlet or low forceps deliveries. In a review of operative vaginal deliveries, Bowes and Katz³¹⁰ found that serious short-term maternal and perinatal morbidity are increased in forceps delivery if the vertex is above +2 cm station in the pelvis, compared with +2 station or lower.

A retrospective, population-based study of 583,340 live-born singleton infants in California found that, among patients in labor for whom spontaneous vaginal delivery did not occur, there was no statistically significant difference in the incidence of neonatal intracranial hemorrhage between delivery by vacuum extraction, delivery by forceps, and cesarean delivery.³¹¹ Another important finding of this study was that the incidence of serious neonatal morbidity was significantly greater when cesarean delivery was performed after a failed attempt at vaginal delivery with either forceps or vacuum extractor, compared with cesarean delivery after a trial of operative vaginal delivery. There were multiple limitations to this study, including lack of information about the level of experience of those who performed the operative deliveries. Such limitations notwithstanding, the study suggested that, if spontaneous delivery cannot be accomplished safely for the mother or infant and the circumstances are not favorable for a relatively easy operative vaginal delivery, the patient should be delivered by cesarean. This contention is supported by evidence that many modern residency training programs in obstetrics and gynecology are not providing sufficient skill in the safe use of forceps.³¹²

Few studies with long-term follow-up of infants delivered with forceps have been published. Friedman and colleagues³¹³ published results from a collaborative perinatal project in which children delivered by mid-forceps demonstrated lower intelligence quotient (IQ) scores and a higher prevalence of suspected speech, language, and hearing abnormalities than did children born spontaneously. McBride and coworkers¹⁶¹ studied 700 5-year-old children, all of whom were born at term, including 175 born by mid-forceps delivery. Using a variety of neurologic, hearing, visual acuity, and development tests, these authors found no differences related to method of delivery among the children who had been born in cephalic presentation. Dierker and associates³¹⁴ compared 110 children 2 years of age or older who had been delivered by mid-forceps with a similar number of children of the same age delivered by cesarean section. They found five cases of abnormal development among the children delivered by mid-forceps and seven cases among those delivered by cesarean section.

Seidman and coauthors³¹⁵ related obstetric interventions to medical examinations and intelligence tests performed on more than 32,000 17-year-old men and women inducted into the Israeli Defense Forces. The mean intelligence scores for those delivered by forceps or vacuum extractor were not statistically different from those delivered spontaneously or by cesarean section.

In a retrospective study of 3417 children, Wesley and coworkers³¹⁶ found no association of forceps delivery (versus spontaneous delivery) with decreased IQ score at 5 years of age. The studies that demonstrated no untoward long-term effect of operative vaginal delivery are those in which the infants were born after 1970. A more conservative attitude about forceps, which has characterized the period since the late 1970s, may have been responsible for the salutary outcomes noted in recent studies of both short-term and long-term effects of operative vaginal delivery.

Mid-forceps deliveries, as defined by the 1991 ACOG criteria, should be undertaken with caution and with a willingness to abandon the procedure in favor of cesarean delivery if there is difficulty with proper application of the instrument or if the head does not easily descend or rotate. The use and teaching of midforceps delivery under the appropriate circumstances and by an adequately trained individual is in accord with current recommendations of the ACOG.³¹⁷

Patel and Murphy³¹⁸ reviewed the role of forceps in modern practice. Their 2004 review concluded that (1) most women prefer spontaneous delivery; (2) obstetricians increasingly choose cesarean section if problems arise during the second stage of labor; (3) injury to the pelvic floor and trauma to the baby are more common with forceps, whereas hemorrhage and maternal-infant separation occur more often after abdominal delivery; and (4) forceps delivery results in less morbidity in subsequent pregnancies. The authors bemoaned the decline in forceps skills among junior clinicians and advocated further research regarding the long-term sequelae of forceps operations.

Vacuum Extraction

Malmström introduced the vacuum extractor into modern obstetrics in 1954.³¹⁹ Since that time, it has largely replaced the use of obstetric forceps in Scandinavia and continental Europe, and it is used with increasing frequency in the United States.³²⁰ Bowes and Katz³¹⁰ reviewed the use of the vacuum extractor for obstetric delivery. The indications for its use are virtually the same as those for the use of forceps:

- Arrest of labor in the second stage
- Maternal indication for shortening of the second stage of labor (e.g., cardiovascular or cerebrovascular disease, maternal exhaustion)
- Fetal distress
- Elective low pelvic delivery

Contraindications for use of the vacuum extractor include the following:

- CPD
- Face or brow presentation
- Breech presentation
- Unengaged fetal head
- Premature infant
- Incompletely dilated cervix

Maternal complications of vacuum extractor delivery, including cervical and vaginal trauma, are generally less frequent and less severe than those of forceps delivery, and this is one of the major advantages of the instrument. Minor fetal complications include cephalhematomas and retinal hemorrhages, which are usually benign and self-limited. More serious complications, such as subgaleal hemorrhage (4%) and intracranial hemorrhage (2.5%), are usually associated with prolonged labor and fetal asphyxia but are probably less common than in forceps deliveries performed under the same circumstances.

Johanson and Menon³²¹ performed a systematic review of nine randomized, controlled trials comparing the vacuum extractor with forceps for assisted vaginal delivery. They concluded that failure to deliver the infant occurred more often with the vacuum extractor than with the forceps. The vacuum extractor was associated with significantly less maternal pelvic trauma but with a greater risk for neonatal cephalhematomas and retinal hemorrhages. A 5-year follow-up study of 278 infants who were involved in a randomized, controlled trial of vacuum extraction versus forceps delivery found no statistical differ-

ence in long-term untoward effects between the two methods.³²² Almost all studies have found a substantial increase in risk of maternal and fetal morbidity when failure to deliver with the vacuum extractor is followed by an attempt to deliver with forceps. For example, Towner and colleagues³¹¹ found that use of both vacuum extraction and forceps resulted in a rate of intracranial hemorrhage that was 7.4 times greater than with spontaneous delivery, and 3.4 times greater than with use of the vacuum extractor as the sole instrument. Also, Gardella and associates³²³ compared 3741 combined vacuum and forceps deliveries with the same number of vacuum-only and forceps-only deliveries. There was a significant increase in both neonatal and maternal injury with sequential use of the instruments. A recommendation to avoid the combination of vacuum extractor followed by forceps is in accord with the current guidelines on operative vaginal delivery published by ACOG.³¹⁷

Two major advantages of the vacuum extractor are the ease with which it can be applied and the need for less anesthesia than is required for forceps delivery. Moreover, it is far easier to teach and to learn the appropriate skill required to use the vacuum extractor safely than to acquire a similar level of skill with forceps delivery. Many of the studies that established the effectiveness and safety of the vacuum extractor compared with obstetric forceps were conducted with the Malmström metal cup or the Bird modification of the Malmström device. Currently, a variety of both rigid and soft polyethylene or silicone vacuum cups are the preferred instruments for vacuum extraction and the ones most commonly used in residency training programs in the United States.³²⁰ Randomized trials of soft versus rigid vacuum extractor cups show that soft cups have lower success rates than rigid cups but are less likely to cause maternal and fetal trauma.³²⁴

The collective evidence of the comparative efficacy and safety of vacuum extraction versus forceps has led some authorities to recommend the vacuum extractor as the instrument of first choice for operative vaginal delivery.³²⁵

Analgesia and Anesthesia for Low-Risk Labor and Vaginal Delivery

History

An interesting monograph by Caton³²⁶ and a shorter account by Caton and colleagues³²⁷ chronicled the history of pain relief for childbirth during the past two centuries. It is safe to say that the plight of women in labor has improved dramatically since the 16th century, when Eufame MacLayne, a woman of some station, was tried by due process, convicted of an act contrary to divine law, chained to a stake atop Castle Hill, and burned. Her only crime was having received “a certain medicine for the relief of pain in childbirth.”³²⁸ Until the 18th century, labor was conducted without the use of effective analgesia or anesthesia. The birth process was simply acknowledged to be a painful, traumatic, and often frightening experience that was to be endured with the aid of only crude and unproven potions. James Simpson, who held the Chair of Midwifery at the University of Edinburgh, was the first to administer chloroform to a woman in labor and became a champion of obstetric anesthesia.³²⁹ His work, and especially his care of Queen Victoria, who enjoyed the birth of one of her many children with the assistance of chloroform, changed both public and professional attitudes about the benefits of providing pain relief for women during labor. Modern obstetric units, many with the service of full-time

obstetric anesthesiologists, provide a wide range of options for pain management, including psychophysiologic methods, parenteral analgesia, and regional analgesia.

One of the most important assets of a modern facility offering a full range of perinatal services is the presence of a qualified obstetric anesthesiologist. The physiologic changes that characterize pregnancy result in metabolic, respiratory, and cardiovascular phenomena not encountered in the nonpregnant state. These changes, together with the presence of the fetus in utero, are a challenge for the anesthesiologist. Furthermore, high-risk obstetric patients frequently have fetal or maternal problems that further complicate the already difficult task of administering anesthesia to two patients simultaneously (see Chapter 56).

The choice of drug and anesthetic technique for labor and delivery depends on the skill and experience of the person who performs the procedure, the progress of labor, other complications of pregnancy or labor, and the desires of the patient. With proper antenatal psychological preparation, many patients require minimal, if any, analgesia or anesthesia throughout labor, and healthy infants are born in most of these cases. Nothing should be done to discourage such a practice. Furthermore, everything should be done to facilitate birthing in quiet, pleasant, and friendly surroundings in which a friend or family members accompany the parturient. There is considerable evidence that a supportive birth attendant (doula) reduces the need for analgesia and anesthesia and, in some populations, reduces the incidence of dystocia.^{189,330}

Analgesia

Sedatives and narcotic analgesics are frequently administered alone or in combination in the first stage of labor. There is increasing evidence that opioids given systemically do not relieve the pain of labor.^{331,332} These drugs do reduce anxiety and result in sedation. All drugs of this type rapidly appear in the fetal circulation when administered to the mother. Predictably, there will be some sedation of the infant, depending on the specific drug given, the amount, the time, and the route of administration.

The drug most commonly used for pain is meperidine in doses of 50 to 100 mg intramuscularly or 25 to 50 mg intravenously. To enhance its effect, provide additional sedation, and prevent nausea, physicians may prescribe a phenothiazine such as promethazine, 25 mg, as well. The half-life of meperidine is increased and is more variable in pregnant women than in nonpregnant subjects. Furthermore, fetal hypoxia reduces the clearance of meperidine from fetal blood.³³³ If the neonate appears depressed as the result of the administration of meperidine to the mother, injection of the narcotic antagonist naloxone may be indicated (0.1 mg/kg intravenously or intramuscularly). Other analgesics, such as butorphanol, nalbuphine, and fentanyl, all of which cause less respiratory depression, are used frequently for intrapartum pain control.³³⁴⁻³³⁶

Systematic reviews of parenteral opioids for relief of labor pain published by Elbourne and Wiseman³³⁷ and Bricker and Lavender³³⁸ included 48 trials comparing a variety of parenteral opioids with placebo, with each other, and with regional analgesia. These reviews concluded that epidural analgesia provides more effective pain relief than does parenteral analgesia. However, there is no clear evidence any one medication or one method of administration used for parenteral analgesia is superior to another. Long-term effects of parenteral opioids used during labor have not been studied extensively, although there is some concern about genetic imprinting at birth for later self-destructive behavior and drug addiction.³³⁹

Paracervical Block

Paracervical block was a popular form of anesthesia for the first stage of labor until it was implicated in several fetal deaths and was shown to be associated with fetal bradycardia in 25% to 35% of cases.³⁴⁰⁻³⁴² In some cases, death was related to direct injection of large doses of local anesthetic agents into the fetus, whereas the fetal bradycardia was probably a response to rapid uptake of the drug from the highly vascular paracervical space.

Although not advocated with enthusiasm by most authorities, this form of anesthesia is still used, especially in hospitals in which epidural anesthesia is not available. If paracervical block is used wisely in low-risk patients, it is safe and effective for the first stage of labor.³⁴³ The anesthetic should be administered with great care to avoid direct fetal injection, and using the smallest amount of drug possible. Chloroprocaine (1% to 2%), rather than lidocaine or mepivacaine, should be used if repeated doses will be required.³⁴⁴ Anyone using paracervical block anesthesia should read the excellent account of this method by Chestnut.³⁴⁵

Pudendal Block

Pudendal block is a common form of anesthesia used for vaginal delivery. When successful, it provides adequate pain relief for episiotomy, spontaneous delivery, forceps or vacuum extraction delivery from a low pelvic station, and repair of perineal, vaginal, or cervical lacerations. Because the local anesthetic agent is injected well away from the parauterine vasculature, uteroplacental blood flow and fetal heart rate are not affected to the same degree as in paracervical block. Occasionally, vaginal hematomas can be caused by pudendal nerve block, but the most dreaded complication is a retrosoas or pelvic abscess.^{346,347} It is surprising that this complication does not occur more frequently, inasmuch as the injection is made through a nonsterile field. The infrequency of infections in the Alcock canal is probably a consequence of the prolonged compression of the paravaginal tissues by the fetal head, which prevents hematoma formation.

The success of pudendal nerve block depends on a clear understanding of the anatomy of the pudendal nerve and surrounding structures. The anatomic study by Klink³⁴⁸ clarified the course of the pudendal nerve, described the variations of the nerve and its branches, and discussed the anatomy in relation to the performance of successful regional anesthesia. This article, with its helpful illustrations, is an excellent resource.

Low Spinal Anesthesia

Low spinal anesthesia, often called saddle block, is an effective means of anesthesia. It is relatively simple to perform and provides prompt, reliable pain relief that is adequate for spontaneous delivery or instrument delivery from the low pelvic or midpelvic station. It usually consists of 4 mg of tetracaine administered in a hyperbaric solution at the L4-L5 interspace with the patient sitting.

Although this technique is intended to anesthetize only the "saddle region," the level of anesthesia sometimes is as high as the T10 dermatome. Because of the ease of administration and the reliability of this form of anesthesia, it has been a favorite of obstetricians practicing in hospitals in which anesthesiologists are available only for cesarean delivery or other emergencies. As a result of the profound sympathetic block that occurs with spinal anesthesia, however, saddle block can be associated with profound hypotension and a decrease in uteroplacental perfusion. Furthermore, it can interfere with the voluntary abdominal

pushing effort far more than epidural anesthesia, frequently resulting in delivery of the infant by forceps. The popularity of this form of obstetric anesthesia is waning because it is being replaced by epidural anesthesia and because many patients insist on unmedicated, natural delivery.

Epidural Analgesia and Anesthesia

Epidural anesthesia is being used with increasing frequency, especially in hospitals where anesthesiologists are available to patients in labor 24 hours a day. In experienced hands, epidural anesthesia has an excellent safety record.³⁴⁹ Although it is the most difficult form of anesthesia to administer, it has the advantage of providing excellent pain relief for the first and second stages of labor and for delivery without altering the consciousness of the mother. Bupivacaine and chloroprocaine are the drugs most commonly used, the former providing more prolonged anesthesia but with a greater delay in onset. The use of combinations of local anesthetics and narcotics also provides excellent analgesia with less motor blockade.³⁵⁰

Continuous lumbar epidural anesthesia has been associated with late decelerations in fetal heart rate suggestive of decreased uteroplacental perfusion in as many as 20% of cases. This is more common with bupivacaine than with chloroprocaine or lidocaine.³⁵¹ Also, the use of oxytocin to augment labor in cases in which continuous epidural anesthesia is used has been reported to increase the frequency of late decelerations noted on fetal monitoring.³⁵² When uterine hypertonus or maternal hypotension is associated with the augmentation of contractions in patients with epidural anesthesia, fetal heart rate patterns indicating uteroplacental insufficiency occur in as many as 70% of cases.³⁵³ Prehydration of the mother and avoidance of the supine position³⁵⁴ can reduce the incidence of uteroplacental insufficiency with epidural anesthesia. The use of drug mixtures of local anesthetics and analgesics results in less motor block; this allows women who have epidural anesthesia to be more mobile during labor, and they are less likely to be confined to the supine position.

Thorpe and Breedlove³⁵⁵ reviewed the benefits and risks of epidural analgesia for labor and delivery. Both retrospective and prospective controlled trials have demonstrated that epidural analgesia results in longer labors and a higher incidence of operative vaginal delivery and cesarean delivery than intravenous analgesia. Some studies have suggested that the untoward effect of epidural analgesia on labor occurs primarily in patients in whom the epidural is placed when the cervix is dilated less than 5 cm³⁵⁶; however, controlled trials by Chestnut and coauthors^{357,358} established that the time of onset of epidural analgesia did not affect length of labor or method of delivery. In a retrospective, case-controlled study, Thompson and colleagues³⁵⁹ showed that those patients who had abnormal labor progress after epidural analgesia often had abnormal labor curves before placement of the epidural block.

Zhang and associates³⁶⁰ used a unique approach to determine whether epidural analgesia prolongs labor and increases the risk of cesarean delivery. A natural experiment occurred wherein the incidence of labor epidural anesthesia was suddenly increased from 1% to 84% in a brief period of time while other conditions remained unchanged. There was no resultant change in overall rate of abdominal delivery, rate of abdominal delivery for dystocia, rate of instrumental delivery, or length of the first stage of labor. The second stage of labor was prolonged by a mean of 25 minutes. Moreover, on-demand epidural analgesia did not increase the risk of fetal head malposition.³⁶¹ The work of these authors confirmed the important studies of others³⁶²⁻³⁶⁴ in finding that labor epidural analgesia does not increase the risk of

cesarean delivery or the use of oxytocin or operative vaginal delivery. The only consistent effect of epidural analgesia is prolongation of the second stage of labor. Therefore, fear of increasing the risk of dystocia should not be used to limit patients' access to this effective analgesic technique.

The relationship between epidural analgesia for labor and delivery and chronic back pain after delivery is controversial. Retrospective studies found an association between epidural analgesia for labor and chronic back pain.³⁶⁵ However, a more recent prospective study, in which women were monitored for 1 year after delivery, found no statistically significant difference in the incidence of persistent back pain among those who did or did not receive epidural analgesia during labor.³⁶⁶

Another problem encountered with epidural analgesia or anesthesia for labor is an increased incidence of intrapartum fever.³⁶⁷ Fever occurs in approximately 30% of laboring patients after 4 to 5 hours of continuous epidural anesthesia. The specific cause of the febrile response is not known, although it could be related to the autonomic block that occurs with epidural anesthesia. Nevertheless, a clinical dilemma occurs in differentiating a "benign" febrile response to the epidural from intra-amniotic infection. As a consequence, most patients who develop a fever in labor are treated with antibiotics, and their infants are evaluated and treated for suspected sepsis.³⁶⁸ At present, there is no clear-cut way to avoid this problem.

An additional benefit of epidural anesthesia for patients undergoing cesarean delivery is that opioids can be injected into the epidural space to provide prolonged postoperative analgesia.³⁶⁹ The rare occurrence of serious respiratory depression (1 in 1200 cases) appears to be the only major complication. Transient nausea, urinary retention, and pruritus have also been reported in patients treated with epidural opioids.

Lieberman and O'Donoghue,³⁷⁰ in a comprehensive systematic review of the unintended effects of epidural analgesia during labor, drew attention to the many unanswered questions that remain despite the large number of studies that have been performed. Because many such studies lacked proper randomization to eliminate selection bias, there is a need for trials comparing epidural analgesia with other forms of analgesia wherein randomization occurs during pregnancy rather than after labor begins. Nevertheless, Lieberman and O'Donoghue contended that current evidence supports the recommendation that women (especially nulliparous women) considering epidural analgesia for labor should be told the following:

- They are less likely to have a spontaneous vaginal delivery.
- The duration of their labor is likely to be longer.
- They will have an increased risk of instrument-assisted delivery, which is associated with an increased risk for serious perineal laceration.
- They are at greater risk of developing a fever during labor, which could lead to an evaluation and treatment of their infant for suspected sepsis.

There is evidence that the use of epidural anesthesia for pain control in labor is related to the size of the delivery service in hospitals in the United States.³⁷¹ In 1997, the use of epidural analgesia in labor was 50% among obstetric services with more than 1500 births per year, compared with 21% among obstetric units with fewer than 500 births per year. Clearly, this must reflect the more frequent availability of 24-hour coverage by anesthesiologists on the obstetric units of the larger hospitals. Proposed solutions to increase the availability of epidural anesthesia for women in labor include allowing certified registered nurse

anesthetists (CRNAs) or adequately trained obstetricians to perform epidural anesthesia. Either of these innovations has economic and medicolegal ramifications that must be considered.

Labor Monitoring

The term "fetal monitoring" has become almost synonymous with continuous electronic fetal monitoring (see Chapter 22). The more comprehensive term, labor monitoring, means the conduct and management of the labor event from its onset to its completion. The primary goal of labor monitoring is to achieve delivery of a healthy infant from a healthy mother with as little trauma as possible. A secondary goal is to accomplish this delivery in a manner that is not degrading to the mother and that enhances and strengthens family relationships in a way that is consistent with the cultural and personal expectations of the patient. In a narrower context, this latter goal has been defined as "reducing bonding failure."³⁷² Certainly, a healthy and supportive family unit augments the growth and development of the newborn. To accomplish these goals requires attention to all the details of the labor and delivery process as they relate to a specific patient's medical, obstetric, and psychosocial situation.

One of the paradoxes of modern obstetric care is that the technologic advances that have contributed substantially to the identification and correction of the pathophysiologic abnormalities of labor may depersonalize the labor event and even introduce phenomena that alter maternal and fetal physiology and create substantial maternal and family anxiety. The outcry against such depersonalization has come from many quarters and has resulted in reexamination of the management of labor and delivery. Indeed, it has been found that many of the traditional hospital obstetric practices, such as the perineal shave, enemas, and isolation of the patient from her family and friends, are not beneficial. More liberal use of ambulation and positions of comfort in labor and delivery have been found to be physiologically beneficial. Furthermore, the presence of family members or supportive friends may decrease anxiety, shorten the duration of labor, and reduce the need for medications.

Perhaps the most important figure in this entire scenario is the bedside nurse in the labor and delivery unit. The nurse's role is to bridge the gap between the most sophisticated obstetric technology and the expectations and needs of the patient and her family. The nurse must thoroughly understand the physiology and pathophysiology of labor; must be able to collect, record, and interpret the data throughout the labor; and must anticipate both maternal and fetal problems. Furthermore, the nurse must provide timely communications to the physicians responsible for the patient's care and frequently must intelligibly and compassionately help to interpret the course of labor to the patient and her family. This implies a one-to-one nurse-patient ratio for patients in active labor. All of these goals should be accomplished in a facility in which there can be an immediate response to a fetal or maternal emergency in the form of prompt delivery or resuscitation if necessary.

Chapter 37

Placenta Previa, Placenta Accreta, Abruptio Placentae, and Vasa Previa

Andrew D. Hull, MD, and Robert Resnik, MD

Bleeding in the later stages of pregnancy has been described as “third-trimester bleeding” or “anteartum hemorrhage.” Late pregnancy bleeding is a significant cause of maternal and fetal morbidity, fetal mortality, and preterm delivery. Traditional accounts of such bleeding have addressed placenta previa, abruptio placentae, and vasa previa, although in fact the only thing that these clinical problems have in common is that they all are concerned, to a greater or lesser extent, with hemorrhage. The etiology, management, and complications of each are quite distinct. In the past, uncertainty in precise diagnosis of the cause of late pregnancy bleeding has led to these conditions being considered together, but the universal availability of ultrasound technology has eliminated much of the diagnostic dilemma.

Bleeding during the second half of pregnancy complicates about 6% of all pregnancies. Placenta previa is ultimately documented in 7% of cases, and evidence of significant placental abruption is found in 13%. In the remaining 80% of cases, the bleeding can be ascribed to either early labor or local lesions of the lower genital tract or no source can be identified.¹ Faced with a woman with late pregnancy bleeding, the clinician must rapidly reach a firm diagnosis and management plan to ensure the optimum outcome for mother and baby. Ultrasonography, electronic fetal monitoring, and, frequently, evaluation of the function of the maternal coagulation system make up the foundation on which both diagnosis and management are developed. Clinical assessment must occur simultaneously with imaging and fetal assessment.

In asymptomatic patients who are without antenatal bleeding but have been identified by prenatal ultrasound as having risk factors (placenta previa, placenta accreta, or vasa previa), timing of delivery is the most important clinical decision that has to be made.

Placenta Previa

Definition and Epidemiology

Advances in the precision of sonographic diagnosis, particularly transvaginal ultrasound (TVUS) technology, as well as an increased understanding of the changing relationship between the placenta and the internal cervical os as pregnancy advances, have rendered traditional definitions and classifications of placenta previa obsolete. *Placenta previa* exists when the placenta covers the cervix either completely or partially or extends close enough to the cervix to cause bleeding when

the cervix dilates or the lower uterine segment effaces. The term “low-lying placenta” should be reserved for cases in which the placenta is seen on transabdominal ultrasound to extend into the lower uterine segment but its precise limits have not been defined, and for cases identified before the third trimester. TVUS allows location of the placenta in relation to the internal cervical os with great precision. When such studies are performed, the placenta may be classified as a *complete previa* if it completely covers the internal os. The term *marginal placenta previa* should be used if the placental edge lies 2.5 cm or closer to the internal os. It has been shown that when the placenta is more than 2 to 3 cm from the cervix, there is no increased risk of bleeding.² A definitive diagnosis of placenta previa should be avoided in asymptomatic patients before the third trimester, because many cases of placenta previa identified early in pregnancy will resolve as pregnancy advances.

Placenta previa affects about 1 (0.5%) of every 200 pregnancies at term.³ There is some evidence that the incidence of placenta previa is increasing.⁴ This increase may be related to the increasing rate of cesarean section observed in all developed countries. A single prior cesarean section or a prior pregnancy complicated by placenta previa increases the incidence of placenta previa in a subsequent pregnancy to as high as 5%,^{1,5,6} rising even further with a history of more prior cesarean deliveries.⁷ Advanced maternal age increases the incidence of placenta previa to 2% after 35 years of age and 5% after age 40.⁷ Multiparity, prior suction curettage, and smoking are all associated with higher risks of placenta previa.⁸⁻¹⁰ The relative risks for these associated factors are summarized in Table 37-1.

Pathogenesis

The underlying cause of placenta previa is unknown. There is a clear association between placental implantation in the lower uterine segment and prior endometrial damage and uterine scarring from curettage, surgical insult, prior placenta previa, and multiple prior pregnancies.

At least 90% of placentas identified as being “low lying” in early pregnancy will ultimately resolve by the third trimester.¹¹ The term “placental migration” is widely used to describe this phenomenon. The placenta clearly does not move; rather, it is likely that the placenta grows toward the better blood supply at the fundus, a process known as trophotropism, leaving the distal portions of the placenta, closer to the relatively poor blood supply of the lower segment, to regress and

atrophy. As the uterus grows and expands to accommodate the developing fetus, there is differential growth of the lower segment, and this may further increase the distance between the lower edge of the placenta and the cervix.

Bleeding from placenta previa may occur before labor as a result of development of the lower uterine segment and effacement of the cervix with advancing gestation. Prelabor uterine contractions may also produce bleeding, as may intercourse or injudicious vaginal examination. Once labor begins, significant bleeding will occur as the cervix dilates and the placenta is forced to separate from the underlying decidua.

Diagnosis

The classic history for placenta previa is that of painless third-trimester bleeding. Several small “herald bleeds” may occur in advance of major hemorrhage, but in up to 10% of cases there is no bleeding until the

onset of labor. Some women experience pain secondary to uterine contractions. Bleeding may be provoked by labor, examination, or intercourse but it usually has no identifiable precipitating cause. The patient is more likely to have a fetus with an abnormal lie, inasmuch as the placenta previa may prevent the fetus from establishing normal polarity. All women presenting with painless vaginal bleeding after 20 weeks’ gestation should be assumed to have a placenta previa until proven otherwise. Transabdominal ultrasound should be quickly utilized to screen for placenta previa. Unless the placenta is clearly fundal and the lower segment is clear, TVUS should then be performed. Transabdominal ultrasound has been shown to be inferior to TVUS for definitive placental localization.^{12,13} Concerns regarding the potential for TVUS to provoke bleeding are unfounded, and several studies have confirmed the safety of a careful TVUS approach (Fig. 37-1).^{7,13,14} The placement of the transvaginal probe should be observed continuously on the ultrasound monitor during insertion, to avoid placing the probe into a potentially dilated cervix. If a transvaginal probe is unavailable, translabial imaging using a regular abdominal probe can produce excellent results, with better visualization of the relationship between the cervix and placenta than is obtained from transabdominal scanning.¹⁵ A digital or speculum examination to inspect the cervix for local causes of bleeding should not be performed until placenta previa has been excluded by ultrasonography.

In the unusual setting of significant late pregnancy bleeding where ultrasound is not available and the diagnosis is not clear, there is still a place for the “double-setup” examination. The patient is taken to the operating room, where preparations are made for a cesarean delivery. A vaginal examination is then performed, beginning in the vaginal fornices and avoiding placing the fingers directly in the cervix. If a placenta previa is detected, cesarean section is then performed. If no placenta previa is found, a search for other causes of third-trimester bleeding ensues.

Implications of Early Pregnancy Diagnosis

The routine use of ultrasonography in the first and second trimesters of pregnancy has led to the frequent observation of a low-lying placenta or a previa.

Transabdominal ultrasound tends to over-diagnose low-lying placenta, especially when the bladder is empty.¹⁶ Even with TVUS, the findings may not correlate with the placental position at term. Several reports confirm that up to 10 times as many women are found to have

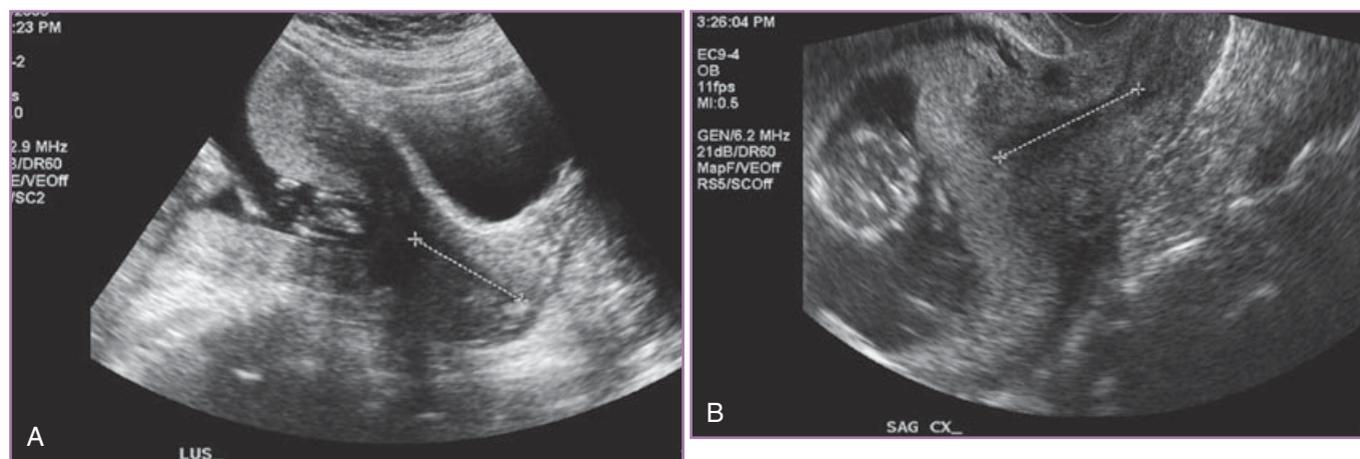

FIGURE 37-1 Ultrasound study performed at 18 weeks’ gestation for fetal anatomy survey. **A**, Transabdominal ultrasound shows an apparent “low-lying placenta.” **B**, Transvaginal ultrasound shows that the placenta completely covers the cervix.

a placenta previa in the second or first trimester than at delivery.^{14,17-21} The earlier in pregnancy a diagnosis of placenta previa is made, the less likely it is that the finding will persist at delivery.²² The likelihood of persistence to term of a placenta previa found in the second trimester is also related to the degree to which the placenta overlies the cervix^{14,17-21} and the thickness of the placental edge.²³ It is recommended that a follow-up ultrasound study be performed between 28 and 32 weeks' gestation to further evaluate the placental position. If there appears to be a significant change in the position of the placental edge over time, a final study should be done at 36 weeks, before making a final decision as to the appropriate route of delivery.

Management

Any woman with vaginal bleeding after 20 weeks' gestation should be assessed on a labor and delivery unit. The primary focus should be on hemodynamic assessment of the mother and assessment of fetal well-being. Vital signs are obtained, and electronic fetal monitoring initiated. One or two large-gauge intravenous lines should be placed, and maternal blood should be sent for determination of the hematocrit and type and screen. For substantial bleeding episodes, 2 to 4 units of blood should be cross-matched. Obstetric units might consider the use of an "Obstetric Hemorrhage Protocol" to facilitate access to the resources of the hospital blood bank for this and any other obstetric hemorrhage (Table 37-2). Rh immune globulin is administered, when appropriate, to Rh-negative, nonimmunized women.

Once the patient is stabilized and fetal condition has been assessed, the definitive cause of the bleeding can be addressed. If the diagnosis is clearly placenta previa and the patient is at or beyond 36 weeks' gestation, delivery is appropriate. If bleeding is excessive or continues, or if there are concerns about the condition of the fetus, the patient should be delivered regardless of gestational age. In all other cases, management may be conservative and has been shown to be safe,^{24,25} with prolongation of pregnancy by an average of 4 weeks after the initial bleeding episode. The closer it is to a gestational age of 36 weeks,

the less likely it is that a significant prolongation of pregnancy will be gained.²⁶ Betamethasone to enhance fetal lung maturation should be administered to patients who are at less than 34 weeks' gestation if expectant management is planned.

There is controversy regarding the role of tocolytics in the setting of hemorrhage from placenta previa. Both β -mimetics and magnesium sulfate²⁷⁻²⁹ have been used in this setting and appear to be associated with significant prolongation of pregnancy without adverse effects.

After the initial presentation with bleeding, patients should remain in hospital until they are free of bleeding for at least 48 hours. Some may then be considered for home management. Several studies have addressed the issue of safety of outpatient management in a controlled setting at home.^{25,30-33} With the exception of one report of an increase in perinatal mortality and morbidity and earlier gestational age,³⁴ it appears to be a safe approach. Patients selected for home management should be asymptomatic with regard to bleeding and abdominal pain, be able to remain at home with limited activity, and have adequate support as well as adequate access to transport to a nearby hospital if bleeding recurs. A second significant bleeding episode usually results in readmission until delivery.

Several strategies have been proposed to reduce the risk of hemorrhage in women with a known placenta previa. Bed rest, reduced activity, and avoidance of intercourse are commonly mandated and seem logical, although there is no conclusive evidence to support these measures. Cervical cerclage was evaluated in two small prospective studies^{35,36} without clear benefit and is not recommended.

All women whose placenta lies within 2 cm of the cervix, as documented by a late third-trimester TVUS scan, should be delivered by cesarean section.³⁷⁻³⁹ An asymptomatic woman whose placenta lies more than 2 cm from the cervical os can be allowed to labor safely.¹⁶ It should be noted that the presence of a low-lying placenta, even if it does not cause intrapartum bleeding, increases the risk of postpartum hemorrhage because of lower uterine segment atony.

Cesarean section for placenta previa should be performed by the most experienced team available because of the substantial risk of intraoperative hemorrhage.⁴⁰ In most instances, a lower uterine segment incision is appropriate. If the placenta is anterior, it is necessary to clamp the umbilical cord immediately to prevent excessive blood loss caused by disruption of the placenta during entry. A vertical incision is also reasonable in such cases and may be preferable if the fetus is premature or if a transverse lie exists.⁴¹ Postpartum hemorrhage may occur from the placental implantation site secondary to atony and may require the use of additional pharmacologic agents to control blood loss, such as methylergonovine maleate (Methergine), 15-methyl prostaglandin F_{2 α} (Hemabate), and high-dose oxytocin, used either singly or in combination. The B-Lynch suture⁴² or local suturing of the placental bed may be needed to control bleeding. In rare cases of refractory hemorrhage, hysterectomy may be required.

Among women known to have a placenta previa who do not require very early delivery, elective delivery should be performed before significant bleeding has occurred. It is reasonable to plan on delivery at or just after 36 weeks' gestation, because there is little fetal advantage after that time, when weighed against the risk of a sudden and possibly excessive bleeding episode. The alternative is to perform an amniocentesis to confirm lung maturity before delivery, but the risk of hemorrhage with delayed delivery usually outweighs the risk of fetal lung immaturity at that gestational age.

The selection of anesthesia to be used for cesarean section in cases of placenta previa should be decided by the obstetrician and anesthesiologist involved with the delivery, in concert with the patient. In the United Kingdom, regional anesthesia was preferred by most obstetric

anesthesiologists in a survey⁴³ and was used in 60% of cases in a retrospective series.⁴⁴ Regional anesthesia is associated with lower operative blood loss and less need for transfusion than general anesthesia,^{3,45} probably because many inhaled anesthetics cause uterine relaxation.

Complications

Placenta Accreta

One of the most serious complications of placenta previa is the development of *placenta accreta*. This condition involves trophoblastic invasion beyond the normal boundary established by the Nitabuch fibrinoid layer. If invasion extends into the myometrium, the term *placenta increta* is used; placental invasion beyond the uterine serosa (at times involving the bladder or other pelvic organs and vessels) is termed *placenta percreta*. Histologic examples of normal placental implantation and placenta accreta are shown in Figure 37-2.

Placenta accreta is associated positively with advanced maternal age, smoking, and parity, but the strongest recognized association is

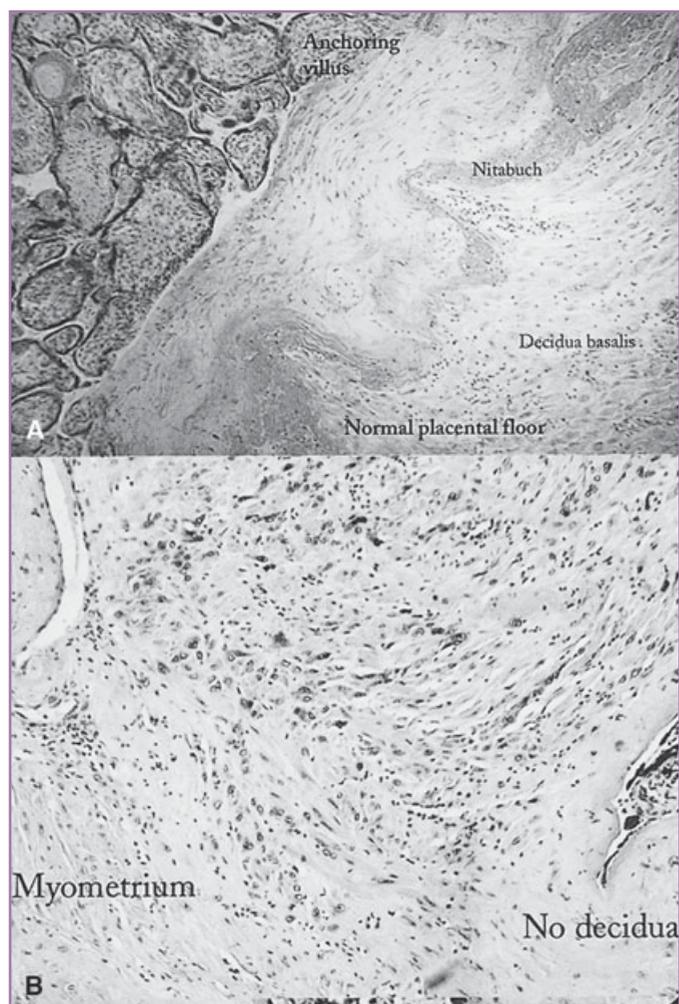

FIGURE 37-2 Histologic appearance of normal placental implantation and placenta accreta. **A**, Histologic section of a normal placental attachment site. Trophoblastic tissue with anchoring villi encroach but do not go through the Nitabuch membrane. **B**, Representative histologic section of placenta accreta, demonstrating invasion of trophoblasts into the myometrial tissue.

with placenta previa and prior uterine surgery.^{46,47} In patients with placenta previa, the risk of accreta is 10% to 25% with one prior cesarean section and exceeds 50% with two or more prior cesareans.⁴⁸⁻⁵⁰ Prevalence appears to be similar in women with these risk factors undergoing second-trimester pregnancy termination.⁵¹

The diagnosis of placental invasion of the myometrium usually can be made by ultrasound,⁵²⁻⁵⁴ with a reported sensitivity and specificity for the diagnosis of approximately 0.8 and 0.95, respectively.^{53,55,56} Magnetic resonance imaging (MRI) has also been used to confirm the diagnosis or better delineate the presence or extent of accreta.⁵³ MRI is also useful in the presence of a posterior placenta and in the assessment of deep myometrial, parametrial, and bladder involvement.^{55,57}

The ultrasound appearance of a normal placental attachment site is shown in Figure 37-3A. Normal attachment is characterized by a homogeneous appearance of the placenta and a hypoechoic boundary

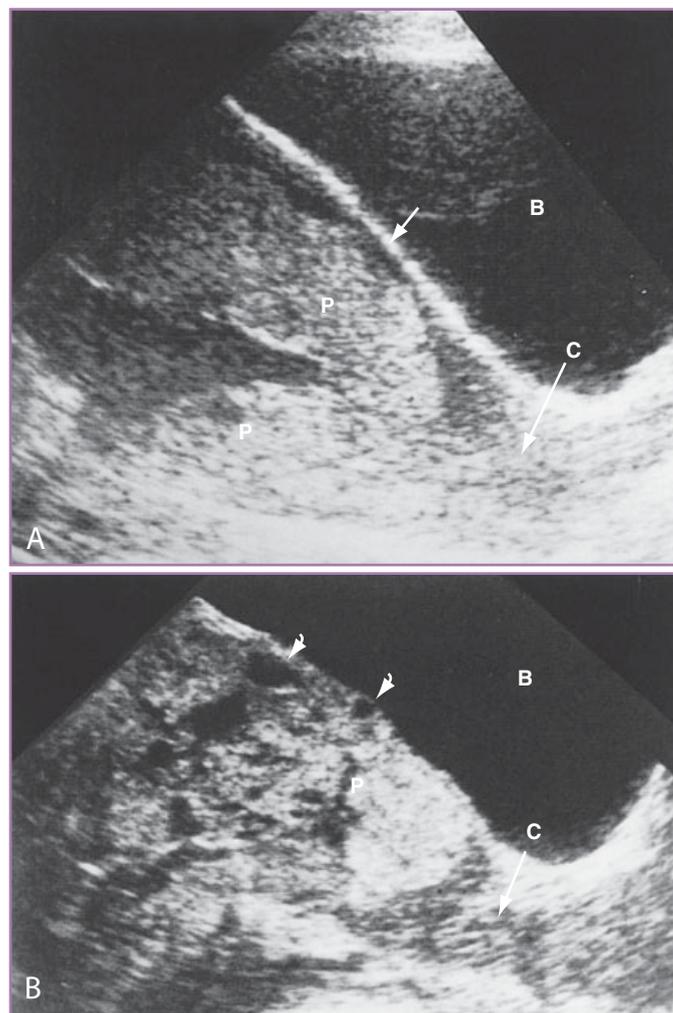

FIGURE 37-3 Ultrasound appearance of a normal placental attachment site and placenta accreta. **A**, Normal placental attachment in an anterior placenta previa. A hypoechoic area separates the bladder wall and the placental tissue, representing myometrium and myometrial vasculature. **B**, Characteristic ultrasound appearance of placenta accreta. Note the lack of a hypoechoic area, as well as obliteration of the well-delineated bladder wall. In addition, there are intraplacental sonolucent spaces (arrows) adjacent to the involved uterine wall. B, bladder; C, cervix; P, placenta.

between the placenta and the bladder that represents the myometrium and the normal retroplacental myometrial vasculature. The bladder wall is intact throughout. In contrast, placental accreta is associated with loss of the normal hypoechoic boundary, and there are usually intraplacental sonolucent spaces adjacent to the involved uterine wall (see Fig. 37-3B). Color-flow and power Doppler sonography have also been reported to facilitate the diagnosis.⁵⁸⁻⁶⁰ Chou and associates⁶⁰ evaluated 80 women with placenta previa to determine the accuracy of color-flow Doppler ultrasonography in distinguishing between uncomplicated placenta previa and placenta accreta. Using their criteria, the antepartum diagnosis of accreta was made in 16 of the 80 women studied and was confirmed histopathologically in 14. The sensitivity and specificity for diagnosis were 0.82 and 0.97, respectively. Although it is clear that larger numbers of patients must be studied by these various modalities to more accurately determine the sensitivities and specificities of diagnosis, various types of ultrasonography and MRI appear to hold promise in making or excluding the diagnosis in most cases.

It is important, if at all possible, to make the diagnosis before delivery, because intraoperative hemorrhage can be massive, and placenta accreta has been reported to be the most common indication for emergency peripartum hysterectomy.^{61,62} In an effort to diminish blood loss, it is recommended that delivery be accomplished through a fundal incision followed by clamping of the cord. The placenta is allowed to remain in situ while the surgeons proceed to a total abdominal hysterectomy. This may require very complex surgical technique and planning, and a pelvic surgeon capable of wide resection of the lower uterine segment and parametrial areas should be available, as well as ample transfusion capability.

Although published reports are not extensive, it has been suggested that balloon occlusion of the aorta or internal iliac vessels may help to prevent excessive blood loss during resection of the lower uterine segment. This involves preoperative placement of balloon-tipped catheters retrograde through the femoral arteries immediately before surgery. The catheters are guided under fluoroscopic direction into the internal iliac arteries and inflated during the dissection. However, the value and safety of this approach have been challenged with the recent reports of no proven benefit and embolic complications.^{63,64} Nevertheless, the placement of catheters does provide the opportunity to manage potential postoperative bleeding with angiographic embolization rather than reexploration.

Conservative management may be an option if there is suspicion of a small focal accreta, if there is a fundal location after a myomectomy or classic cesarean section, or with a posteriorly implanted placenta. A few reports have suggested leaving the uterus and placenta in situ and using methotrexate postoperatively.⁶⁵⁻⁶⁷ However, the numbers of reported cases are very few, and hemorrhagic and infectious complications have usually resulted. Consequently, a definitive surgical approach to this serious obstetric complication is strongly recommended.

Neonatal Complications

It has been suggested that repetitive bleeding from placenta previa is associated with fetal growth impairment,⁶⁸ although this has been disputed.²⁶ Pregnancies complicated by placenta previa have also been reported to be associated with higher rates of fetal anomalies,⁶⁹ neurodevelopmental delay,⁷⁰ and sudden infant death syndrome (SIDS).⁷¹ The reasons for these findings are unknown.

As might be expected, placenta previa and placenta accreta are a cause of preterm birth due to the need for iatrogenic preterm delivery. Accreta has also been reported to have a negative influence on fetal growth (odds ratio, 5.05 compared with controls).⁷²

Vasa Previa

Definition and Epidemiology

Vasa previa is a rare but potentially catastrophic complication in which fetal vessels run through the fetal membranes and are at risk of rupture with consequent fetal exsanguination. It is estimated that vasa previa affects between 1 in 1275 and 1 in 8333 pregnancies.^{73,74}

Pathogenesis

Vasa previa may occur because the insertion of the umbilical cord into the placenta is velamentous, with the umbilical vessels coursing through the fetal membranes before inserting into the placental disk and the unsupported vessels then overlying the cervix. It may also result from the presence of a bilobed or succenturiate placenta with the vessels connecting the placenta similarly overlying the cervix.¹⁶ If the condition goes unrecognized, it is associated with a fetal mortality rate of almost 60%. In addition to a succenturiate placenta⁷⁵ and velamentous insertion, other risk factors include a low-lying placenta observed in the second trimester,⁷⁶ multiple gestation, and in vitro fertilization.⁷⁷

Diagnosis

The key to reducing fetal loss from vasa previa is prenatal diagnosis.¹⁶ Many cases of vasa previa are identified only at the time of vessel rupture in labor. Vaginal bleeding is followed by fetal distress and death if emergent delivery cannot be effected in time. Because the entire fetal cardiac output passes through the cord, it can take less than 10 minutes for total exsanguination to occur. Electronic fetal monitoring may show an initial tachycardia, rapidly followed by decelerations, bradycardia, and a preterminal sinusoidal rhythm.⁷⁸ If a cesarean delivery can be accomplished immediately and with sufficient rapidity, good newborn outcome can be obtained by aggressive postnatal transfusion therapy.⁷⁹

It has been suggested that the blood from the vagina may be tested to confirm its fetal origin, using the Apt or Kleihauer-Betke tests or electrophoresis.⁸⁰ In actual practice, such tests are either unavailable or cannot be done quickly enough to be of any value. Occasionally, fetal vessels have reportedly been felt through the membranes during vaginal examination or visualized on amnioscopy; such observations are really only of historical interest in modern practice.

It is now well established that vasa previa may be diagnosed prenatally using ultrasound.^{81,82} Routine obstetric ultrasound should include an assessment of the placental site and number of placental lobes and an evaluation of the placental cord insertion site. In all cases in which a multilobed or succenturiate placenta or a low-lying placenta or velamentous cord insertion is identified using transabdominal ultrasound, a detailed examination of the lower uterine segment and cervix should be performed using TVUS. Gray-scale ultrasound can identify placental cord insertion in most cases, but color or power Doppler makes the process easier and should be used (Figs. 37-4 and 37-5).⁸¹⁻⁸⁴ There have been several studies evaluating this approach for prenatal detection of vasa previa,^{81,82,84,85} all of which showed high specificity and sensitivity of detection with little impact on the length of scan time. More importantly, in cases in which vasa previa was detected prenatally, there were no fetal deaths from the condition. A recent retrospective, multicenter study showed newborn survival rates of 97% in prenatally detected cases of vasa previa and a fetal loss rate of 56% in cases not identified before the commencement of labor.⁸⁶ Newer imaging modalities such

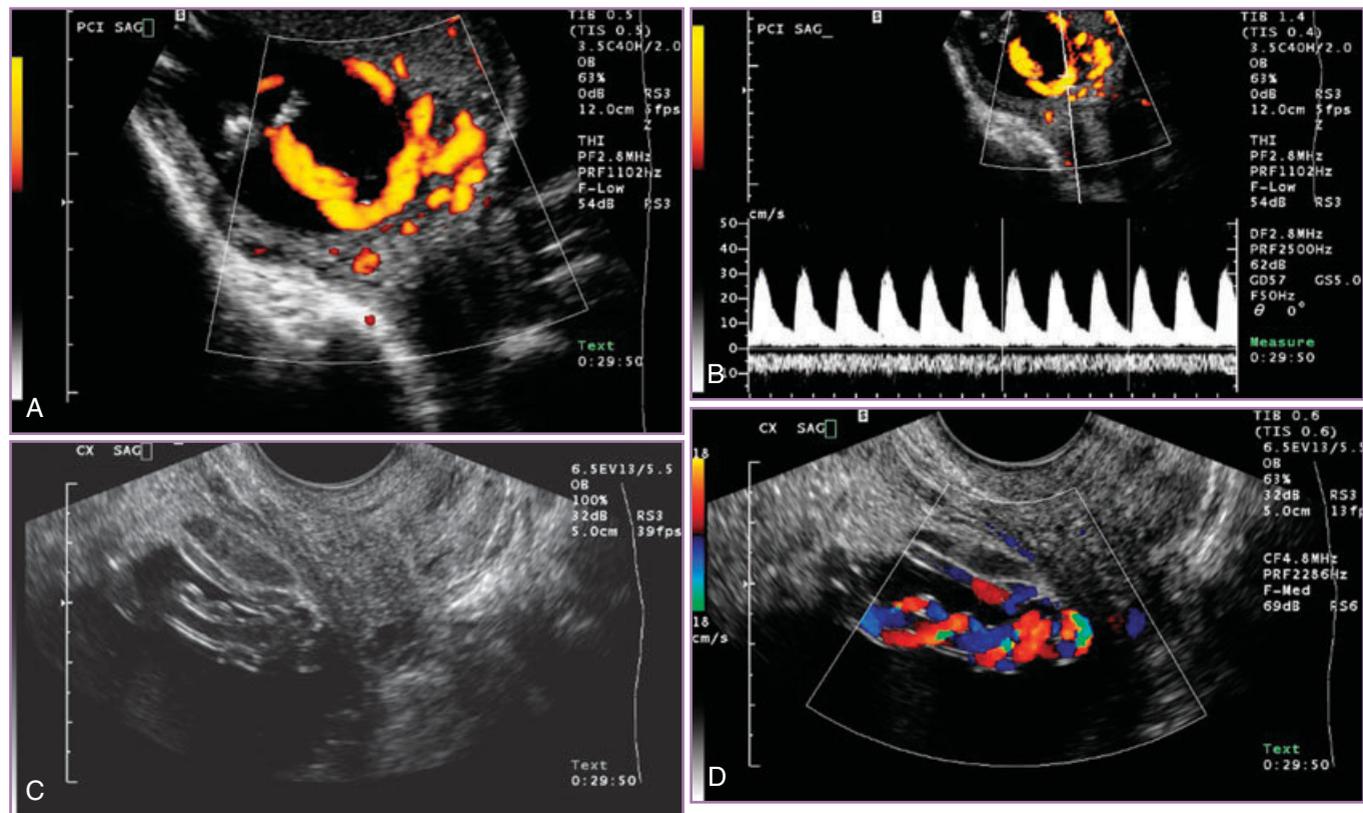

FIGURE 37-4 Vasa previa identified at 18 weeks' gestation on routine ultrasound studies. **A**, Transabdominal power Doppler identifies the umbilical cord possibly overlying the cervix. **B**, A fetal arterial waveform using power and pulse-wave Doppler. **C**, Vasa previa in gray scale on transvaginal ultrasound. **D**, Confirmation of the vasa previa using color Doppler transvaginally.

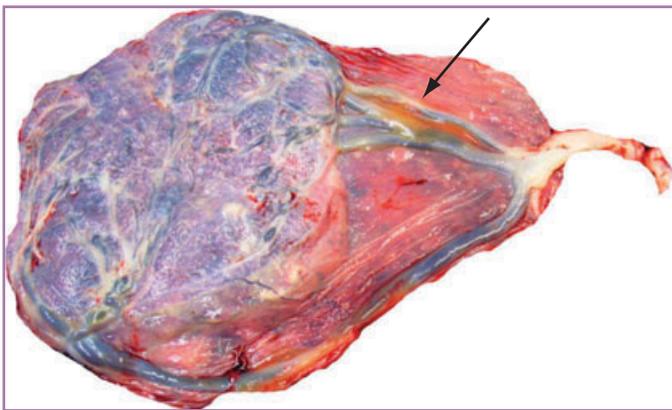

FIGURE 37-5 Vasa previa. The placenta from the case identified in Figure 37-4. The patient was delivered by elective cesarean section at 34 weeks. Arrow shows velamentous cord insertion.

as MRI⁸⁷ and three-dimensional ultrasound have been described in the evaluation of vasa previa.⁸⁷⁻⁸⁹ MRI is of little practical use in routine cases. Although transvaginal three-dimensional power Doppler provides an excellent means of visualizing the entire lower uterine segment for the evaluation of vasa previa, similar information may be obtained by careful use of a two-dimensional vaginal probe. Such imaging combined with maternal positional change, the use of the Trendelenburg position, and gentle manual elevation of the fetal presenting part aid in visualizing the fetal vessels. The latter technique is particularly useful

because the vessels may be compressed by the presenting part and thus difficult to visualize.

Management

There is no uniformity of opinion as to the optimal management strategy for pregnancies with a prenatally diagnosed vasa previa, particularly in regard to the timing of elective delivery. It has been suggested that patients be hospitalized at 30 to 32 weeks and delivered at 35 to 36 weeks' gestation without confirmation of lung maturity by amniocentesis.¹⁶ This approach is based on the 10% risk of membrane rupture before labor and the high associated fetal mortality rate. Our approach has been to assess cervical length weekly from at least 30 weeks using TVUS. If the cervix is 2.5 cm in length or greater, out-of-hospital management continues. The patient is administered beta-methasone just before 34 weeks' gestation and is delivered by cesarean section between 34 and 35 weeks, without additional testing for fetal lung maturity.

Prevention of Adverse Outcomes

A significant reduction in fetal mortality should be possible with a diligent search as previously described. Public and professional awareness has been heightened by such organizations as The International Vasa Previa Foundation (<http://www.vasaprevia.com> [accessed February 8, 2008]). However, a high index of suspicion by the attending physician and a meticulous approach to diagnosis provide the best opportunity for a favorable outcome.

Abruptio Placentae

Definition and Epidemiology

Abruptio placentae is the premature separation of a normally sited placenta before birth, after 20 weeks' gestation. It is a particularly hazardous condition associated with significant maternal and fetal morbidity and mortality. About 1% of all pregnancies are complicated by clinically recognized abruption.⁹⁰⁻⁹³ The degree of abruption ranges across a broad clinical spectrum, from minor degrees of placental separation, with little effect on maternal or fetal outcome, to major abruption associated with fetal death and maternal morbidity. Abruptio sufficient to cause fetal death occurs in about 1 of every 420 deliveries.⁹⁴ If placentas are routinely examined after delivery, evidence of abruption may be found in almost 4% of cases, most of which were unrecognized and of no apparent clinical consequence. There has been an increase of almost 25% in the rate of clinically detected abruption in the United States in recent decades, with a disproportionate increase seen among African-American women.⁹⁵

The incidence of abruption peaks between 24 and 26 weeks' gestation.⁹⁶ Approximately 10% of all preterm births occur because of abruption,⁹⁰ and the infant outcomes are associated with increased rates of perinatal asphyxia,⁹⁷ intraventricular hemorrhage, periventricular leukomalacia,⁹⁸ and cerebral palsy⁹⁹ when compared with gestational age–matched controls. Perinatal mortality in pregnancies complicated by abruption may be declining overall,^{93,100} but the rate continues to be higher than in gestational age–matched controls without abruption.⁹⁶ Placental separation is strongly associated with preterm premature rupture of the membranes (pPROM), in both a causal and a consequential manner.¹⁰¹ Most pregnancies complicated by abruption result in the delivery of an infant weighing less than the 10th percentile for gestational age,¹⁰²⁻¹⁰⁴ suggesting a common pathway linking abruption to placental dysfunction and intrauterine growth retardation (IUGR).

Pathogenesis

Abruptio results from bleeding between the decidua and placenta (Fig. 37-6). The hemorrhage dissects the decidua apart, with loss of the corresponding placental area for gaseous exchange and provision

FIGURE 37-6 Abruptio placentae. A large retroplacental abruption at 30 weeks' gestation is shown.

of fetal nutrition. The process may be self-limited or ongoing with further dissection of the decidua. Dissection can lead to external bleeding if it reaches the placental edge and tracks down between the fetal membranes; circumferential dissection leading to near-total separation of the placenta can occur, particularly with concealed abruption. The underlying event in many cases of abruption is thought to be vasospasm of abnormal maternal arterioles. Some cases may result from venous hemorrhage into areas of the decidua that have become necrotic secondary to thrombosis. Long-standing predisposition to abruption may be inferred from the finding that women destined to suffer abruption have low levels of pregnancy-associated plasma protein A (PAPP-A).¹⁰⁵ Evidence of preexisting placental pathology in women with abruption includes poor trophoblastic invasion,¹⁰⁶ inadequate remodeling of the uterine circulation as reflected by abnormal uterine artery Doppler flow,¹⁰⁷ and the well-established associations among preeclampsia, IUGR, and abruption—all of which may be regarded as primary placental disorders. Abruptio may also occur secondary to acute shearing forces affecting the placenta-decidua interface, such as those that occur with trauma—particularly rapid deceleration injuries (motor vehicle accidents) and the sudden decompression of an over-distended uterus that occurs with membrane rupture in polyhydramnios or delivery of a multiple gestation.

As the abruption process continues, loss of placental function results in fetal hypoxia and may end in fetal death. The acute hemorrhage activates the coagulation cascade, and, with ongoing bleeding, disseminated intravascular coagulation (DIC) may result. Continued bleeding, with maternal hypovolemia and poor tissue perfusion, aggravates the DIC and results in a downward spiral into hemorrhagic shock. Bleeding into the myometrial tissue can lead to a Couvelaire uterus which becomes atonic and increases the risk of uterine hemorrhage after delivery.

Risk Factors and Associations for Abruptio

The most important risk factor for abruption is a history of abruption in a prior pregnancy.¹⁰⁸ One meta-analysis showed an increase of up to 20-fold in the risk of abruption if a prior pregnancy had been similarly affected.¹⁰⁹ With two prior pregnancies complicated by abruption, the risk of recurrence is 25%.⁹⁴

Maternal hypertension is also a significant risk factor for abruption. Chronic hypertension is associated with a fivefold increase in risk, which rises to eightfold with superimposed preeclampsia.⁹⁶ Preeclampsia alone is also strongly linked to abruption and to the severity of abruption.¹¹⁰ It seems plausible that preeclampsia and abruption share many underlying pathologic mechanisms.

Perhaps the most readily preventable risk factor for abruption is cigarette smoking. Cigarette smokers are up to 2.5 times more likely to have an abruption than nonsmokers,¹¹¹⁻¹¹⁵ and they have twice the perinatal mortality of nonsmokers.¹¹⁶ There is a dose-response relationship between the number of cigarettes smoked and the risk of abruption.^{115,117,118} Even women who stop smoking before pregnancy are at increased risk. Substance abuse is closely linked to abruption—any agent that causes vasospasm or transient severe hypertension may be causative.^{119,120} In the United States, as many as 10% of pregnant women who are cocaine and crack cocaine users will experience placental abruption.¹²¹ Multiparity is also positively correlated with a small increase in the risk of abruption.^{1,102} The apparent association between maternal age and abruption is not significant when parity is taken into account.

There has been substantial recent interest in the possible association between thrombophilic disorders and abruption. Some retrospective studies of abruption have found increased rates of thrombophilia.^{122,123}

However, both retrospective¹²⁴ and prospective case-control studies¹²⁵ of women with the factor V Leiden mutation showed no increase in abruption risk. It is established that hyperhomocysteinemia is associated with abruption,¹²³ although, in the absence of hyperhomocysteinemia, the specific *MTHFR* gene mutations themselves do not appear to be associated with an increased risk.^{126,127}

Motor vehicle accidents are the most common traumatic event associated with abruption, and clinical evidence of abruption may not be apparent for 24 hours or longer after the trauma. Women with vaginal bleeding or contractions after a motor vehicle accident should be observed for at least 24 hours; those who are asymptomatic can safely be discharged after 6 hours of monitoring.^{128,129}

Membrane rupture may precede or follow chronic retroplacental bleeding or an acute abruption, and women with ruptured membranes should be monitored carefully for this possibility.^{109,130} Those with early pregnancy bleeding who have a subchorionic hematoma visible on ultrasound are also at increased risk for both pPROM and abruption.¹³¹

Screening tests performed for other indications may identify groups of women who are at increased risk for abruption but may have no other high-risk factors. These tests include maternal first- and second-trimester serum screening for aneuploidy. Women with PAPP-A levels below the 5th percentile at the time of first-trimester serum screening for trisomy 21 have an increased risk of abruption,¹⁰⁵ but low levels of human chorionic gonadotropin (hCG) in the first trimester are not similarly associated.¹³² In one study of routine uterine artery Doppler velocimetry performed at 11 to 14 weeks' gestation as a screen for IUGR and preeclampsia, a pulsatility index higher than the 95th percentile or a PAPP-A value lower than the 10th percentile predicted 43% of pregnancies with a subsequent abruption.¹³³ In an earlier study of uterine artery Doppler ultrasound, persistent notching of the waveform after 24 weeks was associated with increased risk for abruption as well as IUGR and preeclampsia.¹⁰⁷

Women with otherwise unexplained elevated serum levels (>2 multiples of the median [MOM]) of α -fetoprotein (AFP) on second-trimester serum screening for trisomy 21 have long been thought to be at increased risk for a wide range of adverse pregnancy outcomes, including abruption.^{134,135} However, a recent case-matched, prospective study found elevated AFP levels to be associated with an increased risk of abruption but no increase in the frequency of IUGR, preterm delivery, low birth weight, or fetal death.¹³⁶ A recent attempt to establish a critical cutoff value for elevated AFP and increased risk of abruption stressed the low specificity and high false-positive rate of the test.¹³⁶

Elevated hCG values at the time of second-trimester serum screening have similarly been associated with adverse pregnancy outcome, including abruption.¹³⁷ Previously, a value greater than 2.0 MOM was thought to be significant in this context, but one recent case-controlled study showed that the threshold should be set at 3.0 MOM. Even at that level, a positive test had poor predictive value and was not associated with increased risk of abruption.¹³⁸ Abnormal inhibin values do not appear to be predictive of abruption.

Diagnosis

The diagnosis of placental abruption is made based on clinical findings. The classic presentation is that of vaginal bleeding, usually accompanied by abdominal (uterine) pain. Examination often reveals uterine tenderness, and contractions may be present. About 10% of abruptions are concealed, with no vaginal bleeding. If bleeding is present, the amount is often a poor guide to the degree of separation, because there is usually a mixed picture of apparent and concealed

hemorrhage. Fetal compromise is a common finding, and if more than 50% of the placenta is involved, fetal death is likely. Massive concealed abruption often manifests with severe pain, a hard uterus, and a dead fetus; such a picture may occur in association with severe preeclampsia or the recent use of a vasoactive drug such as cocaine.¹³⁹ If abruption occurs in a posteriorly located placenta, severe back pain may be the only symptom; it may be worsened by abdominal palpation that pushes the fetus against the placenta. Abruption may precipitate preterm labor, and it should always be considered in the differential diagnosis for a patient in apparent idiopathic preterm labor.

Although ultrasonography is an integral part of the diagnostic approach to late pregnancy bleeding, its utility is primarily for the exclusion of placenta previa as the cause of hemorrhage. At least 50% of abruptions produce no findings on ultrasound.¹⁴⁰⁻¹⁴² What is visualized by ultrasound depends on the site, scale, and timing of bleeding. In early acute abruptions, blood and clot retained within the uterus appear as hyperechoic or isoechoic collections relative to placental echogenicity.¹⁴³ In cases that remain undelivered, the hematomas resolve over several weeks, becoming hypoechoic and then sonolucent, usually by 2 weeks after the event.¹⁴³ Intrauterine clot may “jiggle” when bounced by the transducer—the “jello” sign. An acute abruption with obvious vaginal bleeding, in which little or no blood is retained within the uterus, may have no specific sonographic findings. Therefore, the absence of ultrasound findings never excludes an abruption.

Cardiotocography is an integral part of the evaluation for late pregnancy bleeding. Abruption is commonly accompanied by uterine contractions that may not be appreciated clinically, particularly after trauma.¹⁴⁴ Fetal heart rate tracings may exhibit a variety of abnormal patterns, including variable and late decelerations, poor variability, prolonged bradycardia, or a sinusoidal pattern; these are not specific to abruption and reflect underlying evolving fetal asphyxia.

Kleihauer-Betke testing is of no diagnostic value in abruption: It may be negative with proven abruption^{128,129,145} or positive when no abruption has occurred. Its only value in this setting is to guide Rh immune globulin dosing in Rh-negative women who are thought to have sustained an abruption.

Chronic abruption-oligohydramnios sequence (CAOS) is a term that was coined to describe women who present with bleeding attributed to abruption and go on to develop oligohydramnios without evidence of ruptured membranes.¹⁴⁶ Twenty-four patients were described, all of whom delivered preterm (average gestational age, 28 weeks). For the most part, the earlier the onset of bleeding, the earlier the delivery. More than half of the women went on to develop pPROM before delivery and after the development of oligohydramnios.

Management

The key to optimizing maternal and fetal outcome in abruptio placentae is the individualization of care. Precise management depends on the extent of maternal and/or fetal compromise and the gestational age. Decision making should be rapid but methodical; delay in diagnosis and inappropriate triage leads to significantly increased perinatal mortality.¹⁴⁷ Twenty percent of all fetal deaths from abruption occur after presentation to the hospital, and 30% of those deaths occur within 2 hours after admission.

Initial assessment should focus on maternal hemodynamic status (remembering that blood pressure may be elevated in the setting of preeclampsia) and fetal well-being. Maternal vital signs should be measured frequently, because they may change suddenly as the abruption evolves. Electronic fetal monitoring should begin immediately and be continuous throughout further assessment and management. A large-

gauge intravenous line should be placed (two lines if the patient is hemodynamically unstable). Initial laboratory studies should include a baseline complete blood count and platelet count, type and screen and cross-match where appropriate, blood urea nitrogen and electrolytes, coagulation studies, and a wall clot. These studies serve as useful baseline references. An indwelling bladder catheter should be placed to allow urinary output to be closely monitored. In unstable or critically ill patients, management may be aided by placement of a central venous pressure line (preferably with a Cordis introducer) or an arterial line. The involvement of the obstetric anesthetic team should be sought early.

After these steps are taken, attention should be directed at excluding a placenta previa (by ultrasound examination) and deciding on the timing and route of delivery. Maternal or fetal compromise mandates immediate delivery, usually by cesarean section unless the patient is in an advanced stage of labor. If the event occurs after 34 weeks' gestation, delivery should not be delayed, because the risks of conservative management outweigh any considerations of prematurity of the fetus. Between 20 and 34 weeks, if mother and fetus are stable, an attempt at conservative management may be considered.^{148,149} Betamethasone should be administered to enhance fetal lung maturity in all such cases. The patient should be monitored closely, because she continues to be at risk of an evolving process. The use of tocolytics is controversial; in most cases, they should not be used. Although studies addressing this issue have found no increase in adverse fetal or maternal events,^{27,141,148-150} no prospective trial has been performed.

If the patient has sustained a mild separation at a premature gestational age and is asymptomatic without evidence of bleeding, discharge home may be considered as an alternative to prolonged hospitalization. Either way, a clear management plan for delivery should be developed based on subsequent events or the reaching of an arbitrary gestational age (usually 37 weeks). The evaluation of patients undergoing expectant management should include regular assessment of fetal growth and tests of well-being, because these fetuses are at increased risk for IUGR.

If an abruption occurs after 34 weeks' gestation and maternal and fetal condition permit, vaginal delivery is preferred. Amniotomy should be performed, and, if needed, an oxytocin infusion should be started. Labor usually progresses rapidly, even without augmentation. However, if progress is slow or maternal or fetal status deteriorates, cesarean section should be performed. If abruption has resulted in fetal death, vaginal delivery is preferred unless there are other obstetric contraindications or the mother is hemodynamically unstable.

Coagulopathy develops in about 10% of abruptions. It usually is related to the severity of the event and is particularly likely to occur if there is fetal demise or massive hemorrhage. An aggressive approach should be used to maintain maternal blood volume and oxygen-carrying capacity, including the use of component therapy (fresh-frozen plasma and platelets). The coagulation tests most frequently used, and the component replacement therapy for women with DIC, are summarized in Tables 37-3 and 37-4.

TABLE 37-3 COAGULATION TESTS USED IN THE DIAGNOSIS OF ABRUPTIO PLACENTAE

Test	What It Measures	Normal Value	Value in Abruption
Bleeding time	Vascular integrity and platelet function	1-5 min	Usually normal; test is of little clinical use in diagnosing abruption
Whole blood clotting time	Platelet function Fibrinolytic activity	Clot formation: 4-8 min Clot retraction: <1 hr Clot lysis: none in 24 hr	Clot formation abnormality indicates severe deficiency Abnormal retraction with thrombocytopenia
Fibrinogen	Fibrinogen level	400-650 mg/100 mL	Usually decreased
Platelet count	Number of platelets	>140,000/mm ³	Usually decreased
Fibrin degradation products	Fibrin and fibrinogen degradation products	<10 µg/mL	Almost always elevated; most sensitive test
Euglobulin clot lysis time	Fibrinolytic activity	None in 2 hr	Difficult to interpret with low fibrinogen levels
Prothrombin time	Factors II, V, VII, X	10-12 sec	Normal to prolonged
Partial thromboplastin time	Factors II, V, XIII, IX, X, XI	24-38 sec	Normal to prolonged
Thrombin time	Factors I, II Circulating split products Heparin effect	16-20 sec	Parallels fall in fibrinogen; good marker of abruption severity
Red blood cell morphology	Microangiopathic hemolysis	Absence of distortion or fragmentation	Presence of distortion or fragmentation is uncommon but indicates risk of renal cortical necrosis

TABLE 37-4 BLOOD REPLACEMENT PRODUCTS

Component	Volume per Unit (mL)*	Factors Present	Effect of 1 Unit
Fresh whole blood	500	RBCs; all procoagulants	↑ Hematocrit 3%
Packed RBCs	200	RBCs only	↑ Hematocrit 3%
Fresh-frozen plasma	200-400	All procoagulants; no platelets	↑ Fibrinogen 25 mg/dL
Cryoprecipitate	20-50	Fibrinogen; factors VIII, XIII	↑ Fibrinogen 15-25%
Platelet concentrate	35-60	Platelets; small amounts of fibrinogen; factors V, VIII	↑ Platelet count approximately 8000/mm ³

RBCs, red blood cells.

*Volume depends on individual blood bank.

Prevention

A prior abruption increases the risk of abruption in a subsequent pregnancy up to 20-fold.¹⁵¹ Modification of risk factors includes treatment of chronic hypertension, smoking cessation, and avoidance of substance abuse. Women with hyperhomocysteinemia should be treated with folate.

Chapter 38

Maternal and Fetal Infections

Patrick Duff, MD, Richard L. Sweet, MD, and Rodney K. Edwards, MD, MS

Infectious disease is the single most common problem encountered by the obstetrician. Some conditions, such as urinary tract infections, endometritis, and mastitis, pose a risk primarily to the mother. Other disorders, such as group B streptococcal (GBS) infection, herpes simplex infection, rubella, cytomegalovirus infection, and toxoplasmosis are of principal concern because of the risk of fetal or neonatal complications. Still others, such as human immunodeficiency virus (HIV) infection and syphilis, may cause serious morbidity for both mother and baby.

This chapter reviews the twenty-nine most common infections that occur during pregnancy. Each section considers the epidemiology, pathogenesis, diagnosis, and treatment of an individual infectious disease with which the obstetrician should be familiar.

Candidiasis (Monilial Vaginitis)

Vulvovaginal candidiasis (VVC) is primarily caused by *Candida albicans*. Other species, such as *Candida glabrata*, *Candida parapsilosis*, *Candida tropicalis*, and *Candida lusitanae*, are responsible for fewer than 10% of cases. *C. albicans* is a saprophytic yeast that exists as part of the endogenous flora of the vagina. The organism is present in the vagina of approximately 25% to 30% of sexually active women.¹ It may become an opportunistic pathogen, especially if host defense mechanisms are compromised. However, the biologic mechanisms that allow this commensal microorganism to become a pathogen are not completely understood.² Systemic candidiasis is a rare event in gravid patients, occurring only in the presence of disease entities causing significant debilitation (e.g., sepsis, malignancy). VVC is a much more common infection and is the second most common cause of vaginitis after bacterial vaginosis.

Epidemiology

Seventy-five percent of women will have at least one episode of VVC during their life, and 40% to 45% will have two or more episodes.¹ *C. albicans* is the predominant yeast isolated (>90% of cases) from patients with VVC, with other species (i.e., *C. glabrata*, *C. parapsilosis*, and *C. tropicalis*) being less commonly recovered. In the past, it was believed that non-*albicans* species were becoming increasingly common, especially in cases of recurrent VVC. However, in a recent study, Sobel and colleagues³ reported that *C. albicans* was recovered from 401 (94%) of 425 women with recurrent VVC.

Predisposing factors associated with vaginal colonization with *C. albicans* include diabetes mellitus, pregnancy, obesity, recent use of antibiotics, steroids, and immunosuppression. Pregnancy is associated with not only increased colonization but also increased susceptibility to infection and lower cure rates. Previously, oral contraceptives were thought to increase colonization of yeast in the vagina. However, with the advent of low-dose oral contraceptives, no increase in *Candida* isolation among oral contraceptive users has been noted.⁴

Other risk factors for *C. albicans* have been described. In a population of women attending a sexually transmitted disease (STD) clinic, Eckert and associates⁵ reported that the principal risk factors were condom use, luteal phase of the menstrual cycle, sexual frequency greater than four times per month, recent antibiotic use, young age, past gonococcal infection, and absence of current bacterial vaginosis. Recently, Beigi and coworkers⁶ noted additional risk factors, including marijuana use, use of depo-medroxyprogesterone acetate, sexual activity within the past 5 days, concurrent *Lactobacillus* colonization, and concurrent GBS colonization.

Symptomatic VVC affects 15% of pregnant women. The hormonal environment of pregnancy, in which high levels of estrogen produce an increased concentration of vaginal glycogen, accounts for the increased frequency of symptomatic infection in gravid patients. In addition, suppression of cell-mediated immunity in pregnancy may decrease the ability to limit fungal proliferation.

Pathogenesis

As mentioned previously, the pathogenesis by which *C. albicans* evolves from a commensal microorganism colonizing the vagina to the pathogenic microbe involved in vulvovaginal vaginitis, invasive *Candida* infections, and disseminated candida sepsis is poorly understood. Kalo-Klein and Witkin⁷ suggested that hormonal status may modulate the immune system, and, as a result, influence the pathogenicity of *Candida* species. They noted that the host responses to *C. albicans* were decreased in the luteal phase. Recently, Giraldo and colleagues⁸ reported that a variant (gene polymorphism) in the gene coding for the mannose-binding lectin (MBL), a critical component of the mucosal innate immune system, was more frequently found in women with recurrent VVC than in those with acute VVC or controls.

The pathogenesis of invasive candidiasis is similar to that associated with bacterial microorganisms. Initially, there must be colonization resulting from adhesion of *C. albicans* to the skin or vaginal mucosa; this is followed by penetration of epithelial barriers, resulting in locally invasive or widely disseminated disease.⁹

Congenital candidiasis characteristically manifests at birth or within the first 24 hours after birth. It usually results from an intrauterine infection or heavy maternal vaginal colonization at the time of labor and delivery. The potential mechanisms for intrauterine *Candida* infection are quite similar to those of bacterial intra-amniotic infection, including hematogenous spread from mother to fetus, invasion of intact membranes, and ascending infection following rupture of the membranes.^{9,10} In contrast to bacterial neonatal sepsis, the presence of an intrauterine foreign body, most commonly a cerclage suture, is a recognized risk factor for congenital candidiasis. VVC has not been associated with preterm birth, preterm labor, low birth weight, or premature rupture of the membranes (PROM).^{10,11}

Recurrent VVC is defined as four or more episodes of symptomatic VVC in 1 year. Recurrent VVC occurs in a small percentage of women (<5%). The pathogenesis of recurrent VVC is poorly understood, and the majority of those affected do not have any apparent predisposing or underlying conditions. *C. glabrata* and other non-*albicans Candida* species are recovered from in 10% to 20% of women with recurrent VVC.^{12,13}

Diagnosis

The clinical manifestations in pregnancy are similar to those in the nonpregnant state; they include pruritus and burning, dysuria, dyspareunia, fissures, excoriations with secondary infection, and pruritus ani. The vaginal discharge is usually thick, white, and curdlike.

The diagnosis of VVC can be made in a woman who had signs and symptoms of vaginitis when either (1) a 10% potassium hydroxide (KOH) wet preparation or Gram staining of a vaginal discharge sample reveals yeasts or pseudohyphae, or (2) a culture discloses yeast.¹² The vaginal pH in women with VVC is normal (<4.5). Women with a positive KOH wet mount should be treated for VVC. Women who have negative KOH smear despite clinical signs and symptoms suggestive of

VVC should have vaginal cultures for yeast. In patients with recurrent VVC, the laboratory should be requested to identify the species of *Candida* recovered.

The clinical manifestations of congenital candidiasis range from superficial skin infection and oral infection to severe systemic disease with hemorrhage and necrosis of the heart, lungs, kidneys, and other organs. The most common route of infection is by direct contact during delivery through an infected vagina. Oropharyngeal candidiasis of the neonate (thrush) is the most frequent manifestation of congenital infection.

Treatment

The regimens recommended by the Centers for Disease Control and Prevention (CDC) for the treatment of VVC are listed in Table 38-1.¹² Short-course topical formulations (i.e., single-dose and 1- to 3-day regimens) effectively treat uncomplicated VVC, providing relief of symptoms and negative cultures in 80% to 90% of patients who complete therapy. Intravaginal preparations of butoconazole, clotrimazole, miconazole, and tioconazole are available over the counter (OTC). According to the CDC, women who previously were diagnosed with VVC are not necessarily more likely to accurately diagnose themselves. Therefore, women whose symptoms persist after use of an OTC preparation or who have a recurrence of symptoms within 2 months should be assessed with office-based testing.¹²

VVC is not usually acquired through sexual intercourse, so treatment of sex partners is not recommended. Treatment of partners should be considered for women who have recurrent VVC and for male sex partners with balanitis.¹²

The CDC recommends that topical azole therapies be the first line of treatment in pregnancy for VVC. These topical medications should be applied for 7 days. For complicated cases of VVC, a longer duration of initial therapy (e.g., 7 to 14 days of topical therapy or a 100-mg, 150-mg, or 200-mg oral dose of fluconazole every third day for a total

TABLE 38-1 RECOMMENDED REGIMENS FOR TREATMENT OF VULVOVAGINAL CANDIDIASIS IN PREGNANT AND NONPREGNANT WOMEN

Antifungal Agent	Formulation	Regimen
Intravaginal Agents		
Butoconazole	2% cream*	5 g intravaginally for 3 days
	2% cream (Butoconazole 1—sustained release)	5 g single intravaginal application
Clotrimazole	1% cream*	5 g intravaginally for 7-14 days
	100 mg vaginal tablet	One tablet qd for 7 days
Miconazole	100 mg vaginal tablet	Two tablets at one time daily for 3 days
	2% cream*	5 g intravaginally for 7 days
	100 mg vaginal suppository*	One suppository qd for 7 days
Nystatin	200 mg vaginal suppository*	One suppository qd for 3 days
	1200 mg vaginal suppository*	One suppository qd for 1 day
Tioconazole	100,000-unit vaginal tablet	One tablet qd for 14 days
Terconazole	6.5% ointment*	5 g intravaginally in a single application
	0.4% cream	5 g intravaginally for 7 days
	0.8% cream	5 g intravaginally for 3 days
	80 mg vaginal suppository	One suppository qd for 3 days
Oral Agent		
Fluconazole	150 mg oral tablet	One tablet in single dose

*Over-the-counter preparation.

From Centers for Disease Control and Prevention: Sexually Transmitted Diseases Treatment Guidelines, 2006. MMWR Recommendations and Reports 55(RR-11):1-94, 2006.

of 3 doses) should be considered. Fluconazole is a U.S. Food and Drug Administration (FDA) class C drug. It should be reserved for highly select patients, such as those who are allergic to topical antifungal medications or who have recurrent persistent infection.¹²

Trichomoniasis

Clinical Presentation

Trichomonas vaginalis is a common cause of vaginitis, with infection often characterized by intense pruritus, strong odor, and dysuria. Physical examination typically shows a malodorous, yellow-green, frothy discharge. However, variations of the gross appearance occur in approximately 50% of cases, with many women showing minimal or no symptoms. The diagnosis may be confirmed by microscopic examination of a smear of the discharge diluted with saline. The examination reveals many leukocytes and bacteria; trichomonads are recognized by their size (slightly larger than leukocytes) and active flagella. The sensitivity of wet mount is only 60% to 70%.¹⁴ Cultures for *Trichomonas* are more sensitive than wet mount, and commercial systems are available to facilitate culture of this parasite. There currently are two point-of-care diagnostic tests available, the OSOM Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge, MS) and the Affirm VP III (Becton Dickenson, San Jose, CA). These tests have better sensitivity than wet mount, but false-positive results may be a problem, especially in low-prevalence populations.

The prevalence of *T. vaginalis* vaginitis in pregnancy ranges from less than 10% to 50%, depending on the patient population. Consequently, it has been difficult to establish whether the incidence of this vaginal infection truly is increased in pregnant women.

Adverse Effects in Pregnancy

An increased rate of PROM at term has been linked to positive genital tract cultures for *T. vaginalis* (27.5% with infection versus 12.8% without; $P < .03$).¹⁵ In the large National Institutes of Health infection and prematurity study, *T. vaginalis* infection at midpregnancy was associated significantly with low birth weight (odds ratio [OR], 1.3; 95% confidence interval [CI], 1.1 to 1.5), preterm delivery (OR, 1.3; CI, 1.1 to 1.4), and PROM (OR, 1.4, CI, 1.1 to 1.6), even after adjustment for confounding factors and other microbes.¹⁶ In addition, trichomoniasis has been associated with increased rates of HIV transmission.^{17,18}

Treatment

The recommended treatment for trichomoniasis is oral metronidazole, 2 g in a single dose. An alternative regimen is metronidazole, 500 mg orally twice a day for 7 days.¹² No consistent association has been demonstrated between use of metronidazole in pregnancy and teratogenesis or mutagenesis in infants.¹⁹ Tinidazole, another nitroimidazole drug, recently was approved by the FDA for treatment of trichomoniasis (2 g orally in a single dose). However, metronidazole should be favored for the treatment of pregnant women because of its superior safety profile. Topical agents often are unsuccessful in relieving symptoms or in eradicating this protozoon.

Among women with asymptomatic trichomoniasis in pregnancy, treatment in the second trimester (two 2.0 g doses 48 hours apart at 16 to 23 weeks, repeated at 24 to 29 weeks) did not result in better pregnancy outcomes than did placebo. Indeed, those given metronida-

zole had a significantly higher frequency of preterm delivery.²⁰ Accordingly, although symptomatic pregnant women with trichomoniasis should be treated to relieve symptoms, routine screening and treatment are not recommended.

Bacterial Vaginosis

Epidemiology and Pathogenesis

This infection was formerly called nonspecific vaginitis, *Gardnerella vaginalis* vaginitis, or *Haemophilus vaginalis* vaginitis; *bacterial vaginosis* (BV) is the preferable term. The condition is marked by a major shift in vaginal flora from the normal predominance of lactobacilli to a predominance of anaerobes, which are increased 100-fold compared with normal secretions. *G. vaginalis* is present in 95% of cases but also is present in 30% to 40% of normal women. *Mycoplasma hominis* in vaginal secretions is increased significantly in cases of BV.

BV is the most common type of infectious vaginitis. Between 10% and 30% of pregnant women fulfill the criteria, but half of them are asymptomatic.

Diagnosis

Clinically, the primary symptoms are discharge and odor. Itching usually is not prominent. Diagnosis of BV is based on the presence of three of the following four clinical features: (1) an amine-like or fishy odor that may be accentuated after addition of KOH or after coitus (owing to the alkaline pH of semen); (2) a thin, homogeneous, gray or white discharge; (3) an elevated pH (≥ 4.5); and (4) on wet mount, true “clue” cells (squamous epithelial cells so heavily stippled with bacteria that their borders are obscured). Typically in cases of BV, clue cells account for more than 20% of epithelial cells, and there are few leukocytes. An experienced observer will note an increase in numbers and kinds of bacteria and a reduction in numbers of lactobacilli. A Gram stain of vaginal secretions also demonstrates the shift in bacteria and clue cells.

Adverse Effects in Pregnancy

Evidence consistently has associated BV with increased likelihoods of preterm delivery,²¹⁻²⁴ clinical chorioamnionitis,²⁵ histologic chorioamnionitis,²⁶ and endometritis.²⁷ The risk for preterm delivery among women with BV has varied (OR, 1.4 to 8) but has been significant in all populations studied.

Treatment

In nonpregnant women, the most consistent cure rates (90%) have been achieved with metronidazole (e.g., 500 mg twice a day for 7 days). Lower cure rates (60% to 80%) are observed with a single 2.0-g dose of metronidazole. Oral clindamycin (300 mg twice a day for 7 days) is effective in treating nonpregnant patients and appears to be safe in pregnancy. Vaginal clindamycin cream (2%) and metronidazole gel (0.75%) also are effective in nonpregnant women. However, the preferred regimens in pregnancy are shown in Table 38-2. There is no longer an exclusion for use of metronidazole in any trimester of pregnancy. A recent meta-analysis showed no evidence of teratogenesis.^{12,28-30}

In view of the consistent association of BV with adverse pregnancy outcomes, clinical treatment trials have been undertaken. Three trials,

all conducted in patients who were considered to be at high risk (on the basis of either a previous preterm birth or other high-risk demographic features), revealed improvement in outcome with prenatal treatment of BV (Table 38-3). In a group of women who experienced a spontaneous preterm birth due to preterm labor or PROM during a previous pregnancy, treatment of BV with oral metronidazole led to a significant reduction in preterm birth, low birth weight, and PROM ($P < .05$ for each).³¹ In a prospective, two-phase trial involving 1260 women, treatment of BV significantly decreased preterm birth ($P < .05$).³² Finally, among women at risk because of a previous preterm birth or low maternal weight, treatment with a combination of metronidazole and erythromycin significantly improved pregnancy outcome compared to placebo in patients who had BV ($P < .006$); in those patients without BV, pregnancy outcome was not improved.³³

In a treatment trial of women at low risk of preterm delivery, oral metronidazole (twice daily for 2 days at 24 weeks, with repeat treatment, if needed, at 29 weeks) led to no reduction in preterm birth overall but produced a significant reduction in the subgroup of women with a previous preterm birth.³⁴ In the Maternal-Fetal Medicine Units Network treatment trial of women with asymptomatic BV, the treatment regimen also was short (two 2.0-g doses at 16 to 24 weeks and again at 24 to 30 weeks, with the repeat treatment at least 14 days after the initial doses). Use of metronidazole in this regimen led to no significant improvement overall or in any subgroup (e.g., women with a previous preterm birth).³⁵ These studies are summarized in Figure 38-1. In view of these disparate results, the American College of Obstetricians and Gynecologists (ACOG)³⁶ concluded in 2001, “Currently, there are insufficient data to suggest [that] screening and treating women at either low or high risk will reduce the overall rate of preterm birth.”

However, Goldenberg and colleagues³⁷ reached a different conclusion, taking into consideration the metronidazole regimen used. We

agree with their recommendation of treatment with oral metronidazole for at least 7 days in women at high risk (e.g., those with previous preterm birth). Screening and treatment of these high-risk women should occur at the first prenatal visit. Recommendations for management of BV in pregnancy are presented in Table 38-4.

Gonorrhea

Gonorrhea, which is caused by the gram-negative diplococcus, *Neisseria gonorrhoeae*, is probably the oldest known STD. Almost 340,000 new infections with *N. gonorrhoeae* were reported in the United States in 2005,³⁸ making gonorrhea the second most commonly reported communicable disease in the nation.

Epidemiology

The CDC received 339,593 reports of gonorrhea in 2005. However, even this volume of reports underestimates the incidence, and public health experts estimate that 600,000 new cases of *N. gonorrhoeae* infection occur each year in the United States. From 1975 through 1997, there was a dramatic decrease of 74% in reported cases of gonorrhea. In 1998, an 8.9% increase occurred, followed by plateauing of the number of reported cases.^{38,39}

In 2003, for the first time, the reported gonorrhea rate was higher among women (118.8 per 100,000 population than among men (113 per 100,000).⁴⁰ Disappointingly, in 2005, both the number of reported cases and the prevalence rate of gonorrhea increased for the first time

in almost a decade. In a recent cross-sectional cohort study, The National Longitudinal Study of Adolescent Health reported that the overall prevalence of gonorrhea in the United States was 0.43% (CI, 0.29% to 0.63%).⁴¹ The prevalence of gonorrhea in pregnancy ranges from 0% to 10%, with marked variations according to risk status and geographic locale.⁴²

TABLE 38-4 RECOMMENDATIONS FOR MANAGEMENT OF BACTERIAL VAGINOSIS IN PREGNANCY

Symptomatic pregnant women with BV can be treated safely in any trimester with oral metronidazole or clindamycin. Routine screening and treatment of BV in asymptomatic women at low risk for preterm birth *cannot* be endorsed (USPTF: D recommendation). Screening for BV may be considered in asymptomatic women at high risk for preterm birth, such as those with previous preterm birth. Women who test positive should be treated. The value of rescreening and retreatment is unclear.

BV, bacterial vaginosis; USPTF, U.S. Preventive Services Task Force.

A number of risk factors for gonorrhea among sexually active women have been elucidated. Young age is the greatest risk factor, with sexually active women younger than 25 years of age being at highest risk for gonorrhea infection. Other risk factors for gonorrhea include previous gonococcal infection, presence of other STDs, multiple sex partners, new sex partners, inconsistent condom use, drug use, and commercial sex work. Nonwhite race, low socioeconomic status, inner-city dwelling, and unmarried status are additional risk factors for infection with *N. gonorrhoeae* (Figs. 38-2 and 38-3).¹²

Pathogenesis

Transmission of *N. gonorrhoeae* occurs almost solely by sexual contact, and the risk of transmission from an infected male to a female partner is 50% to 90% with a single exposure.⁴³ The incubation period is 3 to 5 days.

Infection with *N. gonorrhoeae* in pregnancy is a major concern. Although gonococcal ophthalmia neonatorum has been recognized since the late 19th century as a significant consequence of maternal infection with *N. gonorrhoeae*, it is only in the last 40 years that an association has been recognized between maternal infection with *N. gonorrhoeae* and disseminated gonococcal infection (DGI), amniotic

FIGURE 38-2 Incidence of gonorrhea per 100,000 population, by sex—United States, 1990-2005. The overall incidence of gonorrhea in the United States has declined since 1975 but increased in 2005 for the first time since 1999. In 2005, incidence was slightly higher among women than among men.

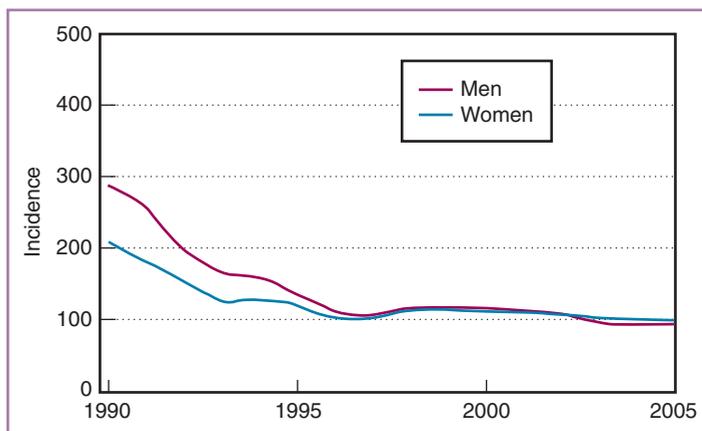

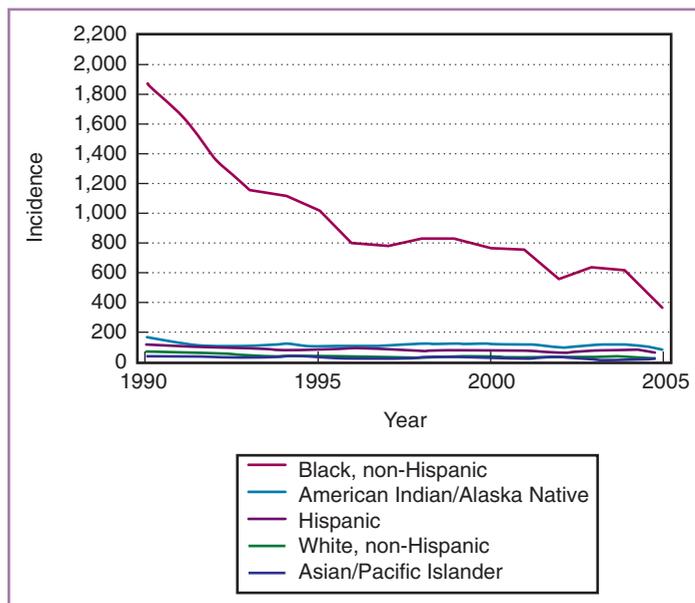

FIGURE 38-3 Gonorrhea incidence per 100,000 population, by race/ethnicity—United States, 1990-2005. Gonorrhea incidence among blacks decreased considerably during the 1990s, but blacks continue to have the highest rate among all races/ethnicities. In 2005, gonorrhea incidence among non-Hispanic blacks was approximately 18 times greater than among non-Hispanic whites.

infection syndrome, and perinatal complications including PROM, chorioamnionitis, preterm delivery, intrauterine growth restriction, neonatal sepsis, and postpartum endometritis.⁴

Adherence of *N. gonorrhoeae* to the mucosal epithelium of the genital tract is the initial step in the pathogenesis of gonococcal infection. Attachment of *N. gonorrhoeae* is mediated by pili and other surface proteins (e.g., porin protein, opacity-associated proteins, reduction-modifiable protein). Lipopolysaccharides, immunoglobulin A, and iron-repressible proteins are additional gonococcal virulence factors. Once *N. gonorrhoeae* attaches to mucosal cells, it enters the cell via endocytosis. Subsequently, the organism releases endotoxin, resulting in widespread cell damage.⁴⁴

Clinical Manifestations

Anogenital Gonorrhea

The clinical manifestations of gonococcal infection are dependent on the site of inoculation and whether the infection remains localized or spreads systematically. The overwhelming majority of women with *N. gonorrhoeae* infection are asymptomatic. This observation is particularly true in pregnancy. The endocervix is the primary site of infection. When symptoms develop, they usually include vaginal discharge and dysuria. On examination, a mucopurulent discharge is usually apparent in the endocervical canal. Inflammation of the Skene or Bartholin glands may occur. In patients who engage in rectal intercourse, a mucopurulent proctitis may also be apparent.

Disseminated Gonococcal Infection

DGI is an important presentation of gonorrhea in pregnancy. Pregnant women, especially during the second and third trimester, appear to be at increased risk for disseminated infection, which has two stages. The early, bacteremic stage is characterized by chills, fever, and typical skin lesions. The lesions appear initially as small vesicles, which become pustules and develop a hemorrhagic base. The center becomes necrotic. Such lesions can occur anywhere on the body but are most frequently present on the volar aspects of the arms, hands, and fingers. They fade without residual scarring. Blood cultures are positive for *N. gonorrhoeae* in 50% of patients in whom culture is done during the bacteremic stage. DGI is occasionally complicated by perihepatitis and rarely by endocarditis or meningitis. Joint symptoms are frequently present during this stage, as well as in the second, septic arthritis phase. This stage is characterized by a purulent synovial effusion. The knees, ankles, and wrists are most commonly involved. Blood cultures during this stage are usually sterile. Gonococci may be isolated from the septic joints during the second stage. The infection may become chronic or progress to septic arthritis and joint destruction.¹²

Pharyngeal Gonorrhea

The majority of patients with pharyngeal infections with *N. gonorrhoeae* are asymptomatic. If they are symptomatic, the most common finding is a mild sore throat and erythema; lesions and exudates may also be present. Pharyngeal gonorrhea is more common during pregnancy than in nonpregnant women.⁴⁵

Neonatal Gonococcal Ophthalmia

Gonococcal ophthalmia neonatorum has been recognized since 1881. Introduction of routine prophylaxis with silver nitrate resulted in a rapid reduction in this complication. Most newborns who have gonorrhea acquire it during passage through an infected cervical canal. Gonococcal ophthalmia is usually observed within 4 days after birth,

but incubation periods of up to 21 days have been reported. A frank purulent conjunctivitis occurs and usually affects both eyes. Untreated gonococcal ophthalmia can rapidly progress to corneal ulceration, resulting in corneal scarring and blindness.

Gonococcal Infection in Pregnancy and in the Neonate

The effects of gonorrheal infection on both mother and fetus were not fully appreciated until 4 decades ago.^{4,46,47} Studies at that time identified an association between untreated maternal endocervical gonorrhea and perinatal complications, including PROM, preterm delivery, chorioamnionitis, neonatal sepsis, and maternal postpartum sepsis.

The amniotic infection syndrome is an additional manifestation of gonococcal infection in pregnancy. This condition is characterized by placental, fetal membrane, and umbilical cord inflammation that occurs after PROM and is associated with infected oral and gastric aspirate, leukocytosis, neonatal infection, and maternal fever. Preterm delivery is common, and perinatal morbidity may be significant.⁴⁶

Diagnosis

The diagnosis of infection with *N. gonorrhoeae* requires sampling of potentially infected sites. Available methods include culture, nucleic acid hybridization tests, and nucleic acid amplification tests (NAATs).⁴⁸ Unlike for *Chlamydia trachomatis* infection, the CDC has not provided guidance with respect to general or targeted screening for gonorrhea infection.⁴⁹ Even in the absence of formal guidelines, gonorrhea screening has been implemented in conjunction with routine chlamydial screening. Implementation of these joint screening protocols has been shown to be cost-effective.

Screening for gonorrhea during pregnancy is clearly cost-effective if the prevalence exceeds 1%. Therefore, the CDC recommends that all pregnant women at risk for gonorrhea, as well as those living in an area where the prevalence of *N. gonorrhoeae* is high, be tested for *N. gonorrhoeae* at their first prenatal visit.¹² Targeted patients include

1. Partners of men with gonorrhea or urethritis
2. Patients known to have other STDs, including HIV infection
3. Patients with multiple sex partners
4. Young, unmarried inner-city women
5. Intravenous drug users
6. Women with symptoms or signs of lower genital tract infection.

The CDC and the ACOG recommend that at-risk women be rescreened for *N. gonorrhoeae* during the third trimester.^{12,50} A recent study demonstrated the value of a repeat screen in the third trimester for *N. gonorrhoeae* among at-risk women who had an initial negative early pregnancy screen.⁴² In this study, 38 (5.1%) of 751 at-risk women had gonorrhea (based on a positive DNA direct assay) at their first prenatal visit. An additional 19 women (2.5%) were newly positive at their third-trimester screen. In other words, approximately one third of at-risk women tested positive for *N. gonorrhoeae* only on the repeat third-trimester screen.

Several reliable nonculture assays for detection of *N. gonorrhoeae* have become available and are increasingly being used.⁴⁸ They include nonamplified DNA probe tests (discussed later) and NAATs such as polymerase chain reaction (PCR), ligase chain reaction (LCR), transcription-mediated amplification (TMA), and strand displacement assay (SDA). These newer technologies compare favorably to culture with selective media. For nonamplified DNA probes, the sen-

sitivity ranges from 89% to 97%, and the specificity is 99%. For NAATs, the sensitivity and specificity are both excellent (>99%). Whereas the introduction of dual, single-swab NAATs for detection of *C. trachomatis* and *N. gonorrhoeae* has simplified testing and facilitated expansion of STD screening to nontraditional settings, there is a downside to single-swab NAATs.⁵¹ First, the prevalence of *N. gonorrhoeae* is substantially lower than that of *C. trachomatis*, especially in most community-based settings.⁵² As a result, when providers intend to screen primarily for *C. trachomatis*, they are also screening for *N. gonorrhoeae*. The potential for false-positive *N. gonorrhoeae* test results increases because the positive predictive value of a test decreases as the prevalence of disease decreases. Second, as NAATs replace culture assays, fewer isolates are available for antibiotic susceptibility testing. As a result, monitoring of trends in antimicrobial susceptibility of *N. gonorrhoeae*, a major public health issue, may be compromised.

Treatment

The treatment of gonococcal infection in pregnant women is similar to that in nonpregnant women, with the exception that tetracycline should not be used for concomitant chlamydial infection. Both asymptomatic and symptomatic infections should be treated.

The treatment of gonococcal infection in the United States has been influenced by two factors. First, there has been increasing prevalence and spread of infections caused by antibiotic-resistant *N. gonorrhoeae*, such as penicillinase-producing *N. gonorrhoeae*, tetracycline-resistant *N. gonorrhoeae*, and chromosomally mediated *N. gonorrhoeae*, which is resistant to multiple antibiotics. Moreover, in recent years, quinolone-resistant *N. gonorrhoeae* (QRNG) has emerged as a major public health problem.^{12,53} QRNG continues to spread and increase in prevalence, making treatment of gonorrhea with quinolones such as ciprofloxacin inadvisable in many geographic areas and populations. According to the CDC,¹² resistance to ciprofloxacin usually indicates resistance to other quinolones. QRNG is common in parts of Europe, the Middle East, Asia, and the Pacific and is becoming increasingly common in the United States. For example, in California the rate of QRNG increased from less than 1% in 1999 to more than 20% in the second half of 2003.⁵⁴ Similarly high rates of QRNG have been reported in Hawaii.⁵⁵ As a result, in 2005, the CDC advised that quinolones should not be used in California or Hawaii.⁵⁶ In 2004, 6.8% of isolates collected by CDC's Gonococcal Isolate Surveillance Project (GISP)⁵⁷ were resistant to ciprofloxacin. QRNG was more common among men who have sex with men (MSM) than among heterosexual men (23.9% versus 2.9%).^{39,58} Subsequently, the prevalence of QRNG increased in other areas of the United States, leading to changes in recommended treatment regimens by other states and local areas. In a 2007 update to its Sexually Transmitted Diseases Treatment Guidelines, the CDC announced that quinolones are no longer recommended for the treatment of gonorrheal infections.⁴⁰⁷

The second factor that influences treatment recommendations is the high frequency (20% to 50%) of coexisting chlamydial infection in women infected with *N. gonorrhoeae*. This finding has led to the recommendation that women treated for gonococcal infection should also be treated routinely for chlamydia.¹² Current CDC recommendations for the treatment of *N. gonorrhoeae* in pregnancy are listed in Tables 38-5 and 38-6.

Ceftriaxone in a single intramuscular injection of 125 mg provides sustained, high bactericidal levels in blood and is safe and effective for treatment of uncomplicated gonorrhea, curing 98.9% of urethral, cervical, and anorectal infections.^{12,59} The antimicrobial spectrum of cefixime is similar to that of ceftriaxone, but the 400-mg dose does not

TABLE 38-5 RECOMMENDATIONS FOR THE TREATMENT OF UNCOMPLICATED GONORRHEA OF THE CERVIX, URETHRA, AND RECTUM

Recommended Regimens (in addition to treatment for chlamydial infection if not ruled out)

Ceftriaxone* 125 mg IM in a single dose
Cefixime* 400 mg PO in a single dose

Alternative Regimens

Spectinomycin* 2 g IM in a single dose
Single-dose cephalosporin* regimens

TABLE 38-6 RECOMMENDATIONS FOR THE TREATMENT OF COMPLICATED GONORRHEA (DISSEMINATED GONOCOCCAL INFECTION, MENINGITIS, ENDOCARDITIS)

Recommended Regimen

Ceftriaxone* 1 g IM or IV q24h

Alternative Regimens

Cefotaxime* 1 g IV q8h
Ceftizoxime* 1 g IV q8h
Spectinomycin* 2 g IM q12h

*Recommended for use in pregnancy.

From Centers for Disease Control and Prevention: Update to CDC's Sexually Transmitted Diseases Treatment Guidelines, 2006: Fluoroquinolones No Longer Recommended for Treatment of Gonococcal Infections. *MMWR Morb Mortal Wkly Rep* 56(14):332-336, 2007.

achieve as high or as sustained serum levels as the 125-mg ceftriaxone dose. Cefixime, in a 400 mg oral dose, cures 97.4% of uncomplicated urethral, cervical, and anogenital gonorrhea.⁵⁹ Ciprofloxacin is safe, is inexpensive, and can be administered orally, but it is no longer universally effective against *N. gonorrhoeae* in the United States. The same holds true for ofloxacin and levofloxacin. In addition, quinolones should not be used during pregnancy.

Several alternative antimicrobial agents are suggested by the CDC for treatment of uncomplicated gonococcal infections of the cervix, urethra, and anorectum. Spectinomycin is effective (cure rate >98%), but it is expensive and is available only as an injection. In addition, it is not readily available any longer. During pregnancy, it is useful for patients who are allergic to cephalosporins. Alternative single-dose cephalosporins include ceftizoxime 500 mg IM, cefoxitin 2 g IM with probenecid 1 g orally, and cefotaxime 500 mg IM. Alternative single-dose oral quinolones (not recommended for pregnancy) include gatifloxacin 400 mg, norfloxacin 800 mg, and lomefloxacin 400 mg. The CDC suggests that cefpodoxime and cefuroxime axetil as additional oral alternatives for treatment of uncomplicated urogenital gonorrhea.¹²

As noted by the CDC, effective management of STDs such as gonorrhea requires treatment of the woman's current sex partner or

partners to prevent reinfection. Patients should be instructed to refer their sex partners for evaluation and treatment. Alternatively, patient-delivered treatment for sex partners is also effective.^{12,60}

Pregnant women should not be treated with quinolones or tetracyclines. Pregnant women infected with *N. gonorrhoeae* should be treated with one of the recommended or alternative cephalosporins. Those who cannot tolerate cephalosporins should be treated with spectinomycin 2 g IM as a single dose, if it is available. Either amoxicillin or azithromycin is recommended as treatment for presumed concomitant chlamydial infection during pregnancy.¹²

Patients with DGI should be hospitalized for initial therapy (see Table 38-6). In addition, patients with DGI should be evaluated clinically for evidence of endocarditis or meningitis. All of the recommended and alternative regimens for DGI should be continued for 24 to 48 hours after improvement begins. At that time, therapy may be switched to cefixime, 400 mg orally twice daily. With gonococcal meningitis and endocarditis, the recommended regimen is ceftriaxone 1 to 2 g IV every 12 hours. Meningitis requires 10 to 14 days of therapy, and treatment for endocarditis should be continued for a minimum of 4 weeks.¹²

With use of recommended treatment, follow-up testing to document eradication of gonorrhea is no longer recommended. Instead, rescreening in 2 to 3 months to identify reinfection is suggested. If other antimicrobial agents are used for the treatment of *N. gonorrhoeae*, follow-up assessment is suggested. Follow-up cultures should be obtained from the infected site 3 to 7 days after completion of treatment. Specimens should be obtained from the anal canal as well as the endocervix; failure to obtain a specimen from the anal canal results in missing 50% of resistant *N. gonorrhoeae* strains. With NAATs, repeat testing should be performed 3 weeks after treatment. Patients who have symptoms that persist after treatment should be evaluated by culture, and isolated organisms should be tested for antimicrobial susceptibility.¹²

Prevention

Primary prevention of gonorrhea requires adopting safe sex practices, including condom use; limiting the number of sexual partners; and ensuring that sexual partners are evaluated and treated. The increasing frequency of asymptomatic gonorrhea infection in women makes screening for *N. gonorrhoeae* during the antepartum period an important aspect of preventing the perinatal morbidity associated with this organism. At-risk patients should be rescreened in the third trimester. Instillation of a prophylactic agent into the eyes of all newborn infants is recommended to prevent gonococcal ophthalmia neonatorum. The recommended agents are erythromycin (0.5%) ophthalmic ointment, tetracycline (1%) ophthalmic ointment, and silver nitrate (1%) aqueous solution.

Chlamydial Infection

C. trachomatis infection is the most common bacterial STD in the United States, with an estimated 3 million new infections annually. The estimated cost of untreated chlamydial infection and their sequelae is more than \$2 billion annually.^{12,61}

In women, untreated chlamydial infection results in substantial adverse reproductive effects, including pelvic inflammatory disease and its sequelae of tubal factor infertility, ectopic pregnancy, and chronic pelvic pain. Chlamydial infection during pregnancy is associated with several adverse maternal outcomes, including preterm deliv-

ery, premature rupture of the membranes, low birth weight, and neonatal death.^{4,62} Untreated *C. trachomatis* infection also may result in neonatal conjunctivitis or pneumonia or both.^{4,63}

C. trachomatis may be differentiated on a serologic basis into 15 recognized serotypes. Three of these serotypes (L1, L2, L3) cause lymphogranuloma venereum. The other serotypes cause endemic blinding trachoma (A, B, Ba, and C) or inclusion conjunctivitis, newborn pneumonia, urethritis, cervicitis, endometritis, pelvic inflammatory disease, and the acute urethral syndrome (strains D through K).⁴

Epidemiology

As noted by Peipert,⁶⁴ the prevalence of *C. trachomatis* infection depends on the characteristics of the population studied. Prevalence rates in the United States vary significantly, ranging from 4% to 12% among family planning clinic attendees, from 2% to 7% among college students, and from 6% to 20% among STD clinic attendees.⁴ Recently, in the National Longitudinal Study of Adolescent Health,⁶⁵ the overall prevalence of chlamydial infection was found to be 4.19%, with women (4.74%; CI, 3.93% to 5.71%) more likely to be infected than men (3.67%; CI, 2.93% to 4.58%). In 2005, more than 975,000 cases of chlamydial genital infection were reported to the CDC, almost 50,000 more than in 2004. The CDC estimates that the true frequency of chlamydial infection each year is 3 million cases, the majority of which are not reported to public health officials.⁶¹

The prevalence of *C. trachomatis* infection among pregnant women is about 2% to 3% but may be higher in certain high-risk populations.⁴ Among pregnant women, risk factors for chlamydial infection include the following:

1. Unmarried status
2. Age younger than 25 years
3. Multiple sex partners
4. New sex partner in past 3 months
5. Black race
6. Presence of another STD
7. Partners with nongonococcal urethritis
8. Presence of mucopurulent endocervicitis
9. Sterile pyuria (acute urethral syndrome)
10. Resident of socially disadvantaged community
11. Late or no prenatal care

Detection rates as high as 25% to 30% have been reported in screening and prospective studies of such populations. In the Preterm Prediction Study of the National Institute of Child Health and Human Development Maternal-Fetal Medicine Units Network, the overall prevalence of *C. trachomatis* among pregnant women was 11%.⁶ In an interesting follow-up study, Sheffield and colleagues⁶⁶ demonstrated that chlamydial infection resolved spontaneously in almost half of infected pregnant women, especially in older women and with increasing time since diagnosis.

Infants born to women with a chlamydial infection of the cervix are at a 60% to 70% risk of acquiring the infection during passage through the birth canal. Approximately 25% to 50% of exposed infants acquire conjunctivitis in the first 2 weeks of life, and 10% to 20% develop pneumonia within 3 or 4 months.⁴

Pathogenesis

Chlamydiae are obligate intracellular bacteria separated into their own order, Chlamydiales, on the basis of a unique growth cycle that distin-

guishes them from all other microorganisms. This cycle involves infection of the susceptible host cell by a chlamydia-specific phagocytic process, so that these organisms are preferentially ingested. After attachment and ingestion, the chlamydiae remain in a phagosome throughout the growth cycle, but surface antigens of chlamydiae appear to inhibit phagolysosomal fusion. These two virulence factors—enhanced ingestion and inhibition of phagolysosomal fusion—attest to an exquisitely adapted parasitism.

Once in the cell, the chlamydial *elementary body*, which is the infectious particle, changes to a metabolically active replicating form called the *reticulate body*, which synthesizes its own macromolecules and divides by binary fission. Chlamydiae are energy parasites; because they do not synthesize their own adenosine triphosphate, energy-rich compounds must be supplied to them by the host cell. By the end of the growth cycle (approximately 48 hours), most reticulate bodies have reorganized into elementary bodies, which are released through mechanical disruption of the host cell to initiate new infection cycles.

Chlamydia are unique bacteria that do not stain with Gram stain. In many respects, they are similar to other bacteria: They contain DNA and RNA, are susceptible to certain antibiotics, have a rigid cell wall similar in structure and content to those of gram-negative bacteria, and multiply by binary fission. However, they differ from other bacteria and resemble viruses in being obligate intracellular parasites. They may be regarded as bacteria that have adapted to an intracellular environment. They need viable cells for multiplication and survival.⁴

Adverse Pregnancy Outcome

Controversy exists as to whether maternal cervical *C. trachomatis* infection is associated with adverse pregnancy outcome. Although some studies have demonstrated an association of maternal chlamydial infection with preterm birth, low birth weight, PROM, and perinatal death,⁶⁷⁻⁶⁹ others have failed to confirm such an association.^{4,70} Harrison⁷¹ and Sweet⁷² and their colleagues demonstrated that a subgroup of infected women in whom immunoglobulin M (IgM) antibody was present were at significantly increased risk for PROM, preterm birth, and delivery of a low-birth-weight infant. These authors postulated that IgM seropositivity reflected recent acquisition and acute chlamydial infection, which may play a more important role than chronic infection.⁶²

In additional attempts to address the role of *C. trachomatis* in adverse pregnancy outcome, researchers have undertaken treatment studies of chlamydial infection in pregnant women. In a historical control study, Ryan and colleagues⁷³ reported that untreated chlamydia-infected pregnant women in a high-prevalence population (21% positive) had a significantly increased incidence of PROM and of low-birth-weight infants and decreased perinatal survival compared with treated women or women not infected with chlamydia. Similarly, Cohen and coworkers⁷⁴ reported that treatment of chlamydial infection resulted in decreased rates of preterm delivery, PROM, preterm labor, and fetal growth restriction. There were experimental design flaws or limitations in both studies. However, because it is unethical to conduct a prospective, randomized, placebo-controlled trial in which some patients are not treated, these studies are the best available to date.

The role of cervical chlamydial infection in producing postpartum endometritis is also controversial. Early studies in the ophthalmology literature demonstrated an association between inclusion conjunctivitis in newborns and an increased risk for postpartum infection in their mothers. In a prospective study, Wager and associates⁷⁵ demonstrated

that pregnant women with chlamydial cervical infection at their initial prenatal visit were at increased risk for endometritis after vaginal delivery. However, multiple other studies have failed to confirm such an association.^{71,72,76-78}

Diagnosis

Until recently, the optimum diagnostic test for chlamydial infection was tissue culture. However, culture requires cold storage, a susceptible tissue culture cell line, a 1-week waiting time for results, and substantial technical expertise. In addition, culture is expensive and, with the advent of NAATs, has been shown to be relatively insensitive (65% to 85%).

Before the introduction of NAATs, antigen-detection methods were widely used. To a large extent, these antigen detection tests have now been replaced by DNA/RNA-based methods, both nonamplified and amplified types. Nonamplified tests such as the Gen-Probe PACE-2 assay (Gen-Probe, San Diego, CA) use DNA/RNA hybridization technology. In a large multicenter study, Black and coauthors⁷⁹ reported that the sensitivity of PACE-2 ranged from 60.8% to 71.6%, and the specificity ranged from 99.5% to 99.6%. An important advantage of DNA probe-based testing is that it can be used in conjunction with a probe for the detection of *N. gonorrhoeae* in a single swab. Additional advantages include ease of transport, ability to batch specimens, and decreased cost. As a result, by the late 1990s, the DNA probe became the most widely used diagnostic test for *C. trachomatis* infection in the United States.

More recently, DNA/RNA amplification technology has been introduced into clinical practice. NAATs have excellent sensitivity and specificity for chlamydial testing. Currently, clinically available NAATs include tests based on PCR (Roche Molecular Systems, Branchburg, NJ), TMA (AMP.CT Gen-Probe), and SDA (Bectun Dickenson, Sparks, MD). LCR-based tests (Abbott Laboratories, Chicago) are no longer available. NAATs have performed better than culture, antigen detection, or DNA probe techniques for detection of *C. trachomatis*.^{12,80,81} A major advantage of NAATs is their ability to identify patients with a low inoculum of *C. trachomatis*. Moreover, NAATs have demonstrated excellent sensitivity and specificity for detecting chlamydia in urine specimens, allowing noninvasive screening for *C. trachomatis*. However, use of a vaginal swab has been shown to have equivalent or better sensitivity and specificity and is better accepted by patients, especially when patient-obtained specimens are used.⁸²⁻⁸⁴

According to the CDC, all pregnant women should be routinely tested for *C. trachomatis* at their first prenatal visit.¹² Women younger than 25 years of age and those at increased risk for chlamydial infection also should be retested during the third trimester to prevent maternal postnatal complications and chlamydial infection in the infant. In addition, the CDC suggests that first-trimester screening might prevent the adverse effects of chlamydial infection during pregnancy (e.g., preterm birth, PROM, low birth weight).

Treatment

Screening of sexually active women for chlamydial infection is a national priority in the United States.^{85,86} Identification and treatment of women infected with *C. trachomatis* prevent horizontal transmission to sex partners and vertical transmission of *C. trachomatis* to infants during birth.¹² In addition, treatment of chlamydial infection early in pregnancy seems to reduce the rate of adverse pregnancy outcomes (e.g., preterm birth, intrauterine growth restriction, low birth weight, PROM).^{4,64}

TABLE 38-7 TREATMENT RECOMMENDATIONS FOR CHLAMYDIAL INFECTION IN PREGNANT WOMEN**Recommended Regimens**

Azithromycin 1 g PO in a single dose
Amoxicillin 500 mg PO tid for 7 days

Alternative Regimens

Erythromycin base 500 mg PO qid for 7 days
Erythromycin base 250 mg PO qid for 14 days
Erythromycin ethylsuccinate 800 mg PO qid for 7 days
Erythromycin ethylsuccinate 400 mg PO qid for 14 days

From Centers for Disease Control and Prevention. Sexually Transmitted Diseases Treatment Guidelines, 2006. MMWR Recommendations and Reports 55(RR-11):1-94, 2006.

The CDC recommendations for treatment of chlamydial infection in pregnant women are listed in Table 38-7. Doxycycline, ofloxacin, and levofloxacin are recommended for nonpregnant women but are contraindicated in pregnancy. In 2006, azithromycin, as a single 1-g dose, was added to the list of recommended regimens for treatment of chlamydial infection during pregnancy. Single-dose therapy with azithromycin definitely improves patient compliance.¹²

Amoxicillin, 500 mg orally three times daily for 7 days, was initially demonstrated to be effective for treatment of chlamydial infection during pregnancy by Crombleholme and colleagues.⁸⁷ Multiple studies have since confirmed the efficacy and safety of amoxicillin, including a Cochrane Collaboration review of 11 randomized trials for the treatment of chlamydia during pregnancy.⁸⁸

Although erythromycin regimens were once the mainstay for treatment of chlamydial infection during pregnancy, the frequent gastrointestinal side effects associated with erythromycin, which lead to noncompliance, have relegated them to alternative status.¹² In a recent observational cohort, Rahangdale and coworkers⁸⁹ reported that the treatment efficacy for erythromycin was 64%, compared to 97% for azithromycin and 95% for amoxicillin. Erythromycin estolate is contraindicated in pregnancy due to drug-related hepatotoxicity. The lower dose, 14-day regimens for erythromycin can be used if gastrointestinal tolerance is an issue, especially for women who are allergic to amoxicillin and azithromycin.

Unlike in nonpregnant women and men, repeat testing (preferably by NAATs) 3 weeks after completion of therapy is recommended for all pregnant women to ensure cure, in light of the sequelae that can occur in the mother and newborn infant if chlamydial infection persists. Sex partners should be referred for evaluation, testing, and treatment. The CDC suggests that, if concerns exist that sex partners will not seek evaluation and treatment, consideration should be given for delivery of antibiotic therapy (either a prescription or medication) by female patients to their sex partners. This approach decreases the rate of persistent or recurrent chlamydia compared with standard partner referral.^{12,90,91}

Prevention

Primary prevention of chlamydial infection requires decreasing the risk of exposure to men infected with *C. trachomatis*. Although abstinence would accomplish this, it is often not a practical approach. Mutual monogamous relationships and safe sexual behaviors (e.g., condom use) are effective. A chlamydia vaccine may be developed in the future.

Secondary prevention requires population-based screening for chlamydia and treatment of infected women and their sex partners. As

discussed previously, routine screening of all pregnant women at the first prenatal visit and screening of all nonpregnant women 25 years of age and younger is recommended. In addition, women older than 25 years of age who are at increased risk for chlamydial infection (e.g., multiple sex partners, new sex partner recently, previous chlamydial infection, other STDs) should be screened. This approach has been shown to both reduce the prevalence of chlamydial infection and decrease the risk of complications such as pelvic inflammatory disease and perinatal transmission.⁸⁶

Human Papillomavirus Infection

Human papilloma virus (HPV) is a double-stranded DNA virus that is a member of the papovavirus family. More than 100 HPV types have been identified; of these, 35 primarily infect the genital tract. HPV is the most common sexually transmitted infection in the United States, with approximately 6.2 million new HPV infections occurring each year.⁹²

HPV infection may result in either clinically apparent, grossly visible disease (e.g., genital warts) or subclinical disease. The majority of HPV infections are asymptomatic, unrecognized, or subclinical. The common genital HPV types can be divided into two major categories based on their oncogenic potential. HPV types in the low oncogenic risk group include types 6, 11, 42, 43, and 44. These types are associated with genital warts, condylomata, and some cases of low-grade squamous intraepithelial lesions. The high oncogenic risk group includes types 16, 18, 20, 31, 45, 54, 55, 56, 64, and 68. These high-risk types are frequently detected in women with high-grade squamous intraepithelial neoplasia and invasive cancers. The majority of the clinically apparent lesions are the classic genital warts (condyloma acuminatum). An estimated 1% of sexually active adults are diagnosed annually with genital warts.

Epidemiology

Sexual transmission is the primary route for transmission of HPV, and both urogenital and anorectal infections are seen.⁴ The highest-risk groups for HPV infection are sexually active adolescents and young adults, with 75% of new HPV infections occurring among those 15 to 24 years old. HPV is highly contagious, and transmission rates are high, with approximately 65% of sexual contacts becoming infected. Although it is rare, perinatal transmission, especially of HPV types 6 and 11, can occur.⁴

Risk factors for HPV infection include early onset of sexual activity, multiple sexual partners, increased frequency of intercourse, exposure to sex partner with genital warts, failure to use condoms, and cigarette smoking.⁴ In addition, Winer and colleagues⁹³ observed that smoking, oral contraceptive use, and report of a new male partner—in particular, one the patient knew for less than 8 months before sex occurred or one who reports having other partners—were predictive of new HPV infection. Furthermore, pregnancy is associated with an increased presence of HPV infection and genital warts, and immunosuppressive states (e.g., HIV infection with low CD4⁺ T-cell count) result in increased viral titers of HPV and more rapid progression of HPV disease-associated cervical intraepithelial neoplasia (CIN).⁴

Respiratory papillomatosis (laryngeal papilloma) is a rare disease in the neonate that is caused by HPV-6 and HPV-11. Laryngeal papillomas can be particularly troublesome, because they may produce

respiratory distress secondary to obstruction and because recurrence after treatment is common. Transplacental and intrapartum transmission of HPV can occur, as well as infection via contact during the neonatal period.⁴

Because genital papillomavirus infection is so common and respiratory papillomatosis is rare, the risk of intrapartum transmission is low, perhaps on the order of 1 case of juvenile respiratory papillomatosis per 1000 children born to infected mothers. Watts and associates⁹⁴ reported that, among 151 pregnant women evaluated for HPV by clinical, colposcopic, and PCR tests at less than 20, 34, and 36 weeks of gestation, 112 (74%) had evidence of HPV. HPV was identified in only 3 (4%) of 80 infants born to women with HPV detected at 34 to 36 weeks' gestation, but it also was found in 5 (8%) of 63 infants born to women in whom HPV DNA was not detected. Tenti and coworkers⁹⁵ also demonstrated that pregnant women with latent HPV infection have a low potential for transmitting the virus to the oropharyngeal mucosa of their newborns. Although these authors reported that HPV DNA was detected in 11 neonates born vaginally to HPV-positive women (vertical transmission rate, 30%; CI, 15.9% to 47%), all infants tested negative by 5 weeks after birth and remained so throughout the 18-month follow-up period. These findings suggest that the infants who were HPV-positive at birth were contaminated and not infected.

Other recent studies have supported the finding that the risk of perinatal transmission of HPV is low.^{96,97} Of these, the most informative was the study by Smith and colleagues.⁹⁶ They detected HPV type-specific concordance in only 1 mother/infant pair among the 6 (3.7%) infants born to 164 mothers with cervical HPV infection. In addition, a third of the HPV-positive newborns were born to mothers who tested negative for HPV DNA during pregnancy.

Pathogenesis

Genital HPV infections are transmitted primarily by sexual activity. Clinical lesions and subclinical infections occur in the urogenital and anorectal areas. As noted previously, the infectivity rate is high, with transmission occurring to sexual partners in approximately 65% of cases. The average incubation period is 2 to 3 months.

The HPV viral genome consists of three major regions; two protein-encoding regions (early and late gene regions) and a noncoding upstream regulatory region (URR). The URR controls transcription of both the early and the late region, resulting in regulation of viral proteins and production of infectious particles. The early region contains open reading frames (ORFs), which are transcriptional units that encode for a series of proteins designated E₁, E₂, E₄, E₅, E₆, and E₇. Early region gene expression controls replication, transcription, and cellular transformation of viral DNA. Most importantly, it also plays a role in unregulated cellular proliferation. Whereas E₆ and E₇ encode proteins involved in viral replication, they are the oncogenic genes and also code proteins critical for host cell immortalization and transformation. The late gene region contains two ORFs (L₁ and L₂), which encode structural proteins responsible for production of the viral capsid. The L₁ protein is the key component of the recently introduced HPV vaccine and is highly immunogenic.⁹⁸

Acute HPV infection occurs when microtrauma secondary to sexual intercourse allows virus to enter the skin or mucosa of the genital tract. The postpubertal adolescent cervix is characterized by a large transformation zone which is more susceptible to minor trauma during sexual intercourse and whose immature columnar epithelial cells are particularly susceptible to HPV. This may explain why young, sexually active adolescents are at the greatest risk for acquiring HPV

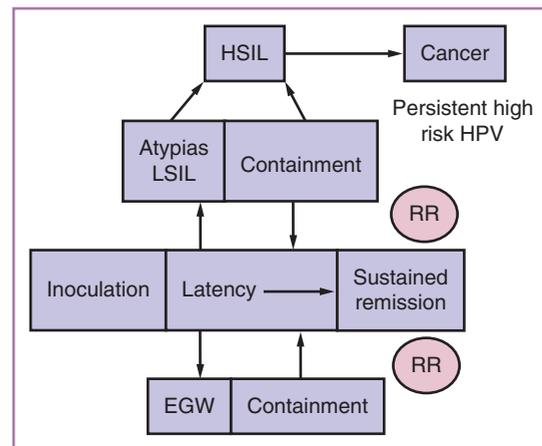

FIGURE 38-4 Natural history of human papillomavirus infection. EGW, external genital warts; HPV, human papillomavirus infection; HSIL, high-grade squamous intraepithelial lesion; LSIL, low-grade intraepithelial lesion; RR, recurrences.

infection. HPV enters cells in the basal layer of the epithelium and matures as it passes through the parabasal, spinous, and granular layers of the epithelium.^{93,99}

Following acute HPV infection, several clinical scenarios can occur (Fig. 38-4). Latent viral infection occurs when the HPV genome is stabilized as a nonintegrated episome and remains in host cells without causing clinical or morphologic changes in the squamous epithelium of the genital tract. Latency can lead to sustained remission, which is the case in the vast majority of HPV infections. Alternatively, active infection may occur, depending on the type of HPV present. Low-risk HPV types, especially 6 and 11, cause proliferation of squamous epithelial cells with resultant formation of genital warts. High-risk oncogenic HPV types may become integrated into the host genome, resulting in CIN. CIN may progress to precancerous lesions (CIN 2 and 3) and, ultimately, to invasive cervical cancer. Alternatively, CIN may resolve spontaneously, especially CIN 1 and, to a lesser extent, CIN 2.

Diagnosis

Genital Warts

The diagnosis of genital warts is usually made by visual inspection. Biopsy is required only in certain circumstances: (1) the diagnosis is uncertain; (2) the lesions do not respond to standard therapy; (3) the disease worsens during therapy; (4) the patient is immunocompromised; or (5) the warts are pigmented, indurated, fixed, bleeding, or ulcerated. Use of HPV nucleic acid tests is not recommended in the routine diagnosis and management of visible genital warts.¹²

Asymptomatic Human Papillomavirus Infection

Because HPV cannot be cultured, detection of asymptomatic infection requires identification of viral nucleic acid (DNA or RNA) or capsid protein.^{12,100} Only the Digene Hybrid Capture 2 (HC 2) High-Risk HPV DNA Test (Qiagen Digene, Gaithersburg, MD) is approved by the U.S. FDA for clinical use. This test uses liquid nucleic acid hybridization to detect 13 high-risk HPV types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68). Type-specific results are not reported; rather, the specimen is identified as positive or negative for high-risk HPV. In particular, the HC2 High-Risk HPV test is approved for triage of

women with Papanicolaou (Pap) test results showing atypical squamous cells of undetermined significance (ASC-US) and, in combination with the Pap test, for cervical cancer screening in women older than 30 years of age.

Less sensitive methods for detection of suspected HPV infection include cytologic evidence of HPV (koilocytosis), colposcopy, biopsy, and acetic acid application. Although they are not available for clinical use, PCR assays targeting genetically conserved regions of the L₁ gene and HPV serologic assays to detect antibodies to the L₁ viral protein have been used in research and epidemiologic studies.

Treatment

Options for treatment of genital warts during pregnancy are limited. The safety of podophyllin resin, podofilox, or imiquimod in pregnancy has not been established. Trichloroacetic acid (TCA) or bichloroacetic acid (BCA), 80% to 90% solution, may be used on a weekly basis. Alternatively, the lesions may be excised by scissors, scalpel, curettage, or electrosurgery. Cryosurgery can be used to treat vaginal lesions.¹² Treatment should be limited to patients who have multiple, confluent lesions.

As noted by the CDC, it is unclear whether cesarean delivery prevents juvenile-onset recurrent respiratory papillomatosis.^{12,101} Therefore, cesarean delivery should not be performed solely to prevent transmission of HPV infection to the newborn. Cesarean delivery should be considered if obstruction of the pelvic outlet is likely or if vaginal delivery would result in excessive bleeding because of multiple confluent lesions.

Prevention

Transmission of HPV occurs through contact with infected genital skin, mucous membranes, or body fluids from a sexual partner with clinical or subclinical HPV infection. As with other STDs, preventing the spread of HPV to a susceptible population is more cost-effective than secondary prevention. Prevention of HPV transmission incorporates the following approaches: (1) abstinence (most effective, but may not be practical); (2) long-term mutual monogamy with a single partner; (3) limiting the number of sexual partners; (4) limiting sexual contacts to men who have been abstinent for a longer period of time; (5) having a circumcised partner; (6) using latex condoms; and (7) receiving the HPV vaccine.

The most exciting new development for prevention of HPV infection is the introduction into clinical practice of prophylactic HPV vaccines. The first such vaccine to become available was the quadrivalent HPV vaccine, Gardasil (Merck & Co., Whitehouse Station, NJ), which protects against HPV types 6, 11, 16, and 18.^{100,102}

Neither routine surveillance for HPV infection nor partner notification is deemed useful for HPV prevention. The rationale for this conclusion is that HPV is so prevalent that most partners are already infected. In addition, no prevention or treatment strategies are recommended for partners. Similarly, no treatment strategies or prevention strategies are recommended for prevention of perinatal transmission of HPV. Therefore, cesarean delivery for prevention of HPV infection in newborns is not indicated.

Urinary Tract Infection

Urinary tract infections (UTIs) are a major public health problem in the United States, affecting approximately 11 million women annually,

TABLE 38-8 CLASSIFICATION OF URINARY TRACT INFECTIONS

Asymptomatic bacteriuria (ASB)
Acute uncomplicated cystitis
Recurrent cystitis
Acute uncomplicated pyelonephritis
Complicated urinary tract infection
Multiple frequent recurrences
High probability of drug-resistant uropathogen
Increased risk for sepsis syndrome

with an associated direct cost of \$1.6 billion.¹⁰³ In women, UTIs are divided into five major categories^{104,105} (Table 38-8).

Women are 14 times more likely to develop UTIs than men. Presumably, this female predominance is the result of several factors, including (1) a shorter urethra in women; (2) continuous contamination of the external one third of the urethra by pathogenic bacteria from the vagina and rectum; (3) failure of females to empty their bladders as completely as males; and (4) movement of bacteria into the female bladder during sexual intercourse.⁴

UTI is the most common medical complication of pregnancy. UTIs occur in up to 20% of pregnancies and account for 10% of antepartum hospitalizations.^{4,106} Among pregnant women, almost all UTIs fall into three categories: (1) ASB; (2) acute cystitis; and (3) acute pyelonephritis. Of critical importance is the recognition that the normal physiologic changes associated with pregnancy (e.g., progesterone effect on ureteral smooth muscle peristalsis, obstruction of the ureters by the enlarging uterus) predispose pregnant women with ASB to the development of acute pyelonephritis. Moreover, UTIs in pregnancy place the fetus and mother at risk for substantial morbidity and even mortality.^{4,104}

Asymptomatic Bacteriuria

Epidemiology

Obstetricians have long recognized the serious nature of symptomatic UTIs in pregnancy. However, it was not until the early 1960s that Kass demonstrated that significant bacteriuria can occur in the absence of symptoms or signs of UTI.¹⁰⁷ He established quantitative bacteriology as the indispensable laboratory aid for the diagnosis, follow-up, and confirmation of cure of UTI. From these studies evolved the commonly accepted definition of ASB: the presence of 10⁵ or more colonies of a bacterial organism per milliliter of urine on two consecutive clean, midstream-voided specimens in the absence of signs or symptoms of UTI. Persistent ASB was identified in 6% of pregnant patients. Acute pyelonephritis developed in 40% of the patients with ASB who received placebo, but pyelonephritis rarely occurred when bacteriuria was eliminated. Kass also noted that rates of neonatal death and prematurity were two to three times greater in bacteriuric women receiving placebo than in nonbacteriuric women or bacteriuric women whose infection was eliminated by antibiotics. He concluded that detection of material bacteriuria would identify patients at risk for pyelonephritis and premature delivery and maintained that pyelonephritis in pregnancy could be prevented by detection and treatment of bacteriuria in early pregnancy. Moreover, Kass estimated that 10% of premature births could be prevented by such a program.¹⁰⁷

Most cases of ASB in pregnancy are detected at the initial prenatal visit, and relatively few pregnant women acquire bacteriuria after the

initial visit. Thus, the bacteriuria antedates the pregnancy. The prevalence of ASB in pregnant women ranges from 2% to 11%, with the majority of investigations reporting 4% to 7%. An increased prevalence of bacteriuria in females has been associated with lower socioeconomic status, diminished availability of medical care, and increased parity. Recently, Thurman and coworkers determined that sickle cell trait carriers are not more susceptible than other pregnant women to ASB.¹⁰⁸

Untreated ASB during pregnancy often leads to acute pyelonephritis. Women with ASB in early pregnancy are at a 20- to 30-fold increased risk of developing acute pyelonephritis during pregnancy, compared to pregnant women without bacteriuria.¹⁰⁹ Studies performed in the 1960s, using sulfonamides or nitrofurantoin, demonstrated that antimicrobial treatment of ASB during pregnancy significantly reduced the risk of developing pyelonephritis, from about 20% to 35% to between 1% and 4%. Before the advent of universal screening for ASB in early pregnancy, the reported rate of acute pyelonephritis in pregnancy was 3% to 4%; afterward, it was 1% to 2%.^{110,111} Similarly, studies in Europe assessing the implementation of screening and treatment programs for ASB in pregnant women demonstrated a significant reduction in the rate of acute pyelonephritis in pregnancy.^{112,113} For this reason, it is important that the presence of bacteriuria be identified. Other claims, such as that ASB predisposes the patient to anemia, preeclampsia, and chronic renal disease, are controversial and unproven.

Kass¹⁰⁷ initially reported an association between ASB and prematurity and observed that eradication of bacteriuria with antimicrobial therapy significantly reduced the rate of preterm delivery. He proposed that early detection and treatment of bacteriuria would prevent 10% to 20% of preterm births. Subsequently, numerous studies demonstrated conflicting results regarding bacteriuria and prematurity. Kincaid-Smith and Bullen¹¹⁴ suggested the hypothesis that underlying renal disease is the major cause of the excessive risk of prematurity or low birth weight among bacteriuric pregnant women. The many different definitions for prematurity used in the literature contributed to this confusion.

More recent studies, including meta-analyses, demonstrated an association between ASB and low birth weight and preterm delivery.¹¹⁵⁻¹¹⁸ Bacteriuria is only one of many factors that may influence the onset of premature labor. Because both the incidence of bacteriuria in pregnancy and the incidence of prematurity vary inversely with socioeconomic status, any relationship between bacteriuria and gestational length and birth weight may be complex and difficult to establish. In an attempt to resolve this controversy, Romero and colleagues¹¹⁵ used the technique of meta-analysis to assess the relationship between ASB and preterm delivery and/or low birth weight. Meta-analysis confirmed a statistically significant increased risk for low-birth-weight infants among bacteriuric women. Their study also demonstrated a significant association between bacteriuria and preterm delivery and showed a statistically significant reduction in the incidence of low birth weight among bacteriuric women treated in eight placebo-controlled treatment trials.

Meis and colleagues¹¹⁷ demonstrated in a multivariate analysis that bacteriuria significantly increased the occurrence of preterm birth (relative risk, 2.03; CI, 1.50 to 2.75). Schieve and colleagues,¹¹⁶ in an analysis of 150,000 births in the University of Illinois Perinatal Network database, reported that women with antepartum UTI were at increased risk for delivering preterm and low-birth-weight infants. With multivariate analysis, the odds ratios were 1.4 (CI, 1.2 to 1.6) and 1.3 (CI, 1.1 to 1.4) for low-birth-weight and preterm birth, respectively. Moreover, Smaill¹¹⁸ reported a meta-analysis of treatment versus placebo trials for ASB in pregnancy that demonstrated a one-third reduction

in the rate of low-birth-weight infants (from 15% to 10%) in women whose bacteriuria was treated. Therefore, it appears that maternal ASB is a risk factor for preterm delivery and low birth weight and that this risk can be reduced by screening and treatment of ASB in pregnant women.¹¹⁹ With recognition that ASB increases the risk for developing acute pyelonephritis and preterm delivery and low birth weight, the ACOG and the U.S. Preventive Services Task Force recommend screening to detect ASB in pregnancy.^{120,121}

Symptomatic UTI is more often found in pregnant women than in nonpregnant women. This observation suggests that some factors present during gestation allow bacteria to replicate in the urine and ascend to the upper urinary tract. Several findings support this view.⁴ The normal female urinary tract undergoes dramatic physiologic and anatomic changes during pregnancy. Briefly, a decrease in ureteral muscle tone and activity results in a lower rate of passage of urine throughout the urinary collecting system. The upper ureters and renal pelves become dilated, resulting in a physiologic hydronephrosis of pregnancy. These changes are caused by the effects of progesterone on muscle tone and peristalsis and, more important, by mechanical obstruction of the enlarging uterus. Changes in the bladder also occur in pregnancy, including decreased tone, increased capacity, and incomplete emptying, all of which predispose to vesicoureteric reflux. Hypotonia of the vesicle musculature, vesicoureteric reflux, and dilation of the ureters and renal pelves result in static columns of urine in the ureters, facilitating the ascending migration of bacteria to the upper urinary tract after bladder infection is established. The hypokinetic collecting system reduces urine flow, and urinary stasis occurs, predisposing to infection.

Alterations in the physical and chemical properties of urine during pregnancy exacerbate bacteriuria, further predisposing to ascending infection. Because of the increased excretion of bicarbonate, urinary pH rises, encouraging bacterial growth. Glycosuria, which is common in pregnancy, favors an increase in the rate of bacterial multiplication. The increased urinary excretion of estrogens may also be a factor in the pathogenesis of symptomatic UTI during pregnancy. In animal experiments, estrogen enhances the growth of strains of *Escherichia coli* that cause pyelonephritis and predispose to renal leukocyte migration, phagocytosis, and complement activity. The cumulative effect of these physiologic factors is an increased risk that infection in the bladder may ascend to the kidneys.

Pathogenic characteristics of microorganisms such as *E. coli* are major determinants of UTI. These include pili (adherence), K antigen (antiphagocytic activity), hemolysin (cytotoxicity), and antimicrobial resistance. Host susceptibility factors include anatomic or functional abnormalities of the urinary tract and uroepithelial and vaginal epithelial cells with increased attachment of uropathogenic *E. coli*. Women who do not secrete the ABO blood group antigens are particularly likely to harbor pathogenic *E. coli* in the urogenital epithelium.

Pathogenesis

In general, the urinary tract is sterile, with the exception of the distal urethra, which is often colonized with bacteria from the skin and vaginal and anal flora. Ascension of bacteria from the urethra into the bladder results in ASB. Bacteria associated with ASB derive from the normal flora of the gastrointestinal tract, vagina, and periurethral area. In addition, instrumentation of the urinary tract (e.g., bladder catheterization) may introduce bacteria into the bladder of patients without prior colonization. In women with ASB, bacteria persist in the urinary tract but do not elicit sufficient enough host response to result in either symptoms or eradication of the bacteria from the urinary tract. Factors such as host susceptibility, bacterial virulence, incomplete bladder

emptying, obstruction, or presence of a foreign body (e.g., catheter) predispose to persistence of bacteria.¹⁰⁹

As noted in many studies, *E. coli* is overwhelmingly the most frequent microorganism recovered in patients with ASB, including pregnant women.⁴ Other gram-negative enterobacteria (e.g., *Klebsiella*, *Proteus*) and gram-positive bacteria such as *Staphylococcus saprophyticus*, GBS, and the enterococcus cause the remaining cases of ASB in young, sexually active women.

A series of studies compared genetic markers or phenotypic expression of potential bacterial virulence factors among *E. coli* strains isolated from various types of UTIs.^{109,122,123} One of those publications¹²³ focused on *E. coli* isolates from pregnant women. Among patients with ASB, *E. coli* strains demonstrated a lower frequency of genetic markers or phenotypic expression of virulence factors than did those recovered from patients with acute cystitis or acute pyelonephritis.

Several studies have shown that the incidence of ASB in nonpregnant women is comparable to the incidence in pregnant women in the same locale.¹⁰⁷⁻¹⁰⁹ It appears that most women in whom bacteriuria is first discovered during pregnancy have acquired ASB earlier in life. Although pregnancy per se does not cause any major increase in incidence of bacteriuria, it does predispose to the development of acute pyelonephritis in bacteriuric patients.

Diagnosis

Although the diagnosis of ASB was originally based on obtaining two consecutive midstream urine cultures containing at least 100,000 colony-forming units per milliliter (CFU/mL) of a uropathogen, a single positive urine specimen is used for clinical diagnosis.^{4,124} Urine cultures are relatively expensive and require 24 to 48 hours for results. Therefore, inexpensive, rapid, office-based screening tests have undergone clinical testing. These include microscopic urinalysis, nitrite and leukocyte esterase dipstick, Gram stain, Uricult dip slide, Cult-Dip Plus, and Uristat test. However, although it is more costly than rapid tests, urine culture remains the screening test of choice for detecting ASB in pregnancy.^{4,124-126}

Recent investigations have reconfirmed the lack of sensitivity and specificity of alternate methodologies for the diagnosis of ASB, particularly in pregnant women.^{127,128} As noted by McNair and colleagues,¹²⁷ the potential serious sequelae of undiagnosed and untreated ASB mandate that urine culture be used to detect ASB in pregnant women. Both the U.S. Preventive Services Task Force and the Infectious Disease Society of America (IDSA) concur with this recommendation.^{109,121} Although there is consensus that all pregnant women should be screened for ASB by urine culture at least once in early pregnancy, no recommendation has been made for or against repeated screening of culture-negative women in later pregnancy. Our approach is not to rescreen culture-negative, asymptomatic women later in pregnancy unless there is a history of recurrent UTIs.

Treatment

Detection and treatment of ASB give the obstetrician an opportunity to prevent significant medical complications of pregnancy. Screening at the original antenatal visit, appropriate treatment, and eradication of bacteriuria significantly reduce the frequency of antenatal acute pyelonephritis. Clinical trials demonstrate that treatment of ASB reduces the risk of acute pyelonephritis in pregnancy by 80% to 90%, to about 1% to 4%.¹²⁹⁻¹³¹ In addition, screening and treatment of ASB significantly reduce the risks for preterm delivery and delivery of a low-birth-weight infant.¹¹⁵⁻¹¹⁸

Treatment should be designed to maintain sterile urine throughout pregnancy, using the shortest possible course of antimicrobial agents

in order to minimize the cost and the toxic effects of these drugs in mother and fetus. Because most antibacterial agents are excreted by glomerular filtration, therapeutic concentrations are readily achieved in the urine. In fact, the concentration of these drugs in urine greatly exceeds that required for the treatment of most UTIs. Even drugs that do not reach therapeutic concentrations in serum, such as nitrofurantoin, reach significant concentrations in urine.¹³²

No single agent is clearly better than another. At present, it is generally accepted that short courses of treatment are preferable, because (1) the duration of initial therapy does not affect the recurrence rate, (2) a short course minimizes the adverse drug effects in mother and fetus, (3) emergence of resistant bacteria is discouraged, (4) patient compliance is enhanced, and (5) costs are kept to a minimum.

Although a 3-day course of antibiotic therapy is recommended for the treatment of uncomplicated UTI in nonpregnant women, until recently a 7-day course was preferred for pregnant women.¹⁰⁵ However, a Cochrane Collaboration systematic review concluded that there was insufficient evidence to recommend a duration of antimicrobial therapy for pregnant women among the single-dose, 3-day, 4-day, and 7-day treatment regimens.¹³³ Most experts prefer the 7-day approach. Treatment of ASB is empiric, and in vitro susceptibility testing is not recommended for the initial positive culture.⁴

A wide variety of antimicrobial agents have been used successfully for management of ASB in pregnancy (Table 38-9). These include β -lactam antibiotics such as ampicillin and cephalosporins which do not pose any significant risk to the fetus. Other commonly used antibiotics include short-acting sulfonamides, nitrofurantoin, and trimethoprim-sulfamethoxazole.

TABLE 38-9 ANTIMICROBIAL TREATMENT OF ASYMPTOMATIC BACTERIURIA AND ACUTE CYSTITIS DURING PREGNANCY

Antimicrobial Agent	Regimen
Single-Dose Treatments**	
Ampicillin*	2 g
Amoxicillin*	3 g
Nitrofurantoin monohydrate macrocrystals (Macrobid)	200 mg
Trimethoprim-sulfamethoxazole DS	320/1600 mg
3-Day or 7-Day Treatments	
Ampicillin*	250 mg qid
Amoxicillin*	500 mg tid
Cephalexin*	250-500 mg qid
Nitrofurantoin monohydrate macrocrystals	100 mg bid
Sulfisoxazole	Initial 2 g dose, then 1 g qid
Trimethoprim-sulfamethoxazole DS	160/800 mg bid
Suppressive Therapy	
Nitrofurantoin monohydrate macrocrystals	100 mg qhs (duration of pregnancy)
Trimethoprim-sulfamethoxazole DS	160/800 qhs (duration of pregnancy)

*Only in geographic areas with low levels of resistance to *Escherichia coli*.

**Should not be used in pregnancy because of unacceptably high rate of failure.

DS, double strength.

The quinolones are not approved for use during pregnancy because of concerns regarding their teratogenic effect on fetal cartilage. However, use of fluoroquinolones for resistant microorganisms is appropriate. In such instances, ciprofloxacin 250 mg twice daily or levofloxacin 250 mg daily may be used. Use of ampicillin or amoxicillin has been questioned for treatment of UTIs, because the predominant etiologic organism is *E. coli*, and resistance rates of *E. coli* to ampicillin in the United States are 30% or greater.¹⁰⁵ Of additional concern is the decreased susceptibility of *E. coli* to trimethoprim-sulfamethoxazole, which ranges from 5% to 15% depending on the geographic area.^{105,134-136}

When short courses of therapy are prescribed for ASB during pregnancy, continuous surveillance for recurrent bacteriuria by repeat urine cultures is essential. It is appropriate to treat recurrent ASB with antimicrobial agents on the basis of the microorganism's sensitivities for the remainder of the pregnancy and for at least 2 weeks after delivery. Alternatively, a short course of therapy with urine culture screening at each prenatal visit may be instituted. Persistent ASB should necessitate continuous antimicrobial therapy for the duration of pregnancy. A single daily dose of nitrofurantoin, 100 mg, preferably after the evening meal, is recommended. Alternatively, short-acting sulfonamide preparations such as trimethoprim-sulfamethoxazole may be prescribed.

Prevention

Because ASB antedates pregnancy and typically is not acquired during pregnancy, there is no prevention strategy available. Recurrent ASB has been noted in up to 30% of pregnant women.¹⁵⁷ Close monitoring with frequent urine cultures after diagnosis and treatment of ASB in early pregnancy can prevent recurrent or persistent ASB. Most importantly, diagnosis, treatment, and eradication of ASB in pregnant women substantially reduce the occurrence of acute pyelonephritis and reduce the incidence of preterm births.

Cystitis in Pregnancy

Acute cystitis is a distinct syndrome characterized by urinary urgency, frequency, dysuria, and suprapubic discomfort in the absence of systemic symptoms such as high fever and costovertebral angle tenderness. Gross hematuria may be present; the urine culture is invariably positive for bacterial growth. The gold standard for diagnosing acute cystitis, in the past, has been a quantitative culture containing at least 100,000 CFU/mL. Stamm and coworkers¹³⁸ demonstrated that a urine culture positive for bacterial growth with more than 100 CFU/mL, in combination with symptoms of dysuria and frequency, is sufficient to confirm the diagnosis of cystitis, particularly if the urine sample was obtained by catheterization.

Epidemiology

The incidence of acute cystitis among pregnant women ranges from 0.3% to 1.3%.¹²³ Harris and Gilstrap¹³⁹ reported a recurrence rate of 1.3% for cystitis during pregnancy. Although increased diagnosis and treatment of ASB reduced the incidence of pyelonephritis at their institution, the incidence of acute cystitis remained constant. On initial screening urine cultures, 64% of the patients who ultimately developed cystitis had negative cultures; in contrast, only a minority of those patients with ASB and acute pyelonephritis had negative cultures. The authors noted that the recurrence pattern in patients with acute cystitis was also different from that in patients with either bacteriuria or acute pyelonephritis. Disease recurred in 75% of patients with acute pyelonephritis who were not given suppressive

antimicrobial therapy, compared with only 17% of patients with acute cystitis.

Acute cystitis tends to occur during the second trimester.¹³⁹ This also differs from the pattern seen with ASB (in which almost all cases are diagnosed in the first trimester) or with acute pyelonephritis (diagnosed in the first and third trimesters). In addition, acute cystitis does not increase the risk for preterm birth, low birth weight, or acute pyelonephritis.^{4,104,124} In fact, the only morbidity associated with acute cystitis in pregnancy is the discomfort that occurs with symptomatic UTI.

Pathogenesis

As reported by Scholes and associates,¹⁴⁰ the major risk factors for acute cystitis in young women are a history of prior acute cystitis and frequent or recent sexual activity. By 24 years of age, approximately 1 in 3 women have experienced at least one episode of acute cystitis, and 30% to 40% have one or more recurrences.¹⁴¹ Nonsecretors of ABO blood group antigens are at increased risk for recurrent cystitis.¹⁴²

As in ASB, the microorganisms associated with acute cystitis originate from the flora of the gastrointestinal tract, vagina, and periurethral area and ascend via the urethra to colonize and infect the bladder. The most common bacteria isolated from the urine of women with acute cystitis is *E. coli* (80% to 85%), followed by *S. saprophyticus*, other gram-negative enterobacteria (e.g., *Klebsiella pneumoniae*, *Proteus mirabilis*), GBS, and the enterococcus.⁴

Diagnosis

In nonpregnant women, the diagnosis of acute uncomplicated cystitis relies on symptoms of dysuria, urgency, and frequency plus evidence of pyuria (microscopic or dipstick). In pregnancy, culture confirmation is recommended.⁴ Once cystitis is suspected, either a catheterized specimen or a clean-catch midstream specimen for urinalysis and culture should be obtained before treatment with antibiotics. However, because of the symptomatology of acute cystitis and the danger of upward extension of the infection to the kidney, it is not advisable to await the results of culture. The constellation of symptoms and demonstration of white blood cells and bacteria on urinalysis should be sufficient grounds for beginning therapy.

Urine dipstick testing has replaced microscopy because it is cheaper, faster, and more convenient. The presence of either nitrite or leukocyte esterase is considered a positive result, with a sensitivity of 75% and a specificity of 82%.¹⁴⁴ Whereas a positive result is highly predictive of UTI, a negative dipstick test does not rule out an infection in acutely symptomatic women.¹⁴³ A clean midstream urine or catheter specimen with greater than 10² bacteria per milliliter obtained from an acutely dysuric woman is diagnostic of acute cystitis.¹³⁸

Treatment

Pregnant women with acute cystitis should receive immediate therapy with an antibiotic agent. The organisms most commonly isolated in acute cystitis are *E. coli*, other gram-negative facultative organisms, *S. saprophyticus*, and GBS. The duration of therapy in cystitis should be 3 to 7 days. Single-dose therapy is not recommended in pregnancy. The antimicrobial agents used to treat cystitis in pregnancy are similar to those for ASB and are summarized in Table 38-9. Relief of symptoms occurs in more than 90% of women within 72 hours after treatment initiation.¹⁴⁴

In pregnant women with acute cystitis, a "test of cure" urine examination should be performed 1 to 2 weeks after completion of therapy. If it is positive, a different regimen than that used initially should be started. Continuous prophylaxis (at bedtime) is recommended for women who have three or more symptomatic UTIs in a 12-month

period. Either nitrofurantoin or trimethoprim-sulfamethoxazole is recommended. Postcoital prophylaxis is an alternative option.⁴

Prevention

Because the risk for acute cystitis is not associated with the presence of ASB, screening for and treatment of ASB early in pregnancy does not reduce the incidence of acute cystitis in pregnancy. Moreover, one of the major risk factors for acute cystitis, use of a diaphragm and spermicide for contraception, is not an issue during pregnancy. However, recurrent acute cystitis can be prevented with daily antibiotic prophylaxis. Nitrofurantoin and trimethoprim-sulfamethoxazole are acceptable alternatives.

Acute Pyelonephritis

Acute pyelonephritis is one of the most common medical complications of pregnancy.^{4,144} Despite recommendations for routine screening of pregnant women and treatment of ASB, the incidence of acute pyelonephritis in pregnancy ranges from 1% to 2.5%. In a recent large prospective cohort at Parkland Hospital, the incidence of antepartum acute pyelonephritis was 14 per 1000 deliveries.¹⁴⁴ Recurrence during the same pregnancy is frequent, occurring in 10% to 18% of cases. In addition, acute pyelonephritis in pregnancy can cause significant maternal morbidity and, in rare instances, maternal and fetal mortality.^{4,106,144}

Epidemiology

As noted, the incidence of acute pyelonephritis in pregnancy ranges from 1% to 2.5%. The incidence varies depending on several factors, including population characteristics, prevalence of ASB, whether routine screening with culture and treatment of ASB occurs, and whether patients receive prenatal care, especially early first-trimester assessment.

The major risk factors for acute pyelonephritis are previous episodes of acute pyelonephritis and the presence of ASB.⁴ In the absence of routine screening and treatment of ASB, up to 40% of pregnant women with ASB will develop acute pyelonephritis. Therefore, screening and treatment of ASB dramatically reduce the incidence of pyelonephritis. With universal screening, the reported incidence is 1% to 2%,^{110,111,145} Among pregnant women not receiving suppressive antimicrobial therapy to prevent acute pyelonephritis for the duration of pregnancy, recurrence has been noted in up to 60%; with suppressive therapy, the recurrence rate is less than 10%.^{4,145} Other predisposing factors for acute pyelonephritis during pregnancy include obstructive and neurologic diseases affecting the urinary tract and the presence of ureteral or renal calculi.

Recently, Hill and coworkers¹⁴⁴ examined the incidence of risk factors among women with acute antepartum pyelonephritis. Overall, 13% had at least one maternal risk factor for antepartum pyelonephritis. As demonstrated in the older literature, the most common risk factor was a previous history of pyelonephritis and ASB. Other factors include young maternal age and nulliparity.

Pathogenesis

Although ASB is no more frequent in pregnant than in nonpregnant women, acute pyelonephritis is a much more frequent sequela during pregnancy. Several factors during pregnancy facilitate bacterial replication in urine and ascent to the upper urinary tract. In the bladder, there is decreased tone, increased capacity, and incomplete emptying; as a consequence, there is a predisposition for vesicoureteric reflux to occur. Moreover, the physiologic hydronephrosis of pregnancy, caused

by the effects of progesterone on muscle tone and peristalsis in the ureters and the mechanical obstruction of the enlarging uterus, facilitates ascent of bacteria into the upper urinary tract.⁴

Alterations in the physical and chemical properties of urine during pregnancy also facilitate ascending infection. Bacterial growth is enhanced by the elevated urinary pH during pregnancy. Glycosuria is more frequent and also enhances bacterial growth. The increased urinary excretion of estrogen also may play a role in the pathogenesis of acute antepartum pyelonephritis. Estrogen has been shown to accelerate the growth of strains of *E. coli* that cause pyelonephritis.^{4,146,147}

Pathogenic mechanisms also exist in the microorganisms associated with acute pyelonephritis. The requisite first step for establishing colonization or infection in the urinary tract is bacterial adherence to urogenital epithelium. *E. coli* attaches to uroepithelium via two adhesions: P fimbriae (pap encoded adhesions) and type 1 pili. The prevalence of *E. coli* strains expressing P fimbriae from patients with acute pyelonephritis (75% to 100%) is significantly greater than among fecal strains from persons without UTI. On the other hand, type 1 pili are almost universally expressed among uropathogenic and fecal commensal *E. coli* strains.¹⁴⁸

The most common bacteria associated with acute pyelonephritis are *E. coli*, *Klebsiella* species, and *Enterobacter* species. Dunlow and Duff⁴⁹ reported that, in a group of women with antepartum pyelonephritis, *E. coli* (80%) was the dominant pathogen, with *K. pneumoniae* (7.4%), *Staphylococcus aureus* (6.7%), and *P. mirabilis* (2%) isolated much less frequently. More recently, Hill and colleagues¹⁴⁴ observed that the predominant microorganisms recovered from patients with acute antepartum pyelonephritis were *E. coli* (70%), *Klebsiella-Enterobacter* (3%), *Proteus* (2%), and gram-positive bacteria, including GBS (10%).

Diagnosis

Acute pyelonephritis is characterized by fever, chills, flank pain, dysuria, urgency, and frequency. Nausea and vomiting may also be present. On physical examination, fever and costovertebral angle tenderness are often present. Laboratory abnormalities include pyuria and bacteriuria. White blood cell casts are highly predictive of acute pyelonephritis. The diagnosis is ultimately confirmed by a positive urine culture.⁴

As noted by Sheffield and Cunningham,¹⁰⁴ the clinical findings of acute pyelonephritis in pregnancy are similar to those described in nonpregnant women. Onset of symptoms is usually abrupt. Fever is universal, and the diagnosis is suspect if it is absent. In 50% of cases occurring during pregnancy, pyelonephritis is unilateral and on the right side. Unilateral left side and bilateral infections are each present in 25% of cases. Most likely, right urethral obstruction secondary to uterine dextrorotation explains the right-sided predominance seen in pregnancy.

Although 10% to 20% of pregnant women with acute pyelonephritis are bacteremic, the usefulness of obtaining routine blood cultures in suspected cases of acute uncomplicated pyelonephritis has been questioned.^{150,151} The rationale for this new approach includes the facts that blood cultures are expensive, the bacterium isolated is invariably the organism recovered from the urine culture, and change of antibiotics usually is based on lack of clinical response rather than culture results.

Pyelonephritis is not only a serious risk for preterm labor and delivery but also a serious threat to maternal well-being. Up to 20% of pregnant women with acute pyelonephritis develop evidence of multiorgan system involvement secondary to endotoxemia and the sepsis syndrome.^{4,152,153} The primary pathogenic mechanism results from endothelial activation followed by capillary fluid leakage and

extravasation, with resultant decreased perfusion of vital organs. This vascular derangement worsens the hypovolemia that is often present as a result of fever and vomiting, leading to hypotension.

Multiple sepsis-related complications have been reported in pregnant women with acute pyelonephritis. Anemia, caused by hemolysis initiated by endotoxemia, occurs in 23% to 66% of these patients. Rarely, evidence of disseminated intravascular coagulation (DIC) may be present. With severe sepsis, DIC is common and is associated with potentially serious complications (e.g., purpura fulminans).^{4,152,153}

Before the recognition that aggressive fluid resuscitation is a critical component of the management of acute pyelonephritis in pregnancy, approximately 20% of pregnant women with acute pyelonephritis had transient renal dysfunction, as documented by decreased creatinine clearance.¹⁵⁴ More recently, with aggressive fluid resuscitation, the rate of renal dysfunction is 7%.¹⁴⁴ Although renal dysfunction may be transient, it is important to recognize its presence so that nephrotoxic antimicrobial agents (e.g., aminoglycosides) can be withheld, used with caution, or not used at all. In addition, antibiotics that are excreted by the kidney should be administered in reduced dosages.

Cunningham and coworkers¹⁵⁵ initially reported that acute pyelonephritis of pregnancy may be complicated by adult respiratory distress syndrome (ARDS). Acute respiratory insufficiency, the most common serious complication of severe sepsis, develops in 2% to 8% of pregnant women with acute pyelonephritis.^{4,155} Hill and associates¹⁴⁴ reported that 7% of pregnant women with acute pyelonephritis developed respiratory insufficiency. The pathophysiology involves cytokine inflammatory injury to vascular endothelium, which leads to increased alveolar membrane permeability. ARDS should be suspected in patients who present with dyspnea, tachypnea, hypoxemia, or a chest radiograph suggestive of pulmonary edema or ARDS.

Towers and colleagues¹⁵⁵ identified several risk factors for ARDS in patients with antepartum pyelonephritis: elevated maternal heart rate (>110 beats/min); use of a tocolytic agent; use of ampicillin as the sole antibiotic; temperature 103° F or higher within the first 24 hours; and fluid overload. More recently, in a study of 440 cases of acute antepartum pyelonephritis, Hill and coworkers¹⁴⁴ reported that women with respiratory insufficiency received more intravenous fluids during the first 48 hours and had higher maximum temperatures, higher heart rates, lower hematocrits, and higher rates of septicemia. Moreover, tachypnea was present only in patients with respiratory insufficiency. Fortunately, most cases with pulmonary capillary injury respond to oxygen supplementation and diuresis. However, intubation and mechanical ventilation are required in severe cases. The cytokine inflammatory response may also lead to uterine contractions.¹²⁴

Treatment

The management of acute uncomplicated pyelonephritis in pregnant women has changed dramatically since the 1990s. Traditionally, patients with acute uncomplicated pyelonephritis were hospitalized and treated with parenteral antimicrobial therapy, but more recent studies have demonstrated that, for women with mild to moderate disease, oral therapy on an outpatient basis is appropriate. In addition, the duration of therapy has been reduced from 6 weeks to 2 weeks.¹⁵⁶⁻¹⁵⁸

Hooton¹⁵⁶ outlined factors that should be considered when selecting agents for empiric treatment of uncomplicated acute pyelonephritis:

1. Antimicrobial spectrum of the agent
2. Pharmacokinetics allowing for infrequent dosing intervals
3. Prevalence of resistance among uropathogens in the geographic area

4. Duration of adequate urinary and renal tissue levels
5. Effect of antimicrobial agent on the fecal and vaginal flora
6. Adverse side effects
7. Cost
8. Public health concerns regarding development of resistance

Limited information has been published to assist in determining optimal antimicrobial regimens and duration of therapy for treatment of acute uncomplicated pyelonephritis in pregnant women. Moreover, the management of acute pyelonephritis has become more complex with the trend for increasing resistance of uropathogens, especially resistance to β -lactam antibiotics (e.g., ampicillin) and trimethoprim-sulfamethoxazole.^{136,156}

For purposes of treatment, patients with acute uncomplicated pyelonephritis may be stratified into two groups: those with severe disease, who require hospitalization and parenteral antibiotics, and those with mild to moderate disease, who can be treated on an outpatient basis with oral agents. As described in the IDSA guidelines, mild disease is characterized by low-grade fever, normal or slightly elevated white blood cell count, and absence of nausea and vomiting.¹³⁶ Patients requiring hospitalization are those with high fevers, high white blood cell counts, vomiting, dehydration, evidence of sepsis, or no response during an initial period of observation.

The management of acute pyelonephritis in pregnant women follows many of the same principles used for nonpregnant women, with several important differences. In general, fluoroquinolones should be avoided in pregnancy, unless no alternative antimicrobial agent is available. Second, although earlier studies suggested that outpatient oral therapy is an acceptable alternative for mild to moderate pyelonephritis,^{151,159,160} most experts currently recommend that pregnant women with acute pyelonephritis be initially assessed during a 12- to 24-hour hospital stay before a decision is made about outpatient management. Finally, because of the potential for renal dysfunction and respiratory insufficiency in pregnant women with acute pyelonephritis, careful monitoring of renal function, urinary output, and respiratory status, including pulse oximetry, is necessary.

Management of acute pyelonephritis in pregnancy is outlined in Table 38-10. Because of the frequency of dehydration, respiratory

TABLE 38-10 MANAGEMENT OF ACUTE PYELONEPHRITIS IN PREGNANT WOMEN

In-hospital observation with assessment for 12-24 hr
Urinalysis and urine culture
Complete blood count, serum creatinine, electrolytes
Frequent monitoring of vital signs (especially for onset of tachypnea)
Monitoring of urine output (consider Foley catheter)
Intravenous crystalloid fluid resuscitation to maintain urine output at ≥ 30 -50 mL/hr
Chest radiograph and arterial blood gas analysis in patients with dyspnea or tachypnea
Intravenous antimicrobial therapy
Patients who respond to initial parenteral antimicrobial and fluid resuscitation may be discharged after 12-24 hr of observation with oral antimicrobial agent to complete 14 days of therapy
Patients with high fever, signs of respiratory insufficiency, poor urine output, evidence of sepsis, or inability to tolerate oral medication require hospitalization

insufficiency, and renal dysfunction associated with acute pyelonephritis in pregnancy, aggressive fluid resuscitation with crystalloid solutions such as lactated Ringer solution or normal saline is critical. Fluid resuscitation must be balanced with the risk of pulmonary edema, so close monitoring of respiratory status with pulse oximetry is imperative. Blood cultures should be obtained from patients who have evidence of sepsis or septic shock or who fail to respond to initial therapy.

Vital signs, including respiratory rate, and urine output should be closely monitored. Tachypnea, hypotension, and oliguria are signs of impending sepsis or septic shock. In gestations beyond 24 weeks, uterine activity and fetal heart rate should be monitored closely. If uterine contractions persist despite rehydration, tocolytic therapy should be considered, with due consideration to the synergistic cardiovascular effects of tocolytics and sepsis. Use of a cooling blanket or acetaminophen or both reduces cardiovascular stress. This is important in early pregnancy, secondary to possible teratogenic effects of hyperthermia.¹⁰⁴ Similarly, if preterm labor is a concern, untreated hyperthermia increases the metabolic needs of the fetus.

A number of antimicrobial regimens may be used to treat acute pyelonephritis in pregnancy (Table 38-11). Given the high incidence of resistance by *E. coli* to ampicillin and first-generation cephalosporins (cephalexin, cefazolin), these agents are not recommended.⁴ Ceftriaxone, 1 to 2 g IV as a single daily dose, is effective and, given its extended spectrum, provides excellent coverage against the major uropathogens (except *Enterococcus*). After discharge, ceftriaxone can be continued as a single daily dose of 1 to 2 g as home parenteral therapy. Alternatively, an oral cephalosporin or trimethoprim-sulfamethoxazole can be given, depending on the results of susceptibility studies. Some authors favor an initial combination of ampicillin plus gentamicin.¹⁰⁴ Patients should respond within 48 hours. For patients who do not

respond, investigation for urinary obstruction or complications of renal infection (e.g., perinephric abscess) should be undertaken. Once hospitalized patients are afebrile and asymptomatic for 24 to 48 hours, they may be discharged to complete a 14-day course of therapy.

Administration of aminoglycosides requires particular caution. Although they are rare with the dosage and duration of aminoglycosides used in the treatment of acute uncomplicated pyelonephritis, both maternal and fetal nephrotoxicity and ototoxicity have been reported, especially with prolonged use. The more frequent occurrence of renal dysfunction in pregnant women with acute pyelonephritis should raise additional concerns regarding the use of aminoglycosides.⁴ Therefore, unless the causative microorganism is resistant to other antimicrobials or the patient is allergic to other agents, aminoglycoside use is best avoided. A possible exception is the pregnant woman with severe septic shock, for whom an aminoglycoside should be used to provide coverage against more resistant gram-negative enterobacteria such as *Pseudomonas aeruginosa*, *Enterobacter* species., or *Citrobacter* species. In pregnant women receiving an aminoglycoside, serum levels should be monitored to ensure adequate serum concentrations and prevent toxicity. Either multidose gentamicin (3-5 mg/kg/24 hours in 3 divided doses) or single-dose gentamicin daily regimen is appropriate.

Prevention

Both secondary and tertiary prevention strategies are critical to prevent acute pyelonephritis during pregnancy. As previously noted, the major factors associated with development of acute pyelonephritis in pregnancy are the presence of ASB which antedates the pregnancy and the physiologic changes of pregnancy that predispose to ascent of bacteria to the upper urinary tract.

There are no known methods of primary prevention for acute pyelonephritis. However, screening for, and eradication of, bacteriuria early in pregnancy substantially reduces the incidence of acute pyelonephritis. Daily nighttime suppressive therapy after treatment of acute pyelonephritis significantly reduces the risk for recurrent acute pyelonephritis during pregnancy or immediately after delivery.

After completion of therapy for acute pyelonephritis during pregnancy, 30% to 40% of women have recurrent bacteriuria. If this is left untreated, approximately 25% develop recurrent pyelonephritis. Harris and Gilstrap¹³⁹ reported that, among patients not receiving suppressive antimicrobial regimens for the duration of pregnancy, 60% had a recurrent episode of acute pyelonephritis. In the group maintained on suppressive therapy, the recurrence rate was only 2.7%. Other studies have reported a similar high rate of recurrence in pregnant women after an episode of acute pyelonephritis if they did not receive suppressive therapy.¹⁶¹

The recommended drug for suppression after treatment of acute pyelonephritis in pregnancy is nitrofurantoin, 100 mg at bedtime for the duration of the pregnancy. Alternatively, trimethoprim-sulfamethoxazole 160/800 mg daily at bedtime may be given, recognizing that the sulfa moiety in the sulfamethoxazole confers a small risk of kernicterus in the newborn if given in the third trimester. An acceptable alternative to daily suppressive therapy is to obtain urine cultures every 2 weeks for the duration of pregnancy in order to detect and promptly treat recurrent bacteriuria.¹⁶² Although recurrent or persistent bacteriuria was found to be more common with this latter approach, the rates of acute pyelonephritis were similar in the urine culture group and the suppressive therapy group. Daily suppressive therapy is more cost-effective than frequent reculturing.

TABLE 38-11 ANTIMICROBIAL TREATMENT OF ACUTE PYELONEPHRITIS IN PREGNANT WOMEN

Agent	Dosage
Outpatient Regimens (14 days)	
Amoxicillin	500 mg tid
Amoxicillin-clavulanate	875/125 mg bid
Trimethoprim-sulfamethoxazole DS	160/800 mg bid
Parenteral Regimens	
Ceftriaxone	1-2 g q24h
Cefepime	2 g q8h
Cefotetan	2 g q12h
Cefotaxime	1-2 g q8h
Trimethoprim-sulfamethoxazole	2 mg/kg q6h
Ampicillin	2 g q6h
PLUS Gentamicin	3-5 mg/kg/day (qd or in 3 divided doses)
Cefazolin	1-2 g q8h
PLUS Gentamicin	3-5 mg/kg/day in 3 divided doses or 7 mg/kg of ideal body weight q24h
OR Aztreonam	1-2 g q8 to 12h (in lieu of gentamicin)
Ampicillin-sulbactam	1.5 g q6h
Piperacillin-tazobactam	3.75 g q6-8h

DS, double strength.

Chorioamnionitis

Bacterial infection of the amniotic cavity is a major cause of perinatal mortality and maternal morbidity. Indeed, in the last few years, significant associations between clinical intra-amniotic infection and long-term neurologic development in the newborn, including cerebral palsy, have been reported (see Chapter 58).

A number of terms for this infection have been used, including “clinical chorioamnionitis,” “amnionitis,” “intrapartum infection,” “amniotic fluid infection,” and “intra-amniotic infection.” The term *clinical chorioamnionitis* is invoked to distinguish the clinical syndrome of fever and uterine tenderness from ASB colonization, subclinical infection of the amniotic cavity, or histologic inflammation of the placenta and fetal membranes in the absence of maternal symptoms.

Clinical chorioamnionitis occurs in 0.5% to 10% of pregnancies.¹⁶³ Histologic chorioamnionitis occurs more frequently than does clinically evident infection, being present in up to 20% of term deliveries and more than half of preterm deliveries.

Pathogenesis

With the onset of labor or with rupture of the membranes, bacteria from the lower genital tract are able to ascend into the amniotic cavity. This is the most common pathway for development of clinical chorioamnionitis. Occasional cases occurring in the absence of membrane rupture or labor support a less frequent hematogenous or transplacental route of infection. For example, fulminating clinical chorioamnionitis with intact membranes may be caused by *Listeria monocytogenes*. Less commonly, the infection may develop as a consequence of obstetric procedures, such as cervical cerclage, amniocentesis, or percutaneous umbilical blood sampling. The absolute risk of chorioamnionitis is low with all of these procedures, occurring in 2% to 8% of patients after cerclage, in fewer than 1% after amniocentesis, and in up to 5% after intrauterine transfusion. Bacteria also may reach the amniotic cavity from extragenital sources such as the urinary tract or periodontal tissue.

Epidemiology

Clinical chorioamnionitis is a leading risk factor for neonatal sepsis. Yancey and coworkers¹⁶⁴ found this infection to have by far the highest odds ratio (OR, 25) for suspected or proven neonatal sepsis, compared with other obstetric risk factors such as preterm delivery, rupture of membranes more than 12 hours, postpartum endometritis, or maternal carriage of GBS.

Risk factors for clinical chorioamnionitis are largely obstetric conditions in patients experiencing protracted labor. They include

- Low parity
- Prolonged labor
- Prolonged rupture of membranes
- Multiple vaginal examinations in labor
- Internal fetal monitoring
- Maternal BV¹⁶⁵⁻¹⁶⁹
- Microbiology

As with other pelvic infections, clinical chorioamnionitis is usually polymicrobial in origin. The most common organisms found in the amniotic fluid of women with chorioamnionitis are *Bacteroides* species

(25%), *G. vaginalis* (24%), GBS (12%), other aerobic streptococci (13%), *E. coli* (10%), and other aerobic gram-negative rods (10%).¹⁷⁰

A role for genital mycoplasmas has been suggested by case reports of their isolation from amniotic fluid of clinically infected patients and by a controlled study reporting that 35% of fluid specimens from patients with chorioamnionitis yielded *M. hominis*, whereas only 8% of matched control fluids had this organism ($P < .001$).¹⁷¹

Present evidence suggests a small role, if any, for *C. trachomatis* in amniotic fluid infections. This organism rarely is isolated in cases of clinical chorioamnionitis, and no significant antibody changes to *C. trachomatis* have been noted in sera of women with this infection. Pregnant women with cervical *C. trachomatis* infections do not have higher rates of intrapartum fever.^{72,172}

Diagnosis

The clinical diagnosis of chorioamnionitis requires a high index of suspicion. Usual laboratory indicators of infection, such as positive stains for organisms or leukocytes and positive cultures, are found much more frequently than is clinically evident infection. Diagnosis typically is based on the signs of maternal fever, maternal or fetal tachycardia, uterine tenderness, foul odor of the amniotic fluid, and leukocytosis. Bacteremia occurs in approximately 10% of the cases. Because peripheral blood leukocytosis occurs commonly in normal labor, a high white blood cell count ($>15,000/\text{mL}$) supports, but is not diagnostic of, infection.

Direct examination of the amniotic fluid, via amniocentesis or aspiration through an intrauterine pressure catheter, may provide important diagnostic information. Positive amniotic fluid Gram stains for bacteria or leukocytes occur significantly more often in women with clinical chorioamnionitis than in matched controls.¹⁷⁰ In patients with suspected amnionitis, low amniotic fluid glucose levels are a good predictor of a positive amniotic fluid culture but a poorer predictor of clinical chorioamnionitis. If the amniotic fluid glucose concentration is greater than 20 mg/dL, the likelihood of a positive culture is less than 2%. If the glucose level is less than 5 mg/dL, the likelihood of a positive culture rises to approximately 90%.^{173,174} Although the test is not readily available to the clinician, an elevated concentration of interleukin 6 (IL-6) in the amniotic fluid is the most sensitive and specific marker for predicting a positive amniotic fluid culture.¹⁷⁴

Management

If acute chorioamnionitis is strongly suspected, most experts agree that prompt institution of intravenous antibiotics and delivery of the fetus are required. However, specific points of management details remain unresolved.

Regarding the timing of delivery, excellent maternal-neonatal outcome has been reported without the use of arbitrary time limits. Gibbs and colleagues¹⁷⁰ reported on a policy in which cesarean delivery was performed only for standard obstetric indications and not for the presence of clinical chorioamnionitis alone. The mean time from diagnosis to delivery was between 3 and 5 hours, and more than 90% of patients were delivered within 12 hours after diagnosis. Those who were delivered vaginally had lower rates of morbidity. No critical interval from diagnosis of chorioamnionitis to delivery could be identified.

Three studies demonstrated a significant advantage for intrapartum rather than immediate postpartum antibiotic treatment (Table 38-12). In a nonrandomized trial, Sperling and coworkers¹⁷⁵ reported a lower incidence of neonatal sepsis when antibiotic treatment was

TABLE 38-12 RATES OF NEONATAL SEPSIS AFTER INTRAPARTUM VERSUS NEONATAL ANTIBIOTIC TREATMENT IN CASES OF INTRA-AMNIOTIC INFECTION

Study	N	Rate of Neonatal Sepsis (%)		
		Intrapartum Treatment	Neonatal Treatment	P
Sperling et al, 1987	257	2.8	19.6	.001
Gibbs et al, 1988	45	0	21	.03
Gilstrap et al, 1988	273	1.5	5.7	.06

begun at the time of diagnosis, compared with treatment begun immediately after delivery. Gilstrap and colleagues¹⁷⁶ found an almost four-fold reduction in neonatal sepsis with use of intrapartum treatment (5.7% versus 1.5%, $P = .06$). In a randomized trial, Gibbs and colleagues¹⁷⁷ used ampicillin (2 g intravenously every 6 hours) plus gentamicin (1.5 mg/kg every 8 hours), initiating treatment either intrapartum or immediately postpartum. In addition, clindamycin was used after umbilical cord clamping if cesarean delivery was performed, because of the high failure rate of ampicillin and gentamicin alone in women delivered abdominally. Maternal outcome was improved, and confirmed neonatal sepsis was decreased by intrapartum treatment. Other regimens employing an extended-spectrum penicillin (e.g., ampicillin plus a β -lactamase inhibitor) or other agents with similar activity may be equally effective, but no comparative trials have been performed.

The duration of postpartum antibiotic therapy needed for patients with clinical chorioamnionitis was addressed in a randomized clinical trial by Edwards and Duff.¹⁷⁸ They showed that one additional dose of a broad-spectrum combination of antibiotics (ampicillin plus gentamicin) was sufficient postpartum therapy for women with clinical chorioamnionitis. As mentioned previously, it is imperative that a drug with excellent anaerobic coverage (e.g., clindamycin, metronidazole) be given intraoperatively to women undergoing cesarean delivery.

Short-Term Outcome

Since 1979, reports from systematically collected data on the outcome of mothers and neonates in pregnancies complicated by intra-amniotic infection have shown a vastly improved perinatal outcome compared with older studies. Maternal outcome is excellent, with no deaths, few cases of septic shock, and rare pelvic abscesses. The cesarean delivery rate is increased twofold to threefold in all studies, usually because of dystocia. Perinatal mortality is increased in cases of clinical chorioamnionitis, but little of the excess mortality can be attributed to infection per se. Among term infants born after clinical chorioamnionitis, perinatal mortality is less than 1%.

Yoder and colleagues¹⁷⁹ published a case-control study of 67 patients with microbiologically confirmed clinical chorioamnionitis at term. There was only one perinatal death, which was unrelated to infection. Cerebrospinal fluid cultures were negative in all 49 infants sampled, and there was no clinical evidence of meningitis. Chest radiographs were interpreted as “possible” pneumonia in 20% and as “unequivocal” pneumonia in only 4%. Neonatal bacteremia was documented in 8%. There was no significant difference in the frequency of low Apgar scores between the chorioamnionitis and control groups.

TABLE 38-13 META-ANALYSIS OF CHORIOAMNIONITIS AS A RISK FACTOR FOR CEREBRAL PALSY AND CYSTIC PERIVENTRICULAR LEUKOMALACIA

Diagnosis	N	RR (95% CI)
Preterm Infants		
<i>Cerebral Palsy</i>		
Clinical chorioamnionitis	11	1.9 (1.4-2.5)
Histologic chorioamnionitis	5	1.6 (0.9-2.7)
<i>Cystic PVL</i>		
Clinical chorioamnionitis	6	3.0 (2.2-4.0)
Histologic chorioamnionitis	7	2.1 (1.5-2.9)
Term Infants		
<i>Cerebral Palsy</i>		
Clinical chorioamnionitis	2	4.7 (1.3-16.2)
Histologic chorioamnionitis	1	8.9 (1.9-40)

CI, confidence interval; PVL, periventricular leukomalacia; RR, relative risk.

Data from Grether JK, Nelson KB: Maternal infection and cerebral palsy in infants of normal birth weight. *JAMA* 278:207, 1997; Wu YW, Colford JM Jr: Chorioamnionitis as a risk factor for cerebral palsy: A meta-analysis. *JAMA* 284:1417, 2000.

Preterm neonates born to mothers with clinical chorioamnionitis experience a higher frequency of complications than do those born to mothers without this disorder. Garite and Freeman¹⁸⁰ noted that the perinatal death rate was significantly higher in 47 preterm neonates with chorioamnionitis than in 204 uninfected neonates with similar birth weights (13% versus 3%, $P < .05$). The group with chorioamnionitis also included a significantly higher number with respiratory distress syndrome (34% versus 16%, $P < .01$) and infection (17% versus 7%, $P < .05$).

Patients with clinical chorioamnionitis are more likely to require cesarean delivery, often for uterine dysfunction, inadequate uterine response to oxytocin, or abnormal labor progress even when uterine activity is adequate. And, when the combination of prematurity and chorioamnionitis occurs, the risk of serious sequelae in the neonate is increased.

Long-Term Outcome

There is increasing evidence that intrauterine infection is associated with increased risks of respiratory distress syndrome, periventricular leukomalacia, and cerebral palsy. The unifying hypothesis for these varying morbidities is that intra-amniotic infection leads to fetal infection and to an overexuberant fetal production of cytokines, which leads in turn to pulmonary and brain cell damage. The “fetal inflammatory response syndrome” has been likened to the systemic inflammatory response syndrome in adults. Several studies have linked maternal infection with cerebral palsy and with cystic necrosis of the white matter in preterm and term infants. Intrauterine exposure to maternal infection is associated with an increased risk of cerebral palsy (OR, 9.3) in infants of normal birth weight.¹⁸¹ The results of a recent meta-analysis are summarized in Table 38-13.

Amniotic fluid concentrations of the inflammatory cytokines, IL-1 β , IL-6, and tumor necrosis factor are higher in preterm infants with periventricular leukomalacia than in those without such lesions.¹⁸² In addition, the presence of cerebral palsy at 3 years of age is more

common in infants delivered preterm with funisitis or elevated amniotic fluid concentrations of IL-6 or IL-8.¹⁸³ Among preterm infants, respiratory distress syndrome has been significantly associated with high levels of tumor necrosis factor in amniotic fluid, with positive cultures of amniotic fluid, and with severe histologic chorioamnionitis, even after adjustment for birth weight, infant gender, race, and mode of delivery. These observations collectively have aroused renewed interest in the importance of the long-term effects of intrauterine infection, as well as strategies to avoid their serious complications.¹⁸⁴ These issues also are addressed in Chapter 58.

Prevention

Numerous approaches have been tested as preventive techniques. Chlorhexidine vaginal washes during labor^{185,186} and selected infection-control measures¹⁶⁸ have been ineffective. Antepartum treatment of BV has not been shown to decrease the rate of chorioamnionitis.¹⁸⁷ Use of broad-spectrum antibiotics in patients with preterm labor but intact membranes appears to be ineffective overall in decreasing chorioamnionitis.¹⁸⁸

Intrapartum prophylaxis to prevent neonatal GBS sepsis decreases the frequency of chorioamnionitis. Use of a screening-based strategy (which results in more women receiving antibiotics) compared with a risk-based strategy produces lower rates of chorioamnionitis.¹⁸⁹ In addition, active management of labor,¹⁹⁰ induction of labor (compared with expectant management) after PROM at term,¹⁹¹ and use of antibiotics in selected patients with PROM¹⁹²⁻¹⁹⁵ have each been shown to decrease the rate of chorioamnionitis.

Episiotomy Infection

Although episiotomy and vaginal laceration repair are commonly performed after a vaginal delivery, infection is an infrequent complication. Shy and Eschenbach¹⁹⁶ classified episiotomy infections according to the extent of the structures involved (Fig. 38-5). The same classification may be used for infections of perineal lacerations.

Simple Episiotomy Infection

A localized infection may involve only the skin and subcutaneous tissue (including the Camper fascia of the perineum) adjacent to the episiotomy. Signs are local edema and erythema with exudate; more extensive findings should raise the suspicion of a deeper infection. Treatment consists of opening, exploring, and débriding the perineal wound. Drainage alone usually is adequate, but appropriate antibiotics should be given if there is marked superficial cellulitis or isolation of group A streptococci. The episiotomy incision should not be immediately resutured. Most episiotomy wounds heal by granulation. Wounds involving the external anal sphincter or rectal mucosa may be repaired after the field is free of infection.

Recently, there has been considerable interest in early repair of episiotomy dehiscence. Such dehiscence usually is associated with infection. Early repair requires prompt and meticulous débridement at the time of diagnosis, followed by antibiotics and frequent cleansing. When the tissue appears healthy (usually after about 1 week or longer),

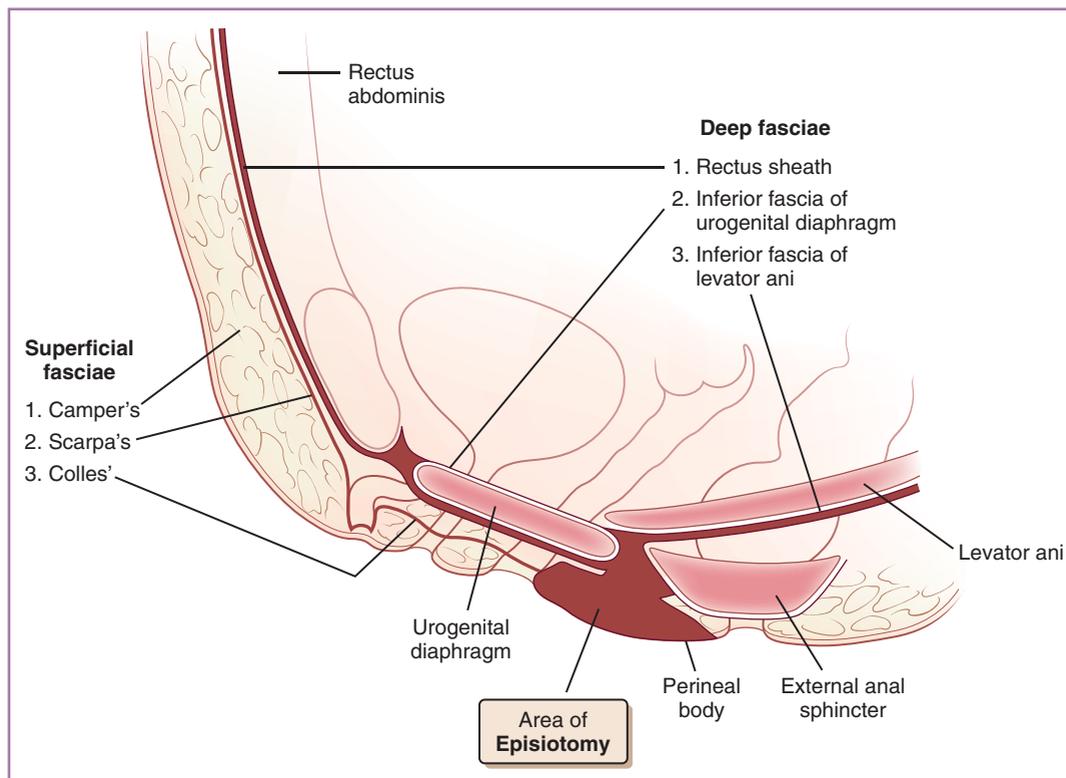

FIGURE 38-5 Structures potentially involved in episiotomy. Paramedian sagittal section of the fascial layers of the perineum. (From Shy KK, Eschenbach DA: Fatal perineal cellulitis from an episiotomy site. *Obstet Gynecol* 54:292, 1979. Reprinted with permission of the American College of Obstetricians and Gynecologists.)

a definitive repair can be undertaken. For fourth-degree lacerations, a bowel preparation should be given before the repair. Such repair is an attractive option compared with the delay of 2 to 3 months recommended in older literature.¹⁹⁷⁻²⁰⁰

Necrotizing Fasciitis

With necrotizing fasciitis, both layers of the superficial perineal fascia (i.e., the Camper and Colles fascias) become necrotic, and infection spreads along the fascial planes to the abdominal wall, thigh, and/or buttock. Typically, the deep perineal fascia (i.e., inferior fascia of the urogenital diaphragm) is not involved. Skin findings are variable but initially include edema and erythema without clear borders. Later, there is progressive, brawny edema of the skin. The skin becomes blue or brown, and bullae or frank gangrene may occur. As the infection progresses, there may be either loss of sensation or hyperesthesia.

Associated findings include marked hemoconcentration, although often after fluid replacement the patient is anemic. Hypocalcemia also may develop, because of the saponification of fatty acids. Traditionally, this infection has been associated with group A streptococci, but anaerobic bacteria also play an important role.

For therapy to be effective, appropriate antibiotics must be combined with adequate débridement. Indications for surgical exploration include extension beyond the labia, unilateral or markedly asymmetric edema, signs of systemic toxicity or deterioration, and failure of the infection to resolve within 24 to 48 hours. At surgery, necrotizing fasciitis may be recognized by separation of the skin from the deep fascia, absence of bleeding along incision lines, and a serosanguineous discharge. Dissection must be wide enough to remove all necrotic tissue.

Myonecrosis

Myonecrosis is an infection that involves the muscle beneath the deep fascia. It often is the result of a myotoxin elaborated by *C. perfringens*, but it occasionally can result from an extension of necrotizing fasciitis. Onset may be early and typically is accompanied by severe pain. Treatment of this condition also consists of extensive débridement and high-dose antibiotics, including penicillin, if clostridia infection is suspected.

Clinicians should recognize that not all puerperal vulvar edema signifies serious perineal infection. In fact, most cases of vulvar edema result from less serious causes, such as hematoma, prolonged bearing-down in labor, generalized edema from preeclampsia, allergic reactions, or trauma. In these instances, however, the edema usually is bilateral, does not extend to the buttock or abdominal wall, and is not accompanied by signs of systemic toxicity.

Puerperal Endometritis

Epidemiology

The frequency of endometritis in women after planned cesarean delivery ranges from 5% to 15%, depending on maternal socioeconomic status. If cesarean delivery is performed after an extended period of labor and ruptured membranes, the incidence of endometritis is approximately 30% to 35% without antibiotic prophylaxis and approximately 15% with prophylaxis. In highly indigent patient populations, the frequency of postcesarean endometritis may be even higher.²⁰¹

Pathogenesis

Endometritis is a polymicrobial infection caused by microorganisms that are part of the normal vaginal flora. These aerobic and anaerobic bacteria gain access to the upper genital tract, peritoneal cavity, and bloodstream as a result of vaginal examinations during labor and manipulations during surgery. The most common pathogens are GBS, anaerobic gram-positive cocci (streptococci and peptostreptococci species), anaerobic gram-negative bacilli (predominantly *E. coli*, *K. pneumoniae*, and *Proteus* species), and anaerobic gram-negative bacilli (principally *Bacteroides* and *Prevotella* species). *C. trachomatis* is not a common cause of early-onset puerperal endometritis but has been implicated in late-onset infection. The genital mycoplasmas, *M. hominis* and *Ureaplasma urealyticum*, may be pathogenic in some patients, but they usually are present in association with other, more highly virulent bacteria.^{201,202}

The principal risk factors for endometritis are cesarean delivery, young age, low socioeconomic status, extended duration of labor, extended duration of ruptured membranes, and multiple vaginal examinations. Preexisting infection of the lower genital tract due to gonorrhea, GBS, or BV also predisposes to ascending infection after delivery.²⁰³

Diagnosis

Patients with endometritis typically have a fever of 38° C or higher within 36 hours after delivery. Associated findings include malaise, tachycardia, lower abdominal pain and tenderness, uterine tenderness, and malodorous lochia. A small number of patients have a tender, indurated, inflammatory mass in the broad ligament, posterior cul-de-sac, or retrovesical space.

The initial differential diagnosis of puerperal fever should include endometritis, atelectasis, pneumonia, viral syndrome, pyelonephritis, and appendicitis. Distinction among these disorders usually can be made on the basis of physical examination and selected laboratory tests such as a peripheral white blood cell count, urinalysis and culture, and, in some patients, chest radiography. Blood cultures are indicated for patients who have a poor initial response to therapy or for those who are immunocompromised or are at increased risk for bacterial endocarditis. Cultures of the lower genital tract and endometrium are rarely indicated. Such cultures are difficult to obtain without contamination from lower genital tract flora. In addition, by the time these culture results are available, most patients already have responded to treatment and have been discharged from the hospital.

Treatment

The most commonly used regimen for treatment of puerperal endometritis is the combination of clindamycin (900 mg IV every 8 hours) plus gentamicin (7.5 mg/kg of ideal body weight every 24 hours). An alternative regimen is metronidazole (500 mg IV every 12 hours) plus penicillin (5 million units IV every 6 hours) or ampicillin (2 g IV every 6 hours) plus gentamicin (7 mg/kg of ideal body weight every 24 hours). Both of these combination regimens provide excellent coverage against all of the potential pelvic pathogens. Broad-spectrum single agents such as cefotetan (2 g IV every 12 hours), ticarcillin plus clavulanic acid (3.1 g IV every 6 hours), ampicillin plus sulbactam (3 g IV every 6 hours), piperacillin plus tazobactam (3.375 g IV every 6 hours), imipenem-cilastatin (500 mg IV every 6 hours), or ertapenem (1 g IV every 24 hours) may be used for treatment of endometritis. However, in most hospital formularies, these broad-spectrum single agents

are more expensive than the generic combination regimens listed earlier.²⁰⁴

Once intravenous antibiotics are begun, approximately 90% to 95% of patients experience defervescence within 48 to 72 hours. Once the patient has been afebrile and asymptomatic for approximately 24 hours, parenteral antibiotics should be discontinued, and the patient should be discharged. As a general rule, an extended course of oral antibiotics is not necessary after discharge.²⁰⁵ There are at least two exceptions to this general rule. First, patients who have had a vaginal delivery and who defervescence within 24 hours are candidates for early discharge. In these individuals, a short course of an oral antibiotic such as amoxicillin-clavulanate (875 mg orally every 12 hours) may be substituted for continued parenteral therapy. Second, patients who have had a staphylococcal bacteremia may require a more extended period of administration of parenteral and oral antibiotics.²⁰⁴

Patients who fail to respond to the antibiotic therapy outlined here usually have one of two problems. The first is a resistant organism. In patients who are treated with clindamycin plus gentamicin, the principal resistant organism is enterococcus. This organism can be adequately covered by adding ampicillin or penicillin to the treatment regimen. For those who are taking a broad-spectrum single agent, potential weaknesses in coverage include some aerobic and some anaerobic gram-negative bacilli. These patients should be changed to the triple-drug regimen (clindamycin or metronidazole, plus penicillin or ampicillin, plus gentamicin).

The second major cause of treatment failure is an abdominal wound infection. Some patients have an actual incisional abscess. In these cases, the wound should be opened to effect drainage, and an antibiotic that has excellent antistaphylococcal coverage should be added to the treatment regimen. Most experts prefer an agent such as nafcillin (2 g IV every 6 hours). Some women do not have frank pus in the incision but rather an extensive cellulitis in the soft tissue around the incision. In these patients, the wound does not have to be opened. However, an antistaphylococcal antibiotic should be added to the treatment regimen.²⁰⁴

Other possible causes of a poor response to treatment include pelvic abscess, septic pelvic vein thrombophlebitis, and drug reaction. The management of pelvic abscess and septic pelvic vein thrombophlebitis is discussed in the following sections. Drug reaction should be suspected if the patient has a peripheral blood eosinophilia and if the temperature elevation corresponds with the time of drug administration. In these individuals, discontinuation of the antibiotic usually results in prompt resolution of fever.

Prevention

Ideally, the best approach to endometritis is prevention of infection. In this regard, prophylactic antibiotics clearly are of proven value in reducing the frequency of postcesarean endometritis, particularly in women having surgery after an extended period of labor and ruptured membranes. The most appropriate agent for prophylaxis is a limited-spectrum (first-generation) cephalosporin such as cefazolin. Cefazolin should be administered in an intravenous dose of 1 g immediately after the neonate's umbilical cord is clamped. Although extended-spectrum penicillins and cephalosporins are effective for prophylaxis, they offer no advantage over cefazolin and are several times more expensive. In addition, widespread use of these drugs for prophylaxis ultimately may limit their usefulness for treatment of an established infection. Patients who have an immediate hypersensitivity reaction to β -lactam antibiotics should receive a single dose of clindamycin (900 mg IV) plus gentamicin (1.5 mg/kg IV) immediately after the umbilical cord is clamped.

Although these antibiotics are used for treatment of overt infections, their administration still is warranted in penicillin-allergic patients who are at high risk for postoperative infection.^{204,205}

Another important method for preventing endometritis is to remove the placenta by gentle traction on the umbilical cord rather than manually. Several investigators^{206,207} have confirmed that, when other factors are controlled, manual removal of the placenta significantly increases the frequency of postcesarean endometritis.

Wound Infection

Epidemiology and Pathogenesis

Wound infection after cesarean delivery usually occurs in association with endometritis rather than as an isolated condition. Approximately 3% to 5% of women with postcesarean endometritis have a concurrent wound infection. The principal risk factors for this complication are low socioeconomic status, extended duration of labor, extended duration of ruptured membranes, preexisting infection such as chorioamnionitis, obesity, insulin-dependent diabetes, an immunodeficiency disorder, corticosteroid or immunosuppressive therapy, and poor surgical technique. The major organisms that cause postcesarean wound infection are *S. aureus*, aerobic streptococci, and aerobic and anaerobic gram-negative bacilli.²⁰⁸

Diagnosis

The diagnosis of wound infection should be of paramount consideration in a woman who has had a poor initial clinical response to antibiotic therapy for endometritis. Clinical examination usually shows erythema, induration, and tenderness at the margins of the abdominal incision and pus exudes from within the incision. Some patients have an extensive cellulitis without actual purulent drainage.

Clinical examination usually is sufficient to establish the correct diagnosis. Culture of the wound exudate should be performed routinely because of the possibility of a methicillin-resistant *Staphylococcus aureus* (MRSA) infection.²⁰⁹

Treatment

If frank pus or significant serosanguineous effusion is present in the incision, the wound must be opened and drained completely. Antibiotic therapy should be modified to provide coverage against staphylococci. Nafcillin, 2 g IV every 6 hours, is an appropriate drug for this purpose. In patients who are allergic to β -lactam antibiotics, vancomycin, 1 g IV every 12 hours, is an acceptable alternative.²⁰⁴

Once the wound is opened, it should be repacked two to three times daily with gauze dampened with saline. A clean dressing should be applied, and the wound should initially be allowed to heal by secondary intention. After all signs of infection have resolved and healthy granulation tissue is apparent, a secondary closure may be considered. Antibiotics should be continued until the base of the wound is clean and all signs of cellulitis have resolved. Patients usually can be treated on an outpatient basis once the acute signs of infection have subsided.

Necrotizing fasciitis is an uncommon but extremely serious complication of abdominal wound infection. It has also been reported in association with infection of the episiotomy site (see earlier discussion). This condition is particularly likely to occur in patients who have insulin-dependent diabetes, cancer, or an immunodeficiency disorder.

Multiple bacterial pathogens, particularly anaerobes, have been isolated from patients with necrotizing fasciitis.

This condition should be suspected if the margins of the wound become discolored, cyanotic, and devoid of sensation. When the wound is opened, the subcutaneous tissue is easily dissected free of the underlying fascia, but muscle tissue is not affected. If the diagnosis is uncertain, a tissue biopsy specimen should be performed and examined immediately by frozen section.

Necrotizing fasciitis is a life-threatening condition that requires aggressive medical and surgical management. Broad-spectrum antibiotics with activity against all potential pathogens should be administered. The patient's intravascular volume should be maintained with infusions of crystalloid, and electrolyte abnormalities should be promptly corrected. Of greatest importance, the wound must be completely débrided and all necrotic tissue removed. In many instances, the required dissection is extensive and is best managed in consultation with an experienced general or plastic surgeon.

Pelvic Abscess

Epidemiology and Pathogenesis

With the advent of modern antibiotics, pelvic abscesses after cesarean or vaginal delivery have become extremely rare. As with wound infections, pelvic abscesses, when they do occur, usually develop in women who initially had postcesarean endometritis. The frequency of pelvic abscess as a complication of endometritis is less than 1%.²⁰¹

Pelvic abscesses typically are located in the anterior or posterior cul-de-sac or within the leaves of the broad ligament. The bacteria usually isolated from abscess cavities are anaerobic gram-positive organisms such as *Peptococci* and *Peptostreptococci* species, anaerobic gram-negative bacilli (particularly *Bacteroides* and *Prevotella* species), and aerobic gram-negative bacilli such as *E. coli*, *Klebsiella*, and *Proteus* species.^{202,203}

Diagnosis

Patients who have a pelvic abscess typically experience persistent fever despite appropriate antibiotic therapy for endometritis. In addition, they usually have malaise, tachycardia, tachypnea, lower abdominal pain and tenderness, and a palpable pelvic mass. The peripheral white blood cell count usually is elevated ($>20,000/\text{mm}^3$), and there is a shift toward immature cell forms. The diagnosis of pelvic abscess may be confirmed by ultrasound, computed tomographic (CT) scanning, or magnetic resonance imaging (MRI).²¹⁰ The latter two tests are slightly more sensitive, but more expensive, than ultrasound.

Treatment

Patients who develop an abscess after delivery usually require surgical drainage in addition to broad-spectrum antibiotic therapy. If the abscess is located in the posterior cul-de-sac, colpotomy drainage may be feasible. For abscesses located anterior or lateral to the uterus, drainage may be accomplished by CT- or ultrasound-guided placement of a catheter drain. If access to the abscess cavity is limited by the interposition of bowel, or if the abscess is extensive, open laparotomy is indicated.²⁰⁷

Patients also must receive antibiotics that have excellent activity against multiple aerobic and anaerobic pathogens. One regimen that has been tested extensively in obstetric patients with serious infections

is the combination of penicillin (5 million units IV every 6 hours) or ampicillin (2 g IV every 6 hours), plus gentamicin (7 mg/kg of ideal body weight every 24 hours), plus clindamycin (900 mg IV every 8 hours) or metronidazole (500 mg IV every 12 hours). If the patient is allergic to β -lactam antibiotics, vancomycin (1 g IV every 12 hours) can be substituted for penicillin or ampicillin. Aztreonam (1 g IV every 8 hours) can be used in lieu of gentamicin if the patient is at risk for nephrotoxicity. Alternatively, broad-spectrum agents, such as one of the carbapenems—imipenem-cilastatin (500 mg IV every 6 hours), meropenem (1 g IV every 8 hours), or ertapenem (1 g IV every 24 hours)—provide excellent coverage against the usual pathogens responsible for an abscess. Intravenous antibiotics should be continued until the patient has been afebrile and asymptomatic for a minimum of 24 to 48 hours. Thereafter, the patient should be treated with a combination of oral antibiotics that cover the major pathogens.²⁰⁴ One appropriate regimen is ofloxacin (400 mg every 24 hours) or levofloxacin (750 mg every 24 hours) plus metronidazole (500 mg twice daily) to complete a total treatment course of 10 to 14 days.¹²

Septic Shock

Epidemiology and Pathogenesis

The term "severe sepsis" refers to infection-induced organ dysfunction or hypoperfusion abnormalities. *Septic shock* implies hypotension that is not reversed with fluid resuscitation and which is associated with multiorgan dysfunction.²⁰⁸ In obstetric patients, the most common predisposing conditions for septic shock are septic abortion, acute pyelonephritis, chorioamnionitis, and puerperal endometritis. Fewer than 2% of patients with any of these conditions develop septic shock. The most common pathogenic organisms are *E. coli*, *K. pneumoniae*, and *Proteus* species. Highly virulent, drug-resistant organisms such as *Pseudomonas*, *Enterobacter*, and *Serratia* species are uncommon except in immunosuppressed patients.²⁰⁹

Aerobic gram-negative bacilli such as *E. coli* have a complex lipopolysaccharide in their cell wall, termed endotoxin. When released into the systemic circulation, endotoxin causes a variety of immunologic, hematologic, neurohormonal, and hemodynamic derangements that ultimately result in multiple-organ dysfunction.²¹¹⁻²¹³

In the early stages of septic shock, patients usually are restless, disoriented, tachycardic, and hypotensive. Although hypothermia may be present initially, most patients subsequently have a high fever. The skin may be warm and flushed owing to a preliminary phase of vasodilation. Later, extensive vasoconstriction occurs, and the skin becomes cool and clammy. Cardiac arrhythmias may develop, and signs of myocardial ischemia may occur. Jaundice, typically due to hemolysis, may be evident. Urinary output decreases, and spontaneous bleeding from the genitourinary tract or venipuncture sites may occur as a result of a coagulopathy. ARDS is a common complication of sepsis and is usually manifested by dyspnea, stridor, cough, tachypnea, bilateral rales, and wheezing. In addition to these systemic signs and symptoms, affected patients also may have specific findings related to their primary site of infection, such as uterine tenderness in women with endometritis or chorioamnionitis or flank tenderness in patients with pyelonephritis.^{212,213}

Diagnosis

The differential diagnosis of septic shock in obstetric patients includes hypovolemic and cardiogenic shock, diabetic ketoacidosis, anaphylac-

tic reaction, anesthetic reaction, and pulmonary embolism. Distinction among these disorders usually can be made on the basis of a detailed history and physical examination and selected laboratory studies. The white blood cell count initially may be decreased in septic shock but subsequently becomes elevated. The hematocrit may be decreased if blood loss has occurred. The platelet count and serum fibrinogen concentration are typically decreased. Serum concentration of fibrin degradation products is usually elevated. The prothrombin time and activated partial thromboplastin time (aPTT) are frequently prolonged. Serum concentrations of transaminase enzymes and bilirubin often are increased. The blood urea nitrogen and serum creatinine concentrations are also increased.

Septic patients should have a chest radiograph to determine whether pneumonia or ARDS is present. In addition, a CT scan, MRI, or ultrasound study may be of value in localizing an abscess. Patients also require continuous electrocardiographic monitoring to detect arrhythmias or signs of myocardial ischemia. Blood samples for culture should be obtained, one drawn percutaneously and one drawn through each vascular device that has been in place longer than 48 hours.²¹¹

Treatment

The first priority in treatment is fluid resuscitation with isotonic crystalloids such as Ringer lactate solution or normal saline or colloids. There is no firm evidence that one type of solution is better than another, although crystalloids are used more commonly. Intravenous fluid administration should be titrated in accordance with the patient's pulse, blood pressure, and urine output. If the initial fluid infusion is not successful in restoring hemodynamic stability, a right-sided heart catheter should be inserted to monitor pulmonary artery wedge pressure. Treatment goals of fluid resuscitation include a central venous pressure of 8 to 12 mm Hg, a mean arterial pressure of 65 mm Hg or higher, urine output of 0.5 mL/kg or greater, and a mixed venous oxygen saturation of 70% or greater.²¹¹

The "7-3 rule" is helpful in guiding fluid resuscitation. Ringer lactate or normal saline should be infused at a rate of 10 mL/min for 15 minutes. If the pulmonary capillary wedge pressure (PCWP) does not increase by more than 3 mm Hg, the bolus should be repeated. If the PCWP increases by 7 mm Hg or more, the fluid bolus should be withheld. The optimal PCWP in septic patients is 12 to 16 mm Hg.²¹³ Transfusion of red blood cells is indicated to maintain a hemoglobin concentration of 7.0 to 9.0 g/L.

If fluid resuscitation alone does not restore adequate tissue perfusion, dopamine should be administered (starting dose, 1 to 3 µg/kg/min) to stimulate myocardial contractility and improve the perfusion of central organs. In some patients with persistent low cardiac output and low blood pressure in the face of adequate fluid resuscitation, dobutamine should be added to the vasopressor therapy to improve cardiac output. In addition, such patients should be treated with intravenous corticosteroids (hydrocortisone, 200 to 300 mg/day for 7 days in 3 or 4 divided doses or by continuous infusion).^{211,214}

Patients in septic shock also should be treated with broad-spectrum antibiotics. The triple combination of penicillin or ampicillin, plus clindamycin or metronidazole, plus gentamicin (in the doses specified earlier for treatment of pelvic abscess) is an excellent initial regimen. Alternatively, a broad-spectrum antibiotic such as imipenem-cilastatin (500 mg IV every 6 hours), meropenem (1 g IV every 8 hours), ertapenem (1 g IV every 24 hours), piperacillin-tazobactam (3.375 g IV every 6 hours), ampicillin-sulbactam (3 g IV every 6 hours), or ticarcillin-clavulanic acid (3.1 g IV every 6 hours) can be administered.

The duration of antibiotic therapy should be 5 to 10 days, depending on the rapidity of the patient's response.²⁰⁴

Patients also may require surgery to evacuate retained, infected products of conception, to drain a pelvic abscess, or to remove an infected intravascular catheter. Indicated surgery never should be delayed because the patient is unstable, because operative intervention may be precisely the step necessary to reverse septic shock.

The patient's core temperature should be maintained as close to normal as possible by use of antipyretics and a cooling blanket. Coagulation abnormalities should be corrected. Insulin should be administered as needed to maintain euglycemia. Granulocyte colony-stimulating factor may be indicated for severely neutropenic patients. Severely ill patients should receive prophylaxis for deep venous thrombosis with either unfractionated or fractionated heparin. They also should receive stress ulcer prophylaxis with histamine₂ (H₂) blockers.^{211,214}

In addition, treatment with activated protein C (24 µg/kg/min for 96 hours) may be of value in decreasing mortality and minimizing organ dysfunction in severely ill patients.²¹⁴ Activated protein C ultimately reduces inflammation by inhibiting platelet aggregation, neutrophil recruitment, and degranulation of mast cells.

Patients should be given oxygen supplementation and observed closely for evidence of ARDS, which is one of the major causes of mortality in patients with severe sepsis.²¹⁵ Oxygenation should be monitored by means of a pulse oximeter or radial artery catheter. If evidence of respiratory failure develops, the patient should be intubated promptly and supported with mechanical ventilation and positive end-expiratory pressure.^{211,215}

The prognosis in patients with septic shock clearly depends on the severity of the patient's underlying illness. In otherwise healthy patients, mortality should not exceed 15%. The prognosis for complete recovery is excellent, provided that the patient receives timely therapy.^{215,216}

Septic Pelvic Vein Thrombophlebitis

Epidemiology and Pathogenesis

Like pelvic abscess, septic pelvic vein thrombophlebitis is extremely rare in modern obstetrics, occurring in approximately 1 of every 2000 pregnancies overall and in fewer than 1% of patients who have puerperal endometritis.²¹⁷ Septic pelvic vein thrombophlebitis occurs in two distinct forms. The most commonly described disorder is acute thrombosis of one (usually the right) or both ovarian veins (ovarian vein syndrome).²¹⁸ Affected patients typically develop a moderate temperature elevation in association with lower abdominal pain during the first 48 to 96 hours after delivery. The pain usually localizes to the side of the affected vein but may radiate into the groin, upper abdomen, or flank. In addition, nausea, vomiting, and abdominal bloating may be present.

On physical examination, the patient usually is found to have tachycardia. Tachypnea, dyspnea, and even stridor may be evident if septic pulmonary embolization has occurred. The abdomen is tender, and bowel sounds often are decreased or absent. Most patients have voluntary and involuntary guarding, and 50% to 70% have a tender, rope-like mass that originates near one cornua and extends laterally and cephalad toward the upper abdomen. The principal conditions that should be considered in the differential diagnosis of ovarian vein syndrome are acute pyelonephritis, nephrolithiasis, appendicitis, broad-ligament hematoma, adnexal torsion, and pelvic abscess.

The second presentation of septic pelvic vein thrombophlebitis has been termed “enigmatic fever.”²¹⁹ These patients usually have been treated initially for presumed puerperal endometritis. Subsequently, they experience some subjective improvement, with the exception of persistent fever. They do not appear to be seriously ill, and positive findings are limited to persistent fever and tachycardia. Disorders that must be considered in the differential diagnosis of enigmatic fever are drug reaction, viral syndrome, recrudescence of connective tissue disease, and pelvic abscess.

Diagnosis

CT and MRI are the diagnostic tests of greatest value in confirming the diagnosis of pelvic vein thrombophlebitis.²²⁰ These tests are most sensitive in detecting large thrombi in the major pelvic vessels. They are not as useful in identifying thrombi in smaller vessels. In some cases, the diagnosis is one of exclusion and is confirmed by observing the patient’s response to an empiric trial of heparin.²¹⁷

Treatment

The traditional treatment for patients with presumed septic pelvic vein thrombophlebitis is therapeutic anticoagulation with intravenous heparin. The dose of heparin should be adjusted to maintain the aPTT at approximately two times normal. Alternatively, medication may be adjusted to achieve a serum heparin concentration of 0.2 to 0.7 IU/mL. Intravenous heparin should be continued for 7 to 10 days, depending on the response to treatment. Long-term anticoagulation with oral agents probably is unnecessary unless the patient has massive clotting throughout the pelvic venous plexus or has sustained a pulmonary embolism. Patients should be given broad-spectrum antibiotics, such as those used for treating pelvic abscess, throughout the period of heparin administration.^{217,221}

Once medical therapy is initiated, there is usually objective evidence of a response within 48 to 72 hours. If no improvement is noted, surgical intervention may be considered. The surgical approach should be tailored to the specific intraoperative findings. In most instances, treatment requires only ligation of the affected vessels. Extension of the thrombosis along the vena cava to the point of origin of the renal veins may require embolectomy. Excision of the infected vessel and removal of the ipsilateral adnexa and uterus are indicated only in the presence of a well-defined abscess. Consultation should be obtained from an experienced vascular surgeon if surgical intervention becomes necessary.²²¹

Mastitis

Epidemiology and Pathogenesis

Mastitis occurs in 5% to 10% of lactating women.²²³ The principal causative organisms are *S. aureus* and *Viridans streptococci*. These organisms are part of the mother’s skin flora and are introduced into the milk ducts when the infant suckles.^{222,223}

Diagnosis

Affected women initially experience malaise, followed by a relatively high fever (39° C or higher) and chills. Thereafter, an erythematous, tender area appears in the affected breast. In addition, patients also may experience pain and tenderness in the ipsilateral axilla, and the milk from the infected breast may be discolored. In a small

percentage of patients, an actual abscess forms within the affected breast.²²⁴

The diagnosis of mastitis is usually established on the basis of the patient’s symptoms and clinical examination findings. Culture of milk from the infected breast is not helpful. However, if an abscess is suspected on physical examination, the contents should be drained and cultured, particularly in light of the recent increase in methicillin-resistant staphylococcal infections.

Treatment

Mastitis usually can be treated successfully with oral antibiotics that have excellent coverage against staphylococci and streptococci. Initially, sodium dicloxacillin, 500 mg orally four times daily, is preferable. In a woman with a history of a mild allergic reaction to penicillin, cephalexin, 500 mg orally four times daily, may be substituted for sodium dicloxacillin. With a history of a serious immediate hypersensitivity reaction to penicillin, clindamycin, 300 mg orally every 6 hours, is an appropriate alternative. The duration of antibiotic therapy depends on the patient’s response to treatment but usually should extend for approximately 7 to 10 days.²⁰⁴

There are no reports to suggest that nursing from the infected breast is contraindicated. Therefore, the patient should be encouraged to continue nursing once the tenderness in the affected breast has decreased.

Hospitalization and treatment with intravenous antibiotics should be considered for immunosuppressed patients and for those who are at particular risk for having complications should staphylococcal bacteremia develop (e.g., patients with prosthetic heart valves). In addition, women with a breast abscess should be hospitalized for intravenous antibiotic therapy and surgical drainage. Appropriate intravenous drugs include nafcillin (2 g every 6 hours), cefazolin (1 g every 8 hours), or vancomycin (1 g every 12 hours). Other agents with excellent antistaphylococcal coverage include linezolid (600 mg every 12 hours) and quinupristin/dalfopristin (7.5 mg/kg every 8 hours). These latter two drugs are extremely expensive and should not routinely be used as first-line agents.²⁰⁴

Prevention

In an effort to prevent mastitis, lactating women should be advised to take measures to prevent drying and cracking of the nipples. Specifically, they should avoid the use of alcohol-based products for cleaning the nipples and should apply a moisturizing agent such as lanolin to the nipple and areola after nursing.

Cytomegalovirus Infection

Epidemiology and Pathogenesis of Maternal and Fetal Infection

Cytomegalovirus (CMV) is a DNA virus that is a member of the herpesvirus family. Like other members of this family, CMV may remain latent in host cells after the initial infection. Recurrent infection is usually caused by reactivation of an endogenous latent virus rather than reinfection with a new viral strain.^{225,226}

CMV is not highly contagious; close personal contact is required for infection to occur. Horizontal transmission may result from transplantation of an infected organ or transfusion of infected blood, sexual contact, or contact with contaminated saliva or urine. Vertical trans-

mission may occur as a result of transplacental infection, exposure to contaminated genital tract secretions during delivery, or breastfeeding. The incubation period of CMV ranges from 28 to 60 days.²²⁷

Among young children, the most important risk factor for infection is close contact with playmates (e.g., from handling toys that are contaminated by infected saliva).^{228,229} Most children who acquire CMV infection are asymptomatic. When clinical manifestations are present, they include malaise, low-grade fever, lymphadenopathy, and hepatosplenomegaly. Most immunocompetent adults with CMV also are asymptomatic or have only mild symptoms suggestive of a flulike illness. However, in an immunosuppressed patient, CMV infection can be quite serious.

The diagnosis of CMV infection is confirmed by viral culture. The highest concentrations of virus are in urine, seminal fluid, saliva, and breast milk, with most cultures becoming positive within 72 to 96 hours. PCR methodology permits identification of viral antigen within 24 hours.^{225,227}

Serologic methods also are of value in establishing the diagnosis of CMV infection. Positive IgM titers usually decline rapidly over a period of 30 to 60 days, but they can remain elevated for many months. There is no single IgG titer that clearly differentiates acute from recurrent infection. However, a fourfold or greater change in the IgG titer over 2 weeks usually is consistent with recent acute infection. Another useful test for differentiating acute from recurrent infection is assessment of the avidity of IgG antibody. Low- to moderate-avidity IgG antibody, combined with the presence of IgM antibody, is consistent with acute infection. If high-avidity IgG antibody is present, the patient typically has recurrent infection.^{230,231}

Approximately 50% to 80% of adult women in the United States have serologic evidence of past CMV infection. However, the presence of antibodies is not perfectly protective against either reinfection or vertical transmission of infection from mother to fetus. Therefore, pregnant women with either recurrent or primary infection pose a risk to their fetus.^{229,232}

Antepartum (congenital) infection results from hematogenous dissemination of virus across the placenta and poses the greatest risk to the fetus. Dissemination is much more likely in the presence of a primary maternal infection. Among women who acquire primary CMV infection during pregnancy, approximately half will infect their fetus. The overall risk of congenital infection is greatest when maternal infection occurs in the third trimester, but the probability of severe fetal injury is highest when it occurs in the first trimester.

Approximately 5% to 15% of infants who develop congenital CMV infection as a result of primary maternal infection are symptomatic at birth. The most common clinical manifestations of severe neonatal infection are hepatosplenomegaly, intracranial calcifications, jaundice, growth restriction, microcephaly, chorioretinitis, hearing loss, thrombocytopenia, hyperbilirubinemia, and hepatitis. Approximately 30% of severely infected infants die, and 80% of survivors have major morbidity. Among the 85% to 90% of infants with congenital CMV infection who are asymptomatic at birth, 10% to 15% subsequently develop hearing loss, chorioretinitis, or dental defects within the first 2 years of life.^{229,232}

Pregnant women who experience recurrent or reactivated CMV infection are much less likely to transmit infection to their fetus. If recurrent infection develops in pregnancy, approximately 5% to 10% of infants become infected; however, none of these neonates will be symptomatic at birth. The most common sequelae are hearing loss, visual deficits, and mild developmental delays.²³²⁻²³⁵

Perinatal infection can occur during delivery as a result of exposure to infected genital tract secretions. Infection also can occur as a result

of breastfeeding. However, when the virus is acquired in one of these ways, infants rarely have major abnormalities.

Diagnosis of Congenital Infection

The most sensitive and specific test for diagnosing congenital CMV infection is the identification of CMV in amniotic fluid by either culture or PCR.^{234,235} This test is of greater accuracy than cordocentesis for two major reasons. First, it can be performed at gestational ages when sampling of cord blood is technically not possible (<20 weeks). Second, fetal anti-CMV-specific IgM antibody is usually not apparent until 23 weeks' gestation or later, which may be many weeks after infection occurred.

Identification of the virus in amniotic fluid by culture or PCR does not necessarily delineate the severity of fetal injury. Fortunately, sonography is invaluable in providing information about the condition of the fetus. The principal sonographic findings suggestive of serious fetal injury are microcephaly, ventriculomegaly, inter-cerebral calcification, fetal hydrops, growth restriction, and oligohydramnios. Less common findings include fetal heart block, echogenic bowel, meconium peritonitis, renal dysplasia, ascites, and pleural effusions.

Treatment

Until recently, no consistently effective therapy for congenital CMV infection was available. However, in 2005, Nigro and colleagues²³⁶ published a prospective cohort study from eight medical centers describing the use of hyperimmune globulin as treatment and prophylaxis for congenital CMV infection. Of 157 women with confirmed primary CMV infection, 148 were asymptomatic and were identified by routine serologic screening; 8 women had symptomatic viral infection, and 1 was identified because her fetus had abnormal ultrasound findings. Forty-five women had had a primary infection longer than 6 weeks before enrollment, underwent amniocentesis, and had CMV detected in amniotic fluid by PCR or culture. Thirty-one of these women received intravenous treatment with CMV-specific hyperimmune globulin (200 U/kg of maternal body weight). Nine of the 31 received one or two additional infusions into either the amniotic fluid or the umbilical cord because their fetuses had persistent abnormalities on ultrasound. Fourteen women declined treatment; 7 of these women had infants who were acutely symptomatic at the time of delivery. In contrast, only 1 of the 31 treated women had an infant with clinical disease at birth (adjusted OR, 0.02, $P < .001$).

In this same investigation,²³⁶ 84 additional women did not have an amniocentesis because their infection occurred within 6 weeks before enrollment, their gestational age was less than 20 weeks, or they declined amniocentesis. Thirty-seven of these women received hyperimmune globulin, 100 U/kg every month until delivery, and 47 declined treatment. Six of the treated women delivered infected infants, as did 19 of the untreated women (adjusted OR, 0.32, $P = .04$). No adverse effects of hyperimmune globulin were noted in either group receiving immunotherapy.

This report by Nigro and colleagues had several shortcomings.²³⁷ The design of the study was neither randomized nor controlled. There are at least some biologic reasons to question whether the remarkable success reported by the authors will be maintained in larger, randomized studies. The authors also did not address the financial and logistic issues associated with screening large obstetric populations for CMV infection, triaging the inevitable patients with false-positive results, offering amniocentesis and targeted sonography to women who

seroconvert, and then treating at-risk patients with hyperimmune globulin. Nevertheless, the authors' observations are extremely interesting and offer the best available therapy for this dangerous perinatal infection.

Prevention

Ideally, preventive measures should be employed to ensure that women do not contract CMV infection during pregnancy. One simple measure is using CMV-negative blood products when transfusing pregnant women or fetuses. In addition, women should be encouraged to use careful hand washing techniques after handling infant diapers and toys. They also should adopt safe sexual practices if they are not already engaged in a mutually faithful, monogamous sexual relationship.^{225,228,237}

Group B Streptococcal Infection

The hemolytic streptococci cause a variety of infections and are significant causes of perinatal morbidity and mortality. In 1933, Lancefield used serologic techniques to subdivide β -hemolytic streptococci into specific groups, designated A, B, C, D, and E. Only groups A, B, and D commonly are involved in human disease.

Group A β -hemolytic streptococcus (*Streptococcus pyogenes*) long has been recognized as a major pathogen in perinatal sepsis.²³⁸ Several case series have documented fulminant puerperal infection, with multi-system dysfunction, resulting from group A streptococci.²³⁹

The Lancefield group B streptococci, GBS (*Streptococcus agalactiae*) can be classified into five major serotypes on the basis of antigenic structure. They originally were thought to be commensal organisms. By the 1960s GBS had been linked to neonatal infections, and by the 1970s they had emerged as the leading cause of neonatal sepsis. Today, GBS still are among the leading organisms in perinatal sepsis and have become the focus of national prevention strategies. In 1995, in surveillance areas set up by the CDC, the rate of perinatal sepsis was 1.3 per 1000 liveborn infants, accounting for an estimated 7000 to 8000 cases per year in the United States.²⁴⁰ Outcome has improved dramatically in recent years, but morbidity still is substantial, particularly in preterm infants. One data set showed an overall case fatality rate of 4%, 2% in term infants but 16% in preterm infants.

GBS have been reported to cause 1% to 5% of UTIs in pregnancy. In addition, a characteristic early onset of puerperal endometritis has been associated with these organisms.

Epidemiology

Asymptomatic rectovaginal colonization with GBS occurs in approximately 20% of pregnant women. The choice of culture medium is a crucial determinant of the prevalence of GBS. The highest yield occurs when a selective medium, such as LIM or Trans-Vag broth, is used as an enriching step before plating on sheep's blood agar.

The single greatest risk factor for colonization with GBS in a newborn is being born to a colonized mother. Without intervention, more than half of infants born to colonized mothers will become colonized.²⁴¹ Also, 16% to 45% of nursery personnel are carriers of GBS infection, and nosocomial acquisition in newborns is common. There clearly is an association between heavy growth of GBS in the maternal genital tract and the development of GBS sepsis in neonates. Yet, a

surprisingly high percentage of neonates with GBS sepsis (perhaps 25%) are born to women with light colonization. Therefore, focusing solely on heavily colonized women in preventive approaches is inadequate.

The documented colonization rate for GBS has been far higher than the attack rate in terms of neonatal infection. Overall, sepsis develops in only 1% of infants of colonized mothers. The following are risk factors for GBS neonatal sepsis²⁴²:

- Prematurity (or low birth weight as its surrogate)
- Maternal intrapartum fever (presumably as a result of chorioamnionitis)
- Membrane rupture for longer than 18 hours
- A previous infant infected with GBS disease
- GBS bacteriuria in this pregnancy

Because of the preponderance of term infants overall, 70% to 80% of cases of neonatal GBS infection in the United States occur in infants born after 36 weeks' gestation.^{243,244} Today, approximately half of cases are early in onset (first week of life). Previously, before implementation of intrapartum antibiotic prophylaxis (IAP), at least three quarters of cases were of the early-onset variety.^{243,244} The most common diagnosis with early-onset disease is bacteremia (89%); meningitis but not bacteremia is diagnosed in 10%, and both bacteremia and meningitis in 1%.²⁴³

Clinical Manifestations in the Neonate

Two clinically distinct neonatal GBS infections have been identified: early- and late-onset disease.²⁴⁵

Early-Onset Infection

Early-onset infection appears within the first week of life, usually within 48 hours. It is characterized by rapid clinical deterioration and a high mortality rate. The association between gestational age and early-onset GBS infection is shown in Table 38-14. In its most fulminant form, early-onset GBS infection manifests as septic shock accompanied by respiratory distress and leads to death within several hours despite appropriate antibiotic therapy. In less severe disease, the clinical findings are similar to those seen in respiratory distress syndrome. Although pulmonary disease predominates in early-onset disease, meningitis may be present in 10% to 30% of cases. The case fatality rate for early-onset disease is now approximately 4.5%.²⁴³ Current nationwide prevention strategies have decreased the number of cases of early-onset GBS sepsis by an estimated 3900 per year and the number of deaths by 200 per year.²⁴⁶

TABLE 38-14 EARLY-ONSET GROUP B STREPTOCOCCAL DISEASE, BY GESTATIONAL AGE, 1993-1998

Gestational Age (Wk)	% of Cases	Case Fatality Rate (%)
≤33	9	30
34-36	8	10
≥37	83	2

Data from Schrag SJ, Zywicki S, Farley MM, et al: Group B streptococcal disease: The era of intrapartum antibiotic prophylaxis. *N Engl J Med* 342:15, 2000.

Late-Onset Infection

Late-onset infection with GBS occurs more insidiously, usually after the first week of life. In the majority of infants, meningitis is the predominant clinical manifestation. Although the mortality rate in late-onset GBS infection is lower (2%) than with early-onset disease, up to 50% of babies with meningitis subsequently demonstrate neurologic sequelae. Late-onset disease may result in localized infections involving the middle ear, sinuses, conjunctiva, breasts, lungs, bones, joints, or skin. Meningitis appears to be related to the serotype of GBS. More than 80% of early-onset GBS infections in which meningitis is present are caused by Lancefield type III organisms; in late-onset disease, 95% of meningitis is attributable to this subtype.

Although early-onset disease is acquired mainly via transmission from the mother's genital tract either before or during parturition, such a route of transmission is not implicated in late-onset disease. Nosocomial transmission of GBS can occur in the nursery from colonized nursing staff or from other infants. Current prevention strategies have not decreased the number of cases of late-onset GBS disease in newborns.^{243,246}

Clinical Manifestations in the Mother

GBS is a major cause of puerperal infection. Features of GBS puerperal infection include the development of a high fever within 12 hours after delivery, tachycardia, abdominal distention, and endometritis. Some patients have no localizing signs early in the course of the infection.

Diagnosis

The diagnosis of maternal asymptomatic genitourinary or gastrointestinal colonization with GBS can be confirmed by culture. Several rapid diagnostic tests are available for detection of GBS from maternal sources, but most methods are insufficiently sensitive. Some newer PCR-based tests seem to be an exception to that statement.^{247,248}

Most colonized neonates are asymptomatic, and the clinical manifestations of neonatal infection are not sufficient for diagnosis in the absence of a positive culture. The diagnosis should be suspected if the clinical manifestations occur in the setting of a risk factor for infection.

Treatment

Penicillin G remains the drug of choice for symptomatic GBS infection in both mother and neonate if the infecting organism has been identified. In most instances, however, treatment must be initiated before the availability of culture results. In these instances, a broad-spectrum approach for empirically treating the mother with chorioamnionitis or puerperal sepsis and the neonate with sepsis is required. Ampicillin frequently is used in such situations and provides adequate treatment for GBS infection. Alternative drugs for patients with a contraindication to penicillin are a cephalosporin in those not at risk for immediate penicillin hypersensitivity or vancomycin in patients who are at risk (e.g., those with immediate urticaria or bronchospasm as manifestations of penicillin allergy). Because of rising resistance, clindamycin and erythromycin no longer can be relied upon to treat GBS infection unless susceptibility to these antibiotics has been demonstrated for a given isolate.

Prevention

Because of the severity of early-onset GBS neonatal infection, major efforts have been directed toward use of IAP in gravid women whose

genital tracts are colonized with GBS. Strategies can be classified as antepartum, intrapartum, neonatal, and immunologic.

Antepartum Strategies

Antepartum strategies to reduce maternal carrier rates generally have been unsuccessful owing to recolonization and are therefore not recommended.

Intrapartum Strategies

Intrapartum strategies have been the most attractive to date from both clinical and cost-effectiveness perspectives.

To standardize a national approach, in 1996, the CDC published recommendations that were also endorsed by the ACOG. These recommendations have been disseminated widely and have resulted in dramatic decreases in early-onset neonatal GBS sepsis.^{244,246} In 2002, these guidelines were revised, based on several studies, including a large case-control series.^{246,247} The main changes in the 2002 guidelines are recommendation of the screen-based approach only, a change in the recommended alternative antibiotics for penicillin-allergic patients, and provision of more specific recommendations for selected clinical scenarios. These guidelines are summarized here (Fig. 38-6).

- All pregnant women should be screened at 35 to 37 weeks' gestation for vaginorectal GBS colonization. IAP should be given at the time of labor or rupture of membranes to those identified as GBS carriers. GBS colonization in a previous pregnancy does not obviate need for screening in subsequent pregnancies; colonization in a previous pregnancy is not an indication for IAP in subsequent deliveries.
- GBS bacteriuria: Give IAP to women with GBS in urine in any concentration.
 - Prenatal screening at 35 to 37 weeks is not necessary in these patients.
 - Treat bacteriuria by usual standards of care.
- Women with previous birth of infant with GBS disease should receive IAP; prenatal screening is not necessary for these women.
- If the result of the GBS culture is not known at the time of labor, give IAP under any of the following circumstances:
 - Less than 37 weeks' gestation
 - Rupture of membranes at least 18 hours earlier
 - Temperature at or greater than 100.4° F (38.0° C)
- In cases of onset of labor or rupture of membranes earlier than 37 weeks with "significant risk for imminent preterm delivery," treat as follows:
 - If the patient had a negative screening culture for GBS within the past 4 weeks, IAP is not indicated.
 - If colonization status is unknown at admission, perform screening culture and initiate IAP; if the culture is negative, stop IAP.
- Specimens

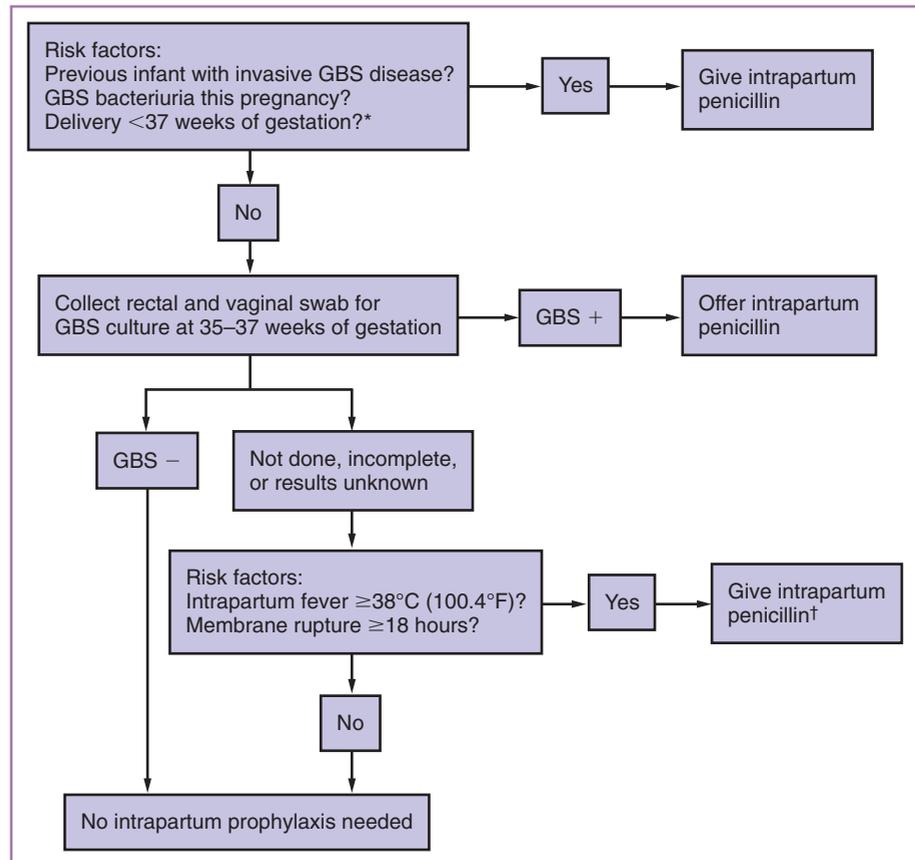

Collection

- Collect specimen from distal vagina and the anorectum.
- Specimen may be collected by patient or provider.
- Do not use a speculum.
- Transport medium is acceptable.
- Label the specimen "GBS culture."

Laboratory processing

- Inoculate into selective broth medium (e.g., LIM, Trans-Vag)
- Methods have been provided for susceptibility testing to clindamycin and erythromycin for GBS isolates from penicillin-allergic women.

FIGURE 38-6 Algorithm for prevention of early-onset group B streptococcal (GBS) disease in neonates, with prenatal screening at 35 to 37 weeks. *If membranes rupture before 37 weeks' gestation and the mother has not begun labor, collect GBS culture and administer antibiotics until cultures are completed and the results are negative. †Broader-spectrum antibiotics may be considered at the physician's discretion, based on clinical indications (e.g., ampicillin plus gentamicin to treat clinical chorioamnionitis). (Adapted from Centers for Disease Control and Prevention: Prevention of perinatal group B streptococcal disease: A public health perspective. *MMWR Morb Mortal Wkly Rep* 45[RR-7]:1, 1996.)

- h. Laboratories “should report results to site of delivery and provider.”
7. Inform patients of results and recommend IAP.
 - a. In the absence of GBS bacteriuria, do not treat GBS genital colonization before the intrapartum period.
8. For cesarean delivery before rupture of membranes and before labor, IAP is not indicated.
9. Penicillin G is the drug of choice.
 - a. The recommended dose for penicillin G is 5 million units initially, then 2.5 million units every 4 hours intravenously until delivery.
 - b. Ampicillin remains an alternative.
 - c. When ampicillin is used, the dose is 2 g intravenously initially, followed by 1 g every 4 hours until delivery.
 - d. For penicillin allergy, clindamycin is no longer a drug of choice, unless susceptibility has been documented. Erythromycin no longer should even be considered as an alternate drug because of the high rate of resistance.
10. For patients with penicillin allergy, treat as follows:
 - a. If not at high risk for anaphylaxis, the drug of choice is cefazolin, 2 g intravenously, then 1 g every 8 hours until delivery.
 - b. If at high risk for anaphylaxis and GBS is susceptible: The drug of choice is clindamycin, 900 mg intravenously every 8 hours.
 - c. If at high risk for anaphylaxis and GBS is resistant to clindamycin or of unknown susceptibility: The drug of choice is vancomycin, 1 g every 12 hours.
11. Routine use of prophylaxis for newborns whose mothers received IAP is not recommended. Antibiotics should be given to infants only if sepsis is suspected clinically.

12. Other items:
 - a. Consider establishing surveillance.
 - b. Improve laboratory protocols for isolation and reporting.
 - c. Ensure communication.
 - d. Educate staff.

The guidelines suggest penicillin G as the drug of choice for IAP and list ampicillin as an “acceptable alternative.” Concern about ampicillin’s broader spectrum of activity is the reason for this recommendation. However, when evaluated in a randomized clinical trial, IAP with either ampicillin or penicillin significantly increased the likelihood of recovery of ampicillin-resistant gram-negative organisms from the lower genital tract, and there was no difference between the two drugs for this effect.²⁴⁹ Because of these data, we believe that the choice of whether to use penicillin or ampicillin for IAP should be based on cost and availability.

Another caveat involves the technique for collection of the screening culture. The guidelines call for sampling the vagina and rectum. However, two thirds of women report at least mild pain associated with collection of the rectal sample.²⁵⁰ Furthermore, Jamie and colleagues²⁵¹ evaluated whether there was any advantage to sampling the vagina and rectum, compared with sampling the vagina and perianal skin. They found no difference in culture positivity in a cohort of 200 women. Therefore, it seems reasonable to obtain samples for screening cultures for GBS colonization from the distal vagina and perianal skin.

Neonatal Strategies

Measures to prevent GBS infection in the newborn have focused on the reports of decreases in neonatal early-onset disease when penicillin

is given at birth. Although initial reports were encouraging, most trials in low-birth-weight infants have not found this approach to be effective. These results are not surprising in view of Boyer and Gotoff's observation²⁵² that up to 40% of neonates in whom GBS sepsis develops are already bacteremic at birth, suggesting that a single dose of penicillin after delivery may be "too little and too late."

Immunologic Strategies

The immunologic approach is appealing, but a vaccine has not yet been developed. Such a vaccine would need to be polyvalent to cover all serotypes involved in early-onset sepsis. One limitation of this approach is that it would not be optimally protective for infants born before 32 weeks of gestation because of modest placental transfer of maternal antibody before that time. Thus, the most vulnerable infants would be left with minimal protection. Nevertheless, it is estimated that a vaccine approach would prevent up to 90% of cases of neonatal GBS infection.²⁵³

Summary

No current approach is foolproof. However, the application of IAP has resulted in a significant reduction in the rate of early-onset neonatal GBS infection. In 2004, the rate was 0.34 per 1000 live births, less than a third of the rate only 10 years before.

Herpes Simplex Infection

Herpes simplex virus (HSV) may infect the mother, the newborn, or, on rare occasions, the fetus. In the adult, typical lesions are vesicular or ulcerative, involving only the skin and mucous membranes. More widespread infection involving the central nervous system (CNS) is an extremely unusual adult complication and most often develops in people with underlying debilitating disease. On the other hand, because of an incompletely developed immune system, the newborn is subject to systemic, and frequently lethal, disease.

Epidemiology

In adults, the virus commonly causes infection of the oral cavity, skin, and lower genital tract. In the past, HSV type 1 (HSV-1) was said to be responsible for infection of the mouth and of the skin above the waist, and HSV-2 was implicated in infection of the genitalia and of the skin below the waist. However, both viruses can cause either genital or oropharyngeal lesions, which are indistinguishable clinically. Furthermore, in some populations, HSV-1 has been reported to account for 30% to 40% of new cases of genital herpes,²⁵⁴ but genital HSV-1 recurs much less commonly than genital HSV-2.^{254,255}

Genital herpes is spread by sexual contact. The prevalence of serum antibodies to HSV-2 is increasing in the United States. Between 1988 and 1994, 21.9% of the population age 12 years or older was found to be seropositive, representing a 30% increase since the period 1976 to 1980 and corresponding to 45 million cases of infection.²⁵⁶ The disease does not appear to be more severe or more protracted in pregnancy.

Clinically, there are three syndromes of genital herpes:

1. *First-episode primary genital herpes* is the clinical presentation in a patient without antibodies to either HSV-1 or HSV-2. Its clinical manifestations include severe local symptoms, with lesions lasting 3 to 6 weeks, regional adenopathy, constitutional symptoms, and, in a small percentage of cases, viral meningitis. However, it should be noted that as many as two thirds of women with HSV-2 antibodies have acquired the infection

asymptomatically.²⁵⁷ This observation represents a major change from previous concepts.

2. *First-episode nonprimary genital herpes* is the initial clinical episode with either HSV-1 or HSV-2 in a patient who has antibodies to the other viral serotype. Because the antibody response is directed against epitopes within areas of homology in the glycoprotein G expressed by each viral type, there is some cross-reactivity. Therefore, the presentation is more similar to recurrent episodes.
3. *Recurrent genital herpes infections* are much milder and shorter, with lesions lasting 3 to 10 days. The course of the infection is shorter, owing to the preexisting presence of antibody to the viral serotype causing the recurrent infection.

When primary genital herpes occurs in pregnancy, there is a high risk of fetal and neonatal involvement, but this risk mainly exists with infection late in pregnancy. Brown and coworkers²⁵⁸ found that serious morbidity occurred in 6 of 15 infants born to women with primary infection in pregnancy and in 4 of 5 born to mothers with primary infection in the third trimester. However, the same group showed that, overall, maternal seroconversion to HSV-2 during pregnancy does not result in greater risks of low birth weight, preterm delivery, fetal growth restriction, stillbirth, or neonatal death.²⁵⁹ When recurrent episodes occur during pregnancy, there appears to be no increase in abortion or low-birth-weight infants.²⁵⁷

Transplacental infection of the fetus resulting in congenital infection is a rare complication of maternal infection, presumably arising from primary infections with viremia. Only a few such documented cases have been reported.²⁶⁰

A major perinatal problem is neonatal herpes infection. Exact estimates of its frequency are subject to error, because up to 50% of infants with culture-proven fatal disease do not show typical lesions on the skin or mucous membranes. In addition, recent treatment recommendations probably have decreased the incidence of neonatal disease. The disease manifests at the end of the first week of life. The presentation may include skin lesions, cough, cyanosis, tachypnea, dyspnea, jaundice, seizures, and DIC.

Neonatal herpes is acquired perinatally from an infected lower maternal genital tract, most commonly during a vaginal delivery. In a study by Brown and colleagues,²⁵⁹ only those women with very recent infection (i.e., presence of virus in the genital tract but without development of type-specific antibody) had infected infants. In that situation, the risk was high (four of nine cases). The risk is considerably lower among women with recurrent, clinically evident infection—in the range of 1% to 2%. In one study, the incidence of infection in infants born vaginally to women with asymptomatic recurrent infection was 0 in 34 cases.²⁶¹ However, asymptotically infected patients can give birth to seriously infected neonates. In a referral nursery, 70% of mothers of infected infants had asymptomatic infections. Among infants with disseminated herpes, the risk of death or serious sequelae exceeds 40%, even with antiviral therapy.²⁶²

Diagnosis

The clinical diagnosis of genital herpes is based on the typical painful crops of vesicles and ulcers in various stages of progression. With primary infection, tender inguinal adenopathy, fever, and other, more marked constitutional symptoms may occur. Primary genital herpes lesions resolve without scarring after 3 to 6 weeks. The frequency of clinically detectable recurrences varies widely among individuals, but about 50% of patients have recurrent disease within 6 months. Recur-

rences are milder, with fewer lesions, fewer constitutional symptoms, and a shorter course (usually 3 to 10 days).

Because many patients present with genital herpes infection after the vesicles have evolved into ulcers, clinical diagnosis based on the classic presentation of grouped, painful vesicles has a low sensitivity and specificity. Furthermore, making the diagnosis of genital herpes has social and future implications. Therefore, first-episode infections should be confirmed by laboratory tests.

The “gold standard” diagnostic test to detect the presence of herpes virus infection has been the viral culture. The virus grows rapidly, and most positive cultures are identifiable at 48 to 72 hours. Culture of vesicular fluid has the highest yield, and the sensitivity of culture decreases with increasing duration of active lesions. The diagnosis of herpes infection can be made using the Tzanck smear or Papanicolaou smear. However, neither of these tests can differentiate among HSV-1, HSV-2, and varicella-zoster virus infection, and neither of them has a high sensitivity or specificity.

PCR to detect HSV DNA probably is the most useful diagnostic test available. Results are available in a matter of hours, and PCR exceeds culture in identifying positive cases. With the use of PCR, the frequency of asymptomatic viral shedding of HSV particles has been shown to be eight times higher than previously reported using culture.²⁶³⁻²⁶⁵

Previously, HSV antibody tests could not discriminate infection with HSV-1 from that with HSV-2. Newer IgG assays that are specific to the respective glycoprotein G of each type now allow clinicians to distinguish between these infections.²⁶⁶ However, the role of serologic testing in making the diagnosis of genital herpes is controversial. Furthermore, cost-effectiveness analyses regarding whether pregnant women should be screened for serologic evidence of prior HSV-2 infection have had mixed results.^{267,268}

Treatment

During clinically evident episodes, treatment consists of supportive measures such as oral analgesics, hygiene, and topical anesthetics. Secondary infections such as candidiasis also should be treated. Many women find that frequent bathing, followed by thorough drying of the affected area with a hair dryer, provides temporary relief.

Acyclovir, an antiviral agent with excellent activity against herpes infection, is a specific inhibitor of viral thymidine kinase. It is available in topical, oral, and intravenous preparations. In nonpregnant individuals, all of these forms have been of value in decreasing the duration of symptoms and of viral shedding in primary genital infection, but oral therapy seems to be superior to topical therapy and equivalent to intravenous therapy for treatment of non-life-threatening infections. The oral form is effective in shortening recurrences significantly (400 mg orally three times daily for 5 days) and in suppressing frequent recurrences (400 mg orally twice daily). Such suppressive therapy with acyclovir has been demonstrated to be safe and effective for 6 years or more.²⁶⁹

For treatment of genital herpes, valacyclovir (Valtrex) and famciclovir (Famvir) have the advantage of better absorption and a longer half-life than acyclovir. Both are indicated for the treatment of recurrent genital herpes, and valacyclovir is indicated for the treatment of first-episode infections. Both drugs are more expensive than acyclovir.

Management of Herpes Infection in Pregnancy

Because of the severity of neonatal herpes infection and the lack of satisfactory therapy, the only current way of preventing neonatal infection is to avoid contact between the fetus and the infected maternal

lower genital tract by means of cesarean delivery. Accordingly, cesarean delivery is recommended when typical herpes lesions are present at labor, regardless of the time since membrane rupture.^{12,270,271}

In 1986, Arvin and colleagues²⁷² reported HSV cultures in a series of 515 pregnant women with recurrent herpes infection. Seventeen women had positive antepartum cultures, but none was positive at delivery. Of 354 asymptomatic mothers, 5 (1.4%) had positive results at delivery, but none had positive antepartum cultures. The likelihood of asymptomatic shedding at delivery was 1.3%. Brown and colleagues²⁵⁹ published a cohort study that included more than 40,000 women. Testing for HSV included both culture and PCR. From the 202 women from whom HSV was isolated at the time of labor, 10 infants developed HSV infection. Those born by cesarean delivery were less likely to develop HSV infection than those born vaginally (1.2% versus 7.7%; $P = .047$).

For gravidas with recurrent genital herpes, treatment with acyclovir (400 mg three times daily) starting at 36 weeks' gestation decreases the proportion of patients with clinical lesions at the time of labor and lessens the need for cesarean delivery.²⁷³ Such an approach has been shown to be cost-effective.²⁷⁴

There are no data supporting a risk to the fetus from maternal administration of acyclovir, valacyclovir, or famciclovir. However, we believe that acyclovir should be the drug of choice for suppression of recurrent genital herpes during the third trimester, because this drug has been the most extensively studied.

Current recommendations for prenatal and intrapartum care include the following:

1. Obstetricians should ask all pregnant women about a history of genital herpes.
2. If the diagnosis of genital herpes has not been previously confirmed by culture or PCR, specimens should be obtained during an active episode of apparent HSV infection.
3. Serial cultures beginning at 34 to 36 weeks are *not* recommended for *asymptomatic* women with a history of herpes infection.
4. The patient with a history of genital herpes should be instructed to come to the hospital early in labor or immediately if PROM has occurred. The patient also should be informed of the low risk of asymptomatic infection at delivery (1%) and the low risk of neonatal infection after delivery through an asymptotically infected genital tract.
5. When the patient arrives in labor or with membrane rupture, a careful pelvic examination should be performed. If no lesions are present, the delivery can be managed normally. If lesions are observed, cesarean delivery is recommended to prevent neonatal herpes.

Women with nongenital herpes do not require any special precautions during labor and delivery, apart from barrier isolation of the infected skin, gown and glove precautions, and proper disposal of linen and dressings. Precautions should be taken to avoid contact of the newborn with the infected maternal skin. After the lesions have become encrusted, the mother may handle and feed her infant.

Human Immunodeficiency Virus Infection

Epidemiology

HIV infection is caused by an RNA retrovirus. Two major strains of the virus have been identified, HIV-1 and HIV-2; each major strain has

several substrains. HIV-1 infection is more widely prevalent throughout the world. HIV-2 infection is uncommon in the United States except among patients who have traveled to areas of the world where this infection is endemic (e.g., sub-Saharan Africa) or who have shared needles with, or had sex with, someone from that area of the world.²⁷⁵

In the United States, HIV infection is more common in African-American and Hispanic women than in Caucasians. The most common mechanism of transmission of infection is heterosexual contact. Intravenous drug use also is an extremely important mechanism of transmission. Transmission through organ donation, artificial insemination, or blood transfusion is exceedingly rare. Important risk factors for sexual transmission of HIV infection include multiple sexual partners; receptive anal intercourse; unprotected intercourse; concurrent STDs, especially those that cause genital ulcers; sexual contact with an uncircumcised male; severe illness in the infected partner; sex during menstruation; and bleeding during intercourse (e.g., from sexual assault).²⁷⁶

Pathogenesis

HIV infection typically evolves through four major stages. The first stage of infection is the *acute retroviral illness*.²⁷⁷ Within several weeks after exposure, the patient typically develops a severe flulike illness characterized by malaise, poor appetite, weight loss, low-grade fever, and generalized lymphadenopathy. Over a period of several weeks, this phase of the illness gradually resolves, and the patient enters the *latent phase of infection*. In this phase of the infection, the viral load in the plasma tends to be relatively low, and the virus is primarily concentrated in lymphatic tissue, where it replicates at a slow rate. With appropriate anti-retroviral therapy and supportive care, the latent phase of illness may extend beyond 10 years in many patients. Over time, however, the viral load progressively increases, and patients enter a *symptomatic phase* of the infection. Eventually, all infected patients develop *acquired immunodeficiency syndrome (AIDS)*, albeit at a much slower rate than in the early years of the HIV epidemic.

Diagnosis

Opportunistic diseases are the hallmark of HIV infection. The most common serious opportunistic disease in women is *Pneumocystis jiroveci* pneumonia; second most common is *Mycobacterium avium-intracellulare* infection. Other important opportunistic diseases include tuberculosis, toxoplasmosis, CMV infection, candidiasis, and non-Hodgkin lymphoma.²⁷⁸

The initial screening test for HIV infection should be the enzyme immunoassay (EIA) for HIV-1 and HIV-2. If this test is positive, a confirmatory test such as the Western blot or immunofluorescent assay (IFA) should be performed. If both tests are positive, the probability of a false-positive sequence is extremely low.

The CDC now recommends universal screening for HIV infection in pregnant women. The “opt out” strategy is the one most likely to ensure compliance with screening. With this strategy, HIV testing is considered part of the routine prenatal laboratory panel. Patients must specifically decline the screening test; otherwise, it is routinely performed.

Treatment

In the absence of any intervention, the risk of perinatal transmission of HIV infection is approximately 25%.²⁷⁹ With the interventions outlined in this section, perinatal transmission should be reduced to less

than 2%.²⁸⁰ Most cases of transmission occur at the time of delivery. Antenatal transmission is possible, typically as a result of invasive antepartum procedures such as amniocentesis or chorionic villus sampling. Postnatal transmission also can occur from breastfeeding. The principal risk factors for perinatal transmission of HIV infection are

- History of previously affected infant
- Severe maternal disease
- Preterm delivery
- Intrapartum blood exposure as a result of events such as vaginal lacerations, episiotomy, or instrumental delivery
- Time since rupture of membranes greater than 4 hours
- Invasive antepartum procedures
- Chorioamnionitis
- Concurrent STDs
- Vaginal delivery in the presence of an elevated viral load

At the time of her first prenatal appointment, the HIV-infected patient should have a CD4⁺ count and viral load measurement to assess her degree of immunosuppression. She should be screened for all other STDs, such as gonorrhea, chlamydia, syphilis, hepatitis B, and hepatitis C. She also should be tested for tuberculosis. If her CD4⁺ count is greater than 200 cells/mm³, the purified protein derivative (PPD) should be a reliable screening test. If the CD4⁺ count is less than 200/mm³, a negative test may be the result of anergy, and such patients should have a chest radiograph to be certain that tuberculosis is not present. Patients should be tested for toxoplasmosis and CMV infection as well, because both can cause serious perinatal infection, which can be successfully treated with either antibiotics or immunotherapy.

In an effort to prevent opportunistic infections, the HIV-positive pregnant woman should be vaccinated for pneumococcal infection, influenza, hepatitis A and B, and meningococcal infection. She also should receive prophylactic antibiotics to protect against other pathogens.²⁷⁸ If her CD4⁺ count is less than 200/mm³ and she previously has had an infection with *P. jiroveci*, she should receive trimethoprim-sulfamethoxazole-DS, 1 tablet daily. This medication also provides protection against toxoplasmosis infection. If her tuberculin skin test is positive and her chest radiograph shows no evidence of active disease, she should receive prophylaxis with isoniazid (INH), 300 mg orally each day, plus pyridoxine, 50 mg daily. The latter drug is administered to prevent peripheral neurotoxicity from isoniazid. If the patient's CD4⁺ count falls to a range of 50 to 75 cells/mm³, she should receive prophylaxis against *M. avium-intracellulare* with azithromycin, 1200 mg orally each week. If a patient has recurrent candidiasis, she can be treated with fluconazole, 150 mg orally, each day. If her CD4⁺ count falls to less than 50/mm³, she also should receive prophylaxis with fluconazole to prevent cryptococcal infection. A patient with recurrent herpes simplex infection should receive prophylaxis with acyclovir, 400 mg PO twice daily.

The single most important intervention is treatment with highly active antiretroviral therapy (HAART).^{281,282} The ACTG-076 trial²⁷⁹ was the first to demonstrate that treatment of pregnant women with prophylactic zidovudine is highly effective in reducing the rate of perinatal transmission of HIV infection. In that trial, the observed frequency of transmission was reduced from 26% in the placebo group to 8% in those patients who received zidovudine. Subsequent uncontrolled studies showed that treatment of the mother with combination chemotherapy reduces the rate of perinatal transmission to less than 2%.²⁸⁰

The antiretroviral agents currently available are summarized in Table 38-15. The combination of zidovudine (300 mg) and lamivudine

TABLE 38-15 DRUGS FOR TREATMENT OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Agent	Usual Adult Dose	Major Adverse Effects
Nucleotide Analogue		
Tenofovir (Viread)	300 mg qd	GI irritation, elevation in transaminase concentrations, decrease in serum carnitine, nephrotoxicity
Nucleoside Analogues		
Abacavir (Ziagen)	300 mg bid	Hypersensitivity reaction
Didanosine (DDI, Videx) or Videx EC	200 mg bid 400 mg qd	Pancreatitis and peripheral neuropathy
Emtricitabine (Emtriva)	200 mg qd	Headache, diarrhea, nausea, rash, hyperpigmentation, hepatitis
Lamivudine (3TC, Epivir)	150 mg bid or 300 mg qd	Marrow suppression
Stavudine (d4T, Zerit)	40 mg bid	Peripheral sensory neuropathy
Zalcitabine (ddC, Hivid)	0.75 mg q8h	Peripheral neuropathy, pancreatitis
Zidovudine (AZT, Retrovir)	300 mg bid	Marrow suppression
Combination Nucleoside Analogues		
Combivir (zidovudine + lamivudine)	1 tablet bid	Marrow suppression
Trizivir (zidovudine + lamivudine + abacavir)	1 tablet bid	Marrow suppression
Non-nucleoside Reverse Transcriptase Inhibitors		
Delavirdine (Rescriptor)	400 mg tid	Rash, hepatitis
Efavirenz (Sustiva)	600 mg qd	Rash, CNS changes. Drug is teratogenic and should not be used in pregnancy.
Nevirapine (Viramune)	200 mg bid	Rash, hepatitis
Unique Triple Combination		
Atripla (efavirenz + emtricitabine + tenofovir)	Single daily dose: 600/200/300 mg	Lactic acidosis, severe hepatomegaly, steatosis
Protease Inhibitors		
Amprenavir (Agenerase)	1200 mg bid	Rash and GI irritation
Atazanavir (Reyataz)	400 mg qd	Hyperbilirubinemia, prolonged Q-T interval, hyperlipidemia
Darunavir (Prezista)—must be given with ritonavir	600/100 mg bid	Diarrhea, nausea, headache, increased transaminase activity, increased serum lipids
Indinavir (Crixivan)	800 mg tid	Nephrolithiasis, GI upset
Lopinavir/ritonavir (Kaletra)	3 gelatin capsules (133.3/33.3 mg) bid	Diarrhea, nausea, fatigue, headache, asthenia
Nelfinavir (Viracept)	1250 mg bid	Diarrhea, fatigue, poor concentration
Ritonavir (Norvir)	100-400 mg bid	GI irritation, seizures, hepatitis, diabetes, marrow suppression
Tipranavir (Aptivus)—must be given with ritonavir	500/200 mg bid	Hepatitis, diarrhea, nausea, vomiting, abdominal pain
Saquinavir:		
Hard gel cap (Invirase)	400 or 1000 mg bid	GI irritation, peripheral neuropathy, headache, rash
Soft gel cap (Fortovase)	1200 mg tid	
Fusion Inhibitor		
Enfuvirtide (Fuzeon)	90 mg bid	GI irritation, rash, hypotension, injection site reaction

CNS, central nervous system; GI, gastrointestinal tract.

(150 mg) (Combivir, twice daily) plus ritonavir (400 mg) and lopinavir (100 mg) (Kaletra, twice daily) is recommended. The patient's response to treatment should be evaluated by obtaining serial measurements of viral load. If a clear response to treatment has not occurred within 12 to 16 weeks, the patient should have viral genotyping to determine whether she has a resistant organism. If resistance is identified, the entire antiviral regimen should be changed in accordance with the susceptibility pattern identified.

If the therapy reduces the patient's viral load to less than 1000 copies/mL, vaginal delivery is acceptable, provided that there are no other indications for cesarean delivery. During labor, every precaution should be taken to minimize contact between the infant's skin and

mucous membranes and contaminated maternal blood and genital tract secretions. Specifically, amniotomy, scalp monitoring, scalp pH assessment, episiotomy, and instrumental delivery should be avoided if at all possible. Although all of these agents have potentially serious side effects in the mother, only efavirenz is clearly teratogenic in the fetus.

If the patient does not have an optimal response to therapy and her viral load remains greater than 1000 copies/mL, she should be delivered by cesarean at approximately 38 weeks' gestation, before the onset of labor and rupture of membranes. Amniocentesis should not be routinely performed before this procedure, because it poses a small risk of transmitting HIV infection to the infant.

Regardless of the method of delivery, the patient should receive intravenous zidovudine during delivery (2 mg/kg for 1 hour, then 1 mg/kg/hr until delivery). For patients scheduled for cesarean delivery, the infusion should begin approximately 4 hours before surgery. Infants delivered to infected mothers typically are treated with antiretroviral agents for at least 6 weeks after delivery.²⁸³⁻²⁸⁷

If the HIV status of the patient is unknown and she is admitted in labor, a rapid serologic screening should be performed. Current assays should yield reliable results within 1 hour. Management of seropositive patients and their infants should proceed as outlined earlier until definitive testing is completed.^{288,289}

Listeriosis

Epidemiology and Pathogenesis

Listeriosis is an infection caused by *L. monocytogenes*, a motile, non-spore-forming, gram-positive bacillus. Although seven species of *Listeria* are recognized, *L. monocytogenes* is the principal human pathogen. Patients who are immunocompromised and pregnant women and their newborns are particularly susceptible to infection with *L. monocytogenes*. Of concern to the obstetrician is the association between maternal listerial infection and stillbirth, preterm labor, and fetal infection. High perinatal morbidity and mortality rates have been reported for listerial infection in pregnancy.²⁹⁰⁻²⁹⁴

As with GBS infection, neonatal listeriosis has been divided into two serologically and clinically distinct types. *Early-onset* disease, associated with serotypes Ia and IVb, takes the form of a diffuse sepsis with involvement of multiple organs, including the lungs, liver, and CNS. *Early-onset* listeriosis is associated with a high rate of stillbirth and a high neonatal mortality rate. It appears to occur more frequently in low-birth-weight infants. *Late-onset* listeriosis manifests as meningitis, usually in term infants born to mothers with uneventful perinatal courses. Neurologic sequelae, such as hydrocephalus and mental retardation, are common with late-onset disease. In addition, a mortality rate approaching 40% has been reported.²⁹⁰⁻²⁹⁴

It is possible that an ascending route of infection from cervical colonization with *L. monocytogenes* plays a role in the pathogenesis of neonatal infection. However, the more important and more common route of infection is hematogenous dissemination of the organism through the placenta, which leads to placental abscesses and ultimately to fetal septicemia.

Human listeriosis manifests in both epidemic and sporadic forms. The *epidemic* form is associated with contamination of food and food products. Foods that particularly pose a risk include fresh, unpasteurized cheeses (e.g., Mexican “queso fresco”) and processed meats such as hot dogs.²⁹⁵ Cherubin and colleagues²⁹³ reviewed more than 120 cases of listeriosis. They identified pregnancy and neonatal status as two of the major risk factors for this disease. Indeed, the deaths associated with listeriosis occurred predominantly among premature and stillborn infants delivered to infected pregnant women. Moreover, the earlier the stage of gestation when infection manifested, the higher the risk of fetal death. Listerial infection tends to adversely affect immunocompromised adults and fetuses or neonates with immature immune systems.

The *sporadic* form of listeriosis occurs more commonly than the epidemic form. The incidence of listeriosis appears to be decreasing. The crude incidence in 2003 was 3.1 cases per 1 million population. The decrease in the last decade is thought to be the result of a lower prevalence of *L. monocytogenes* contamination of ready-to-eat foods.²⁹⁶

Diagnosis

Many pregnant women with listeriosis are asymptomatic. When symptomatic, they present with a flulike syndrome characterized by fever, chills, malaise, myalgias, back pain, and upper respiratory complaints. Such symptoms occur in two thirds of cases.²⁹⁷ The viral-like prodrome characterizes the bacteremic stage of listeriosis. Gellin and Broome²⁹¹ suggested that this is probably the time when the placenta and fetus are seeded with *L. monocytogenes*. Maternal infection tends to be mild and is not associated with significant morbidity. However, diffuse sepsis may occur on occasion. No specific clinical manifestations have been demonstrated that help to distinguish listeriosis from other infections that may occur during pregnancy. Therefore, pregnant women presenting with these symptoms in the late second or early third trimester should be evaluated for possible listeriosis.

Early-onset neonatal listeriosis occurs in infants who are infected in utero, often before the start of labor, and manifests during the first few hours to days of life. Late-onset neonatal listeriosis occurs in term infants who appear healthy at birth and manifest infection several days to weeks after delivery.²⁹¹ Meningitis is more common than sepsis with late-onset disease. Either intrapartum transmission or nosocomial transmission after delivery can result in late-onset infection.²⁹¹

Because of the high mortality rate associated with both early- and late-onset neonatal listerial infection, it is crucial that the obstetrician maintain a high index of suspicion that any febrile illness in pregnancy may be due to *L. monocytogenes*. In patients with these symptoms, cervical and blood cultures should be obtained for *L. monocytogenes* as soon as possible. Because colonies of *L. monocytogenes* may be mistaken on the Gram stain for diphtheroids and therefore ignored, it is important to inform the microbiologist that listerial infection is a concern. In febrile pregnant women, a Gram stain revealing gram-positive pleomorphic rods with rounded ends is highly suggestive of, and should be presumed to be, *L. monocytogenes*.

Treatment

Penicillin G and ampicillin are effective in vivo against *L. monocytogenes*. Current opinion holds that optimal therapy includes a combination of ampicillin plus an aminoglycoside. Maternal treatment consists of ampicillin (1 to 2 g intravenously every 4 to 6 hours) and gentamicin (2 mg/kg intravenously every 8 hours). For the newborn, the ampicillin dosage is 200 mg/kg/day in 4 to 6 divided doses. The duration of treatment is usually 1 week. A single case report has suggested that, following documentation by amniocentesis of intrauterine listerial infection, antibiotic treatment without immediate delivery may be successful and may result in a normal healthy fetus.^{298,299} An earlier study³⁰⁰ also suggested that rapid diagnosis and aggressive antibiotic management in the antenatal patient with listeriosis may reduce the complications of this illness. In addition, these authors reviewed reported cases of listerial septicemia and antepartum antibiotic use: There was one maternal death, and 16 of 20 infants survived. These data compared favorably to the perinatal mortality rate of 33% to 73% observed in cases of untreated maternal disease.

Mumps

Epidemiology and Pathogenesis

The diagnosis of mumps is usually made on the basis of clinical examination. Mumps is an acute, generalized nonexanthematous infection

with a predilection for the parotid and salivary glands. The infection also can affect the brain, pancreas, and gonads. Mumps is caused by an RNA virus that is a member of the paramyxovirus family. It is transmitted by saliva and respiratory droplet contamination and has been recovered from salivary and respiratory secretions from 7 days before the onset of parotitis until 9 days afterward. The usual incubation period is 14 to 18 days.

Diagnosis

The prodrome of mumps consists of fever, malaise, myalgias, and anorexia. Parotitis follows within 24 hours and is characterized by swollen and tender parotid glands. In most cases, parotitis is bilateral. The submaxillary glands are involved less often and almost never without parotid gland involvement. The sublingual glands rarely are affected. Although mumps usually is a self-limited and complication-free disease, it can cause aseptic meningitis, pancreatitis, mastitis, thyroiditis, myocarditis, nephritis, and arthritis.

Adverse Effects in Pregnancy

Mumps in pregnant women is generally benign and no more severe than in nonpregnant patients. Aseptic meningitis in pregnant patients is neither more common nor more severe. Mortality in association with mumps is extremely rare in both pregnant and nonpregnant patients.

Mumps during the first trimester is associated with a twofold increase in the incidence of spontaneous abortion. There is no association between maternal mumps infection and preterm delivery, fetal growth restriction, or perinatal mortality.³⁰¹

Whether mumps infection may result in congenital disease remains controversial.³⁰² Despite animal studies in which mumps virus induced congenital malformations, definitive evidence of a teratogenic potential for mumps virus in humans has not been reported. Siegal³⁰³ noted that the rate of congenital malformations in infants born to women who had mumps during pregnancy (2 of 117) was no different than the rate in infants born to uninfected mothers (2 of 123). The predominant concern has been the postulated association between maternal mumps infection and the development of subsequent congenital cardiac abnormalities, specifically endocardial fibroelastosis.³⁰⁴ The issue remains unresolved.

Treatment

The treatment of mumps both in pregnant and nonpregnant patients is symptomatic. Analgesics, bed rest, and application of cold or heat to the parotid glands are useful. Maternal mumps is not an indication for termination of pregnancy. The live-attenuated mumps vaccine is effective in preventing primary mumps. Ninety-five percent of vaccinated susceptible subjects develop antibodies without clinically adverse reactions. The duration of protection afforded by immunization is not known.

Although mumps vaccine virus has been recovered from fetal and placental tissue when vaccination occurred during pregnancy, there is no evidence that the vaccine virus is teratogenic in humans. Nevertheless, given the innocuous nature of mumps in pregnancy, immunization with the mumps live-virus vaccine in pregnancy is contraindicated on the theoretical grounds that the developing fetus might be harmed. However, mumps vaccination should not be considered an indication for pregnancy termination. Women vaccinated with mumps vaccine should not become pregnant for at least 1 month.

Parvovirus Infection

Epidemiology and Pathogenesis

Parvovirus infection is a rare, but potentially extremely serious, perinatal complication. The infection is caused by a DNA organism, the B19 parvovirus. The virus is transmitted primarily by respiratory droplets and infected blood products. Immunity to parvovirus increases progressively throughout childhood and young adult life. Approximately 50% to 60% of women of reproductive age have evidence of prior infection, and immunity is long-lasting.^{305,306}

The incubation period for parvovirus is 10 to 20 days. The most common clinical manifestation of infection is erythema infectiosum (fifth disease). Erythema infectiosum is usually manifested by a low-grade fever, malaise, myalgias, arthralgias, and a “slapped cheek” facial rash. An erythematous, lacelike rash also may extend onto the torso and upper extremities. In children, parvovirus infection also can cause transient aplastic crisis. This same disorder may occur in adults who have an underlying hemoglobinopathy.³⁰⁶

When maternal parvovirus infection occurs during pregnancy, the virus can cross the placenta and infect red cell progenitors in the fetal bone marrow. The virus attaches to the i antigen on red cell stem cells and suppresses erythropoiesis, thereby resulting in severe anemia and high-output congestive heart failure. This same antigen also is present on fetal myocardial cells, and, in some fetuses, the viral infection causes a cardiomyopathy that further contributes to heart failure.³⁰⁶

The most obvious manifestation of congenital infection is hydrops fetalis. The risk of hydrops is directly related to the gestational age at which maternal infection occurs. If infection develops during the first 12 weeks of gestation, the risk of hydrops varies from less than 5% to approximately 10%. If infection occurs during weeks 13 through 20, the risk of infection decreases to 5% or less. If infection occurs beyond the 20th week of gestation, the risk of fetal hydrops is 1% or less.³⁰⁷⁻³⁰⁹

Diagnosis

The best way to confirm the diagnosis of maternal parvovirus infection is through serologic testing. Table 38-16 illustrates the possible combinations of serologic test results that may occur in women who are being evaluated for possible parvovirus infection.

Once maternal infection is confirmed, the fetus should be evaluated for evidence of anemia. The best test for assessment of anemia is ultrasound assessment of middle cerebral artery (MCA) via Doppler velocimetry. Serial examinations should be performed for at least 8 weeks

TABLE 38-16 POSSIBLE RESULTS OF SEROLOGIC TESTS FOR PARVOVIRUS AFTER DOCUMENTED EXPOSURE

IgM	IgG	Interpretation
Negative	Negative	Susceptible
Negative	Positive	Prior immunity—protected against second infections
Positive	Negative	Acute infection—within previous 7 days
Positive	Positive	Subacute infection >7 days and <120 days

Ig, immunoglobulin.

after documentation of maternal seroconversion, because the incubation period for fetal infection may be longer than that observed in children and adults.

The most obvious ultrasound manifestation of fetal anemia is hydrops. However, by the time sonographic evidence of hydrops is present, the fetal hematocrit is likely to be less than 20%. Therefore, a more precise way to detect evolving fetal anemia is to assess Doppler velocimetry in the fetal MCA.³¹⁰ Increases in peak systolic velocity in this vessel correlate well with fetal hematocrit. If velocimetry indicates fetal anemia, a cordocentesis should be performed to determine the fetal hematocrit. If anemia is confirmed, an intrauterine blood transfusion should be performed.

Treatment

Two retrospective studies have demonstrated that intrauterine transfusion is lifesaving in the setting of congenital parvovirus infection. The first investigation was published by Fairley and colleagues.³¹¹ They reviewed 66 cases of fetal hydrops caused by parvovirus infection. Twenty-six fetuses were dead at the time of diagnosis, and two were electively aborted. Twelve of the 38 live fetuses had an intrauterine transfusion, three of whom died. Among the 26 fetuses who did not receive an intrauterine transfusion, 13 died. The odds ratio for fetal death in infants who received a transfusion was 0.14 (CI, 0.02 to 0.96). A second important study was published by Rodisand associates.³¹² They surveyed specialists in maternal-fetal medicine and reported the outcomes of 460 cases of parvovirus infection. Twenty-seven of 164 fetuses who received an intrauterine transfusion died. Of the 296 fetuses who did not receive an intrauterine transfusion, 138 died. The observed difference in outcome was highly significant ($P < .001$). Although cases of spontaneous resolution of fetal hydrops have been reported, the studies presented here clearly support a firm recommendation for intrauterine transfusion (Level II—2 evidence, “A” recommendation).

Infants who survive intrauterine infection with parvovirus usually have an excellent long-term prognosis.³¹³ However, isolated case reports have been published documenting neurologic morbidity and prolonged, transfusion-dependent anemia.^{314,315} More recently, Nagel and colleagues³¹⁶ reported an 8-year follow-up of 16 hydropic fetuses who received intrauterine transfusions for congenital parvovirus infection and survived. Eleven (68%) of the children were normal, and 5 (32%) had delayed psychomotor development. In light of these reports, a third-trimester ultrasound to reassess fetal growth and evaluate the anatomy of the CNS, together with long-term surveillance for neurologic problems, seems to be a prudent course of management.

Rubella

Epidemiology

Rubella (also called “German measles” or “3-day measles”) is caused by an RNA virus. Rubella infection develops primarily in young children and adolescents and is most common in the springtime. Major epidemics of rubella occurred in the United States in 1935 and 1964; minor sporadic epidemics occurred approximately every 7 years until the late 1960s. With licensure of an effective vaccine in 1969, the frequency of rubella declined markedly. In 1999, the incidence of rubella was 0.1 per 100,000.³¹⁷ Persistence of this infection appears to be caused by failure to vaccinate susceptible individuals rather than by a lack of immunogenicity of the vaccine.³¹⁸

The rubella virus is spread by respiratory droplets. From the upper respiratory tract, the virus travels quickly to the cervical lymph nodes and then is disseminated hematogenously throughout the body. The incubation period is approximately 2 to 3 weeks. The virus is present in blood and nasopharyngeal secretions for several days before appearance of the characteristic rash and continues to be shed from the nasopharynx for several days after appearance of the rash. Therefore, the patient may be contagious for a period of 7 to 10 days.³¹⁸

Antibody against rubella does not normally appear in the serum until after the rash has developed. Acquired immunity to rubella usually lasts for life. Second infections have occurred after both natural infections and vaccination, but recurrent infections usually are not associated with serious illness, viremia, or congenital infection.

Clinical Presentation

Most infections with rubella are subclinical. Of those individuals who do show symptoms, most have mild constitutional symptoms such as malaise, headache, myalgias, and arthralgias. The principal clinical manifestation of rubella is a widely disseminated, nonpruritic, erythematous, maculopapular rash. Postauricular adenopathy and mild conjunctivitis also are common. These clinical manifestations usually are short-lived and typically resolve within 3 to 5 days.

Diagnosis

The differential diagnosis of rubella includes rubeola, roseola, other viral exanthems, and drug reaction. Rubella usually can be distinguished from these other conditions on the basis of the characteristic rash and serologic testing. Serum IgM antibody concentration reaches a peak 7 to 10 days after the onset of illness and then declines over a period of 4 weeks. The serum concentration of IgG rises more slowly, but antibody levels persist throughout the lifetime of the individual.³¹⁸

Congenital Rubella Infection

Because of the success of rubella vaccination campaigns, the incidence of congenital rubella syndrome (CRS) in the United States has declined dramatically. Fewer than 50 cases of congenital rubella occur each year. However, approximately 10% to 20% of women in the United States remain susceptible to rubella, and their fetuses are at risk for serious injury should infection occur during pregnancy.³¹⁹

Rubella virus crosses the placenta by hematogenous dissemination, and the frequency of congenital infection is critically dependent on the time of exposure to the virus. The fetus is not at risk from infection before the time of conception. However, approximately 50% to 80% of infants exposed to the virus within 12 weeks after conception will manifest signs of congenital infection. The rate of congenital infection declines sharply with advancing gestational age, so that very few fetuses are affected if infection occurs beyond 18 weeks of gestation.^{320,321}

The four most common anomalies associated with CRS are deafness (affecting 60% to 75% of fetuses), eye defects such as cataracts or retinopathy (10% to 30%), CNS defects (10% to 25%), and cardiac malformations (10% to 20%). The most common cardiac abnormality is patent ductus arteriosus, although supraventricular pulmonary stenosis is perhaps the most pathognomonic. Other possible abnormalities include microcephaly, mental retardation, pneumonia, fetal growth restriction, hepatosplenomegaly, hemolytic anemia, and thrombocytopenia.³²⁰⁻³²³

A variety of tests have been proposed for the diagnosis of CRS. Fetal blood, obtained by cordocentesis, can be used to determine the total

and viral-specific IgM concentration. However, cordocentesis technically is difficult before 20 weeks' gestation, and fetal immunoglobulins usually cannot be detected before 22 to 24 weeks. Chorionic villi, fetal blood, and amniotic fluid samples all can be tested via PCR for rubella antigen. Because of its lower complication rate, amniocentesis is the procedure of choice. Although these tests can demonstrate that rubella virus is present in the fetal compartment, they do not indicate the degree of fetal injury. Furthermore, the possibility of false-positive test results cannot be excluded. Accordingly, detailed ultrasound examination is the best test to determine whether serious fetal injury has occurred as a result of maternal rubella infection. Possible anomalies detected by ultrasound include growth restriction, microcephaly, CNS abnormalities, and cardiac malformations.

The prognosis for infants with CRS is guarded. Approximately 50% of affected individuals have to attend schools for the hearing-impaired. An additional 25% require at least some special schooling because of hearing impairment, and only 25% are able to attend mainstream schools.³²²

Prevention of Rubella Infection

Ideally, women of reproductive age should have a preconception appointment when they are contemplating pregnancy. At that time, they should be evaluated for immunity to rubella. If serologic testing demonstrates that they are susceptible, they should be vaccinated with rubella vaccine before conception occurs. If preconception counseling is not possible, patients should have a test for rubella at the time of their first prenatal appointment. Women who are susceptible to rubella should be counseled to avoid exposure to other individuals who may have viral exanthems.

If a susceptible woman subsequently is exposed to rubella, serologic tests should be obtained to determine whether acute infection has occurred. If acute infection is documented by identification of IgM antibody, the patient should be counseled about the risk of CRS. The diagnostic tests for detection of congenital infection should be reviewed, and the patient should be offered the option of pregnancy termination, depending on the assessed risk of serious fetal injury.

Pregnant women who are susceptible to rubella should be vaccinated immediately after delivery. The rubella vaccine is available in monovalent, bivalent (measles-rubella), and trivalent (measles-mumps-rubella) forms. Approximately 95% of patients who receive rubella vaccine seroconvert, and antibody levels persist for at least 18 years in more than 90% of vaccinees.

Adverse effects of vaccination are minimal, even in adults. Fewer than 25% of patients experience mild constitutional symptoms such as low-grade fever and malaise. Fewer than 10% of vaccinees have arthralgias, and fewer than 1% develop frank arthritis. Other complaints, such as pain and paresthesias, have been rare. Women who have received the vaccine cannot transmit infection to susceptible contacts, such as young children in the home, and vaccinated women may breastfeed their infants. In addition, the vaccine can be administered in conjunction with immunoglobulin preparations such as Rh immune globulin.^{319,323} Women who receive rubella vaccine should practice secure contraception for at least 1 month after vaccination.³²⁴

To decrease the occurrence of rubella, recommended public health policies include vaccinating all children aged 12 to 15 months or older and all adolescents and adults not known to be immune, unless they are pregnant or have other contraindications to vaccination. Also, all prenatal patients should be screened as early as possible in pregnancy.³¹⁸ Contraindications to vaccination include febrile illness, immunosup-

pression, and pregnancy. Precautions also are necessary in the rare individual with neomycin allergy.

Rubeola

Epidemiology

The measles (rubeola) virus is a single-stranded RNA paramyxovirus that closely is related to the canine distemper virus. The wild virus is pathogenic only for primates, and humans are the only natural host.

The virus is spread by respiratory droplets and is highly contagious. Between 75% and 90% of susceptible contacts become infected after exposure. Before a measles vaccine was available, essentially all children experienced natural measles infection. Since licensure of the first measles vaccine in 1963, the incidence of infection has decreased by almost 99%. As expected, children younger than 10 years of age have shown the greatest decline in incidence. During the mid-1980s, almost 60% of reported cases affected children older than 10 years of age, compared with only 10% of cases occurring during the period from 1960 to 1964.³²⁵

In recent years, two major types of measles outbreaks have occurred in the United States. One type has developed among unvaccinated preschoolers, including children younger than 15 months of age. Another type has occurred among previously vaccinated school-age children and college students. Approximately one third of the cases in the latter type of outbreak have been in individuals who were previously vaccinated. Presumably, these cases result from either *primary failure* to respond to the first vaccine or *secondary failure*, a situation in which an adequate serologic response develops initially but immunity wanes over time.^{325,326}

The clinical manifestations of measles usually appear within 10 to 14 days after exposure. The most common signs and symptoms are fever, malaise, coryza, sneezing, conjunctivitis, cough, photophobia, and Koplik spots (blue-gray specks on a red base that develop on the buccal mucosa opposite the second molars). Patients typically develop a generalized nonpruritic maculopapular rash that begins on the face and neck and then spreads to the trunk and extremities. It usually lasts for approximately 5 days and subsequently recedes in the same sequence in which it appeared. The duration of illness is approximately 7 to 10 days (hence, the name, the "10-day measles"). Patients are contagious from 1 to 4 days before the onset of coryza until several days after appearance of the rash. Immunity to measles should be lifelong after wild virus infection and is mediated by both humoral and cell-mediated mechanisms.

Although measles is typically a minor illness, some patients develop serious sequelae. Otitis media occurs in 7% to 9% of infected patients; bronchiolitis and pneumonia affect 1% to 6%. A severe form of hepatitis also may occur. In a report by Atmar and associates,³²⁷ 7 (54%) of 13 pregnant women with measles developed hepatitis.

Encephalitis occurs in approximately 1 in every 1000 cases of measles. It results from both viral infection of the CNS and a hypersensitivity reaction to the systemic viral infection. Measles encephalitis may lead to permanent neurologic impairment, including mental retardation; the mortality rate from this complication is approximately 15% to 33%. Another unusual, but extremely serious, complication of measles is subacute sclerosing panencephalitis. This complication occurs in 0.5 to 2 cases per 1000. It usually develops about 7 years after the acute measles infection and is more common in children who had measles before the age of 2 years. The disorder is characterized by

progressive neurologic debilitation and has an almost uniformly fatal outcome.^{325,327}

A final complication is *atypical measles*. This disorder is a severe form of measles reinfection that affects young adults previously vaccinated with the formalin-inactivated killed measles vaccine that was distributed in the United States from 1963 to 1967. Affected patients have extremely high antibody titers to measles, and they experience high fever, pneumonitis, pleural effusion, and a coarse maculopapular, hemorrhagic, or urticarial rash. Although the disease usually is self-limited, atypical measles can lead to hepatic, cardiac, and renal failure. Interestingly, affected patients are not contagious to others.^{325,328}

Five clinical criteria should be present to establish the diagnosis of measles: fever of 38.3° C or higher, characteristic rash lasting longer than 3 days, cough, coryza, and conjunctivitis. Although the virus can be cultured, the mainstay of diagnostic tests is detection of antibody to measles. The hemagglutination inhibition assay and the enzyme-linked immunosorbent assay (ELISA) are the most useful serologic tests for determination of a patient's susceptibility to measles and for confirmation of infection. The serologic confirmation of acute measles virus infection is based on detection of IgM-specific antibody or a fourfold change in the IgG titer in acute and convalescent sera. The acute titer for IgG antibody should be obtained within 3 days after the onset of the rash, and the convalescent titer should be obtained 10 to 20 days later.

Obstetric Considerations

Several reports have documented an increase in maternal mortality associated with measles infection during pregnancy; most deaths have been caused by pulmonary complications. In one of the earliest investigations, Christensen and colleagues³²⁹ described an epidemic of measles in Greenland in 1951. Four (4.8%) of 83 pregnant women who developed measles died. An unspecified number of these women also had active tuberculosis. In the report by Atmar and associates,³²⁷ one (8%) of 13 pregnant women with measles died because of severe respiratory infection. Eberhart-Phillips and coworkers³³⁰ evaluated 58 pregnant women with measles. Thirty-five (60%) required hospitalization, 15 (26%) developed pneumonia, and 2 (3%) died.

Reports also have described a slight increase in the frequency of preterm delivery and spontaneous abortion among women who developed measles during pregnancy. In the study by Eberhart-Phillips and colleagues,³³⁰ 13 (26%) of 50 women with continuing pregnancies delivered preterm. Fortunately, the frequency of congenital anomalies is not increased significantly in women who contract measles during pregnancy.

Although congenital anomalies are rare, infants of mothers who are acutely infected at the time of delivery are at risk for *neonatal measles*. This infection typically develops within the first 10 days of life and results from transplacental transmission of the virus. The mortality rate in preterm and term infants with neonatal measles has been reported to be as high as 60% and 20%, respectively.³³¹

Preventive Measures

Ideally, all women of reproductive age should have evidence of immunity to measles before attempting pregnancy. Originally, public health officials thought that a single injection of live measles vaccine when a child was approximately 15 months of age provided lifelong immunity. As noted previously, however, several recent outbreaks of measles have occurred due to secondary vaccine failures. Accordingly, the Advisory

Committee on Immunization Practices (ACIP) recommends that all individuals who have not been infected with the live virus receive a second dose of the vaccine at 4 to 6 years of age. If this second dose is not administered in childhood, it should be administered before a woman plans her first pregnancy. There are only three contraindications to use of the live measles vaccine: pregnancy, severe febrile illness, and history of anaphylactic reaction to egg protein or neomycin.³³²

If a susceptible pregnant woman is exposed to measles, she should immediately receive passive immunoprophylaxis with immune globulin, 0.25 mL/kg intramuscularly, up to a maximum dose of 15 mL. If she develops measles despite immunoprophylaxis, she should be observed for evidence of serious complications such as otitis media, hepatitis, encephalitis, and pneumonia. Secondary bacterial infections should be treated promptly with antibiotics. Administration of aerosolized ribavirin may be of benefit to patients with severe viral pneumonitis.³³³

The affected patient should be counseled that the risk of injury to her fetus is very low. The most effective method of evaluating the fetus for in utero infection is detailed ultrasound examination. Findings suggestive of in utero infection include microcephaly, growth restriction, and oligohydramnios. If the mother developed measles within 7 to 10 days of delivery, the neonate should receive intramuscular immunoglobulin in a dose of 0.25 mL/kg. These infants subsequently should receive the live measles vaccine when they are 15 months of age.³³³

Syphilis

Syphilis is a chronic systemic infection resulting from the spirochete *Treponema pallidum*. It has been recognized for several centuries that primary, secondary, and early latent syphilis in pregnant women cause infection of the fetus, with resultant stillbirths, congenital abnormalities, and active disease at birth. Because of this significant morbidity, great emphasis has been placed on routine screening of all pregnant women for syphilis. Acquisition is usually through sexual contact.

Epidemiology

Since the startling prediction in 1937 by United States Surgeon General Thomas Parran that 10% of Americans would be infected with syphilis during their lives, the rates of primary and secondary syphilis have dramatically decreased, finally reaching a nadir in 2000 (Fig. 38-7).³³⁴ This striking decline was associated with the institution of public health control measures and the availability of penicillin. The generally downward trend in the syphilis rate was temporarily interrupted in the late 1970s and early 1980s when the rates of primary and secondary syphilis began increasing, in large part due to increases among men having sex with men. After the advent of the HIV/AIDS epidemic and public health efforts promoting safer sex, the rates of syphilis resumed their downward trend.

However, in the late 1980s another transient epidemic of primary and secondary syphilis occurred in the United States.⁴ Coincident with this rise was a dramatic increase in reported cases of congenital syphilis.³³⁵ After a low of 108 cases of congenital syphilis in 1978, there were 350 cases reported in 1986, and 3850 cases in 1992, with an incidence rate of 100 per 100,000 live births (Fig. 38-8). Almost 90% of congenital syphilis cases occurred among blacks or Hispanics, and 50% of the cases occurred among mothers receiving no prenatal care. Reasons for this dramatic upsurge include exchange of drugs (e.g., "crack" cocaine) for sex; decreased funding for syphilis control; treatment of penicillinase-producing *N. gonorrhoeae* with spectinomycin, which

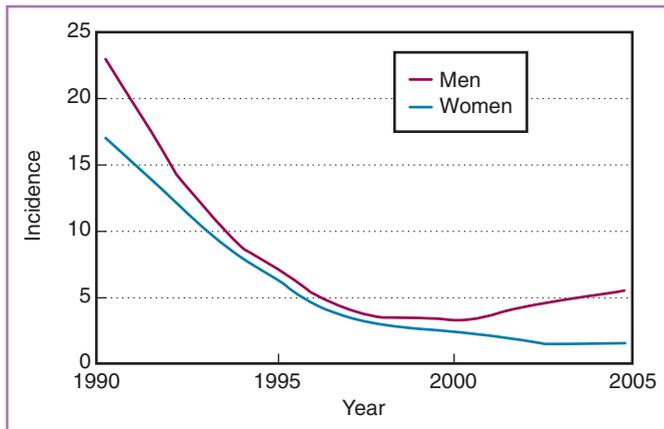

FIGURE 38-7 Incidence of primary and secondary syphilis per 100,000 population, by sex—United States, 1990-2005. During 2004-2005, the incidence of primary and secondary syphilis in the United States increased slightly, from 2.7 to 3.0 cases per 100,000 (from 0.8 to 0.9 per 100,000 in women, and from 4.7 to 5.1 per 100,000 in men).

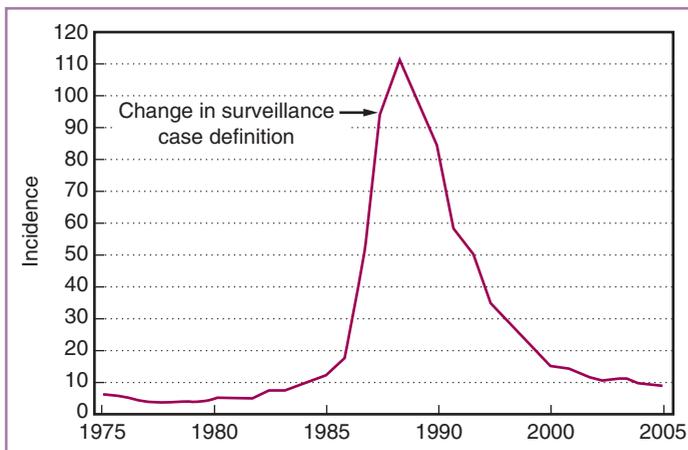

FIGURE 38-8 Incidence of congenital syphilis (per 100,000 live births) among infants aged 0 to 12 months—United States, 1975-2005. The incidence of congenital syphilis has declined since 1991. In 2005, the rate was 8.0 cases per 100,000 live births.

does not treat incubating syphilis; and the use of revised reporting guidelines for congenital syphilis, which were introduced in 1989.

Following this latest epidemic, the rates of primary and secondary syphilis fell from their peak in 1990 (18.4 cases per 100,000 population and more than 112,000 reported cases of primary and secondary syphilis) to a nadir in 2000 (2.1 cases per 100,000 population and fewer than 6000 reported cases of primary and secondary syphilis). This was the lowest rate since syphilis reporting began in 1941. Concomitant with the plummeting rates of primary and secondary syphilis, the rates of congenital syphilis also dramatically fell, declining from 3850 cases in 1992 to 451 cases in 2002.³³⁶

As a result of this dramatic decline in syphilis rates, the CDC launched the National Syphilis Elimination Plan in 1999. However, this plan for elimination of syphilis in the United States has proved overly optimistic.³³⁷⁻³³⁹

Pathogenesis

T. pallidum is efficiently transmitted during sexual contact, and syphilis is acquired in 50% to 60% of partners after a single sexual exposure to an infected individual with early syphilis. Spirochetes may gain access through any break in the skin or via microscopic tears in genital tract mucosal surfaces, which occur almost universally during sexual intercourse. The mean incubation time is 21 days, with a range of 10 to 90 days.⁴

The primary stage of syphilis is characterized by the chancre, which appears at the site of entry for *T. pallidum*. The chancre is a painless, nontender, ulcerated lesion with a raised border and an indurated base. The most common site for the chancre is the genital area. In men, the lesion is easily apparent, and syphilis is often diagnosed in its primary stage. In women, the lesion most commonly is on the cervix or in the vagina and is not recognized. Therefore, the chancre often escapes detection in women, and it is unusual to diagnose the primary stage of syphilis in females. Usually only a single chancre is present, but multiple chancres occur in up to 30% of cases. Painless inguinal lymphadenopathy is frequently present. The primary chancre, even without treatment, heals spontaneously in 3 to 6 weeks.

After resolution of the primary stage, the patient enters the secondary or spirochetemia (bacteremia) stage of syphilis. Syphilis always disseminates during the secondary stage. Any organ can potentially be infected, especially the CNS. Although the secondary stage of syphilis is characterized by involvement of all major organ systems by *T. pallidum*, it manifests most commonly with skin and mucous membrane lesions. These clinical manifestations of secondary syphilis include a generalized maculopapular rash that begins on the trunk and proximal extremities and spreads to the entire body, especially involving the palms and soles; mucous patches; condyloma latum; and generalized lymphadenopathy. These mucocutaneous lesions are highly contagious.

Even without treatment, the manifestations of secondary syphilis spontaneously clear within 2 to 6 weeks, and the latent stage of syphilis is entered, in which there is no apparent clinical disease. In the era before the availability of penicillin, about 25% of such patients had a recrudescence of secondary syphilis. Because these relapses usually occurred within 1 year, the term “early latent period” was applied to this time period. In the late latent stage (>1 year), patients are not contagious by sexual transmission, but the spirochete may still be transplacentally transmitted to a fetus.^{340,341}

Without treatment, one third of patients progress and develop tertiary syphilis, characterized by involvement of the cardiovascular, central nervous, or musculoskeletal, and/or various organ systems with gummas (late benign tertiary syphilis).³⁴⁰ One half of patients with tertiary syphilis develop late benign syphilis (gummas), one fourth develop cardiovascular disease, and one fourth have neurologic disease. The cardiovascular manifestations of tertiary syphilis include aortic aneurysm and aortic insufficiency. In the CNS, tertiary disease produces general paresis, tabes dorsalis, optic atrophy, and meningovascular syphilis. The Argyll-Robertson pupil (i.e., pupil does not react to light but accommodates) is virtually pathognomonic of tertiary syphilis. The pathogenesis of tertiary syphilis is based on the tropism of *T. pallidum* for arterioles, which results in obliterative endarteritis with subsequent tissue destruction.

Congenital Syphilis

The clinical spectrum in congenital syphilis includes stillbirth, neonatal death, nonimmune hydrops, clinically apparent syphilis during the

early months of life (early congenital syphilis), and the classic stigmata of late congenital syphilis (see Table 38-17).⁴ The most severe adverse pregnancy outcomes occur with primary or secondary syphilis. Pregnant women diagnosed with syphilis are usually in the latent stage and have had the disease for longer than 1 year. Consequently, about two thirds of infants with early congenital syphilis are asymptomatic at birth and do not develop evidence of active disease for 3 to 8 weeks. Chancres do not occur unless the disease is acquired at the time of passage through the birth canal. The characteristic manifestations of early congenital syphilis (onset at <2 years of age) include a maculopapular rash that may progress to desquamation or formation of vesicles and bullae, snuffles (a flulike syndrome associated with a nasal discharge), mucous patches in the oral pharyngeal cavity, hepatosplenomegaly, jaundice, lymphadenopathy, pseudoparalysis of Parrot due to osteochondritis, chorioretinitis, and iritis.³⁴¹

Untreated or incompletely treated early congenital syphilis will progress to the classic manifestations of late congenital syphilis. These include Hutchinson teeth, mulberry molars, interstitial keratitis, eighth-nerve deafness, saddle nose, rhagades, saber shins, and neurologic manifestations (mental retardation, hydrocephalus, general paresis, optic nerve atrophy, and Clutton joints). These stigmata associated with late congenital syphilis are the result of scarring induced by early lesions or reactions to persistent inflammation.³⁴¹

T. pallidum can cross the placenta and infect the fetus as early as the 6th gestational week.³⁴² Clinical manifestations are not apparent until after 16 weeks of gestation, when fetal immunocompetence develops. Therefore, the risk to the fetus is present throughout pregnancy, and the degree of risk is related to the quantity of spirochetes in the maternal bloodstream. Transmission may also occur intrapartum via contact with active genital lesions in the mother. Women with primary or secondary syphilis are more likely to transmit infection to their offspring than are women with latent disease. Maternal primary syphilis and secondary syphilis are associated with a 50% probability of congenital syphilis and a 50% rate of perinatal death; early latent syphilis, with a 40% risk of congenital syphilis and a 20% mortality rate; and late latent syphilis, with a 10% risk of congenital syphilis.^{343,344} Similar high rates of morbidity and mortality among the infants of mothers with untreated syphilis of less than 4 years' duration were reported in 1959 by Inraham,³⁴⁵ who noted a perinatal death rate of 43% (29% stillborn, and 14% neonatal); among liveborn infants, 41% had congenital syphilis.

Experience during the syphilis epidemic in the late 1980s and early 1990s confirmed that untreated syphilis is associated with significant and frequent adverse effects on pregnancy. Ricci and associates³⁴⁶ reported that, among 56 cases of congenital syphilis, 19 (35%) were stillbirths, and the perinatal mortality rate was 464 per 1000 live births. Preterm labor and delivery were significantly more common, infants with congenital syphilis had significantly lower birth weights, and 21% had intrauterine growth restriction. McFarlin and coworkers³³⁵ reviewed 253 cases of maternal syphilis. They reported a preterm delivery rate of 28%; 10 (13.9%) of 72 cases of congenital syphilis were stillbirths. In addition, the manifestations of congenital syphilis are usually less severe in association with long-standing maternal disease than with early syphilis of less than 1 year's duration. Coles and colleagues,³⁴⁷ in a review of 322 cases of congenital syphilis in upstate New York from 1989 to 1992, reported that 31 (10%) stillbirths and 59 (19%) newborns with clinical evidence of congenital syphilis were documented. Factors believed to contribute to the development of congenital syphilis included infection late in pregnancy, treatment less than 30 days before delivery, misdiagnosis or inappropriate treatment of the mother, and no serologic testing during pregnancy.

Diagnosis

The most definitive methods for diagnosing early syphilis are dark-field microscope examination or direct fluorescent antibody tests of lesion exudates or tissue.¹² A presumptive diagnosis can be made using serologic testing. The serologic tests are classified into two types: nonspecific tests for reagin-type antibodies and specific antitreponemal antibody tests.

Nonspecific antibody tests include the Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin (RPR) test. These are used for screening. All pregnant women should be screened at the initial prenatal visit. High-risk patients should be rescreened at 28 weeks of gestation. In areas with high rates of congenital syphilis, rescreening at admission in labor is also recommended. In populations in which prenatal care is less than optimal, RPR-card test screening is recommended at the time pregnancy is diagnosed, with treatment of patients who have a reactive test. The CDC recommends that any woman who delivers a stillborn infant after 20 weeks of gestation should be screened for syphilis. In addition, the CDC advises that no infant should leave the hospital without the maternal serostatus for syphilis having been assessed at some time in pregnancy.¹²

Treponema-specific tests are employed for confirming the diagnosis of syphilis in patients who have reactive VDRL or RPR results. These tests include the fluorescent treponemal antibody absorption (FTA-ABS) test and the *T. pallidum* particle agglutination (TP-PA) test.

Usually the nonspecific test result becomes nonreactive after treatment. In some patients, a low titer may persist for a long time, in some cases for life. Once reactive, specific treponemal tests usually remain positive for life. In pregnancy, it is best to consider all seropositive women as infected unless an adequate treatment history is documented and sequential serologic antibody titers have declined.

It is critical to recognize that when the syphilitic chancre first appears, both the nonspecific test results and the treponemal-specific test results may be nonreactive. Therefore, lesions suspicious for syphilis should be sampled for detection of spirochetes and submitted to the laboratory for dark-field examination and fluorescent-antibody staining.

Although the CNS is involved in almost half of the patients with early syphilis, fewer than 10% of patients with untreated syphilis progress to symptomatic late neurosyphilis. If patients are treated appropriately for early syphilis, neurosyphilis should be extremely rare. The CDC has stated that, unless clinical signs or symptoms of neurologic involvement are present, lumbar puncture is not recommended for routine evaluation in primary or secondary syphilis. In patients with latent syphilis, prompt CSF examination should be performed if any of the following conditions is present¹²:

1. Clinical evidence of neurologic involvement (e.g., cognitive dysfunction, motor or sensory deficits, ophthalmic or auditory symptoms, cranial nerve palsies, symptoms or signs of meningitis)
2. Evidence of active tertiary syphilis (e.g., aortitis, gummas, iritis)
3. Treatment failure
4. HIV infection with latent syphilis or syphilis of unknown duration

Recently, it has been suggested that only HIV-infected patients with neurologic manifestations or a serum RPR result of 1/32 or greater require a lumbar puncture.³⁴⁸ Marra and colleagues³⁴⁹ studied 326 patients with syphilis in an attempt to define clinical and laboratory

features that identify patients with neurosyphilis. Sixty-five patients (20.1%) had neurosyphilis. In multivariate analysis, an RPR titer of 1/32 or greater increased the odds of neurosyphilis almost 11-fold in HIV-uninfected individuals and almost sixfold among HIV-infected patients. In HIV-infected subjects, a CD4⁺ of 350 cells/mL or less conferred a 3.10-fold increased odds of neurosyphilis.

No single test is adequate to diagnose neurosyphilis in all patients. Therefore, the diagnosis is based on various combinations of tests, including reactive serologic tests, abnormal CSF cell count, elevated protein, and/or a reactive CSF VDRL, with or without clinical manifestations. CSF studies demonstrating pleocytosis, elevated protein levels, and a reactive CSF VDRL are diagnostic of neurosyphilis. On occasion, however, results may be nonreactive when neurosyphilis is present. Recently, it has been suggested that increased levels of tau protein may be useful in discriminating neurosyphilis from syphilis without nervous system involvement.³⁵⁰

The diagnosis of reinfection or persistence of active syphilis can be made in patients previously known to have syphilis by following the titer of the quantitative VDRL. With successful therapy, the VDRL titer should decrease and become negative or very low within 6 to 12 months in early syphilis and within 12 to 24 months in late syphilis (>1 year's duration). A rising titer indicates the need for further diagnostic measures, such as a lumbar puncture, and appropriate treatment.

The diagnosis of congenital syphilis is easily confirmed in the clinically apparent case in which a jaundiced, hydropic baby with florid disease and a large, edematous placenta are delivered and laboratory studies confirm the presence of the disease. However, most infected newborns are asymptomatic at birth. Although the cord blood may give a positive nonspecific test result for syphilis, the diagnosis of congenital syphilis is complicated by the transplacental transfer of maternal nontreponemal and treponemal IgG antibodies to the fetus.¹²

As a result, the interpretation of reactive serologic tests for syphilis in infants is difficult. Therefore, treatment decisions must be frequently made on the basis of (1) identification of syphilis in the mother; (2) adequacy (or lack thereof) of maternal treatment; (3) presence of clinical, laboratory or radiologic evidence of syphilis in the infant; and (4) comparison of maternal (at delivery) and infant nontreponemal serologic titers using the same test and same laboratory.¹² Any infant with a positive VDRL result but no clinical evidence of syphilis should have serial monthly quantitative VDRL tests for at least 9 months. A rising titer indicates active disease and the need for therapy. Infected infants may be asymptomatic and the serum VDRL may be normal if maternal infection occurred late in pregnancy.

In 1998, the CDC implemented a new case definition for congenital syphilis surveillance (Table 38-17). A diagnosis of congenital syphilis can be confirmed by identifying spirochetes in suspicious lesions, body fluids, or tissues with dark-field microscopy, silver staining, immunofluorescence, or PCR for *T. pallidum* DNA.³⁵¹ Several new laboratory tests have been introduced to facilitate the diagnosis of congenital syphilis. These include PCR and the rabbit infectivity test (RIT).

Treatment

All pregnant women who have a history of sexual contact with a person with documented syphilis, dark-field microscope confirmation of the presence of spirochetes, or serologic evidence of syphilis via a specific treponemal test should be treated. In addition, patients in whom the diagnosis cannot be ruled out with certainty or those who have been previously treated but now show evidence of reinfection, such as dark-

TABLE 38-17 CONGENITAL SYPHILIS CASE DEFINITION

Confirmed Case

Infant in whom *Treponema pallidum* is identified by dark-field microscopy, fluorescent antibody, or other specific stains in specimens from lesions, placenta, umbilical cord, or autopsy material

Presumptive Case

1. Any infant whose mother had untreated* or inadequately treated syphilis at delivery, regardless of signs or symptoms†

OR

2. Any infant or child who has a reactive treponemal test for syphilis and any one of the following:
 - a. Evidence of congenital syphilis on physical examination
 - b. Evidence of congenital syphilis on long-bone radiography
 - c. **Reactive CSF VDRL test**
 - d. Elevated CSF white blood cell count (>5/mm³) or protein concentration (>5 mg/dL)
 - e. Reactive test for FTA-ABS-19S-IgM antibody

CSF, cerebrospinal fluid; FTA-ABS, fluorescent treponemal antibody absorption; IgM, immunoglobulin M; VDRL, Venereal Disease Research Laboratory.

*On penicillin therapy or penicillin given <30 days before delivery.

†Clinical signs in an infant include hepatosplenomegaly, characteristic skin rash, condyloma lata, snuffles, jaundice, pseudoparalysis, anemia, thrombocytopenia, and edema. Stigmata in children older than 2 years of age include interstitial keratitis, nerve deafness, anterior bowing of shins, frontal bossing, mulberry molars, Hutchinson teeth, saddle nose, rhabdoid, and Clutton joints.

From Centers for Disease Control and Prevention: Congenital Syphilis Case Definition. Atlanta, GA: U.S. Department of Health and Human Services, CDC, 1998.

field microscope confirmation or a fourfold rise in titer on a quantitative nontreponemal test, should receive appropriate treatment.

Treatment schedules for syphilis recommended by CDC in 2006 are shown in Table 38-18. Penicillin administered parenterally is the preferred treatment for all stages of syphilis.¹²

The preparation of penicillin used and the length of treatment are determined by the stage and clinical manifestations of the disease. Although several alternatives to penicillin might be effective in non-pregnant penicillin-allergic patients, parenteral penicillin G is the only therapy with documented efficacy for syphilis during pregnancy. In pregnancy, parenteral penicillin G is effective for treating maternal infection, preventing transmission to the fetus, and treating established fetal infection. Therefore, the CDC recommends that pregnant patients with syphilis in any stage who are allergic to penicillin should be desensitized and treated with penicillin.¹²

Desensitization is a relatively safe and straightforward procedure that can be accomplished orally or intravenously. Oral desensitization is generally believed to be safer and easier to perform. Patients should be desensitized in a hospital setting, because serious IgE-mediated allergic reactions can occur. Desensitization can be accomplished in approximately 4 hours (Table 38-19), after which the first dose of penicillin is administered. After desensitization, patients must be maintained on penicillin continuously for the duration of their therapeutic course.

Although erythromycin was at one time considered an alternative to penicillin for the treatment of syphilis during pregnancy, its efficacy for treatment of syphilis in the fetus and for prevention of transmis-

TABLE 38-18 CDC-RECOMMENDED TREATMENT OF SYPHILIS DURING PREGNANCY, 2006

Diagnosis	Treatment
1. Primary, secondary, and early latent syphilis (<1 yr)	Benzathine penicillin G, 2.4 million units IM in a single dose
2. Late latent syphilis (>1 yr), latent syphilis of unknown duration, and tertiary syphilis	Benzathine penicillin G, 7.2 million units total, administered as 3 doses of 2.4 million units IM each at 1-wk intervals
3. Neurosyphilis	Aqueous crystalline penicillin G, 18-24 million units per day administered as 3-4 million units IV every 4 hr or by continuous infusion for 10-14 days OR Procaine penicillin, 2.4 million units IM daily, plus probenecid 500 mg PO qid, both for 10-14 days
4. Penicillin-allergic	Pregnant women with a history of penicillin allergy should have allergy confirmed and then be desensitized

sion is inadequate. Although doxycycline and tetracycline are alternatives for nonpregnant patients, they usually are not used in pregnancy.

Concern has been raised as to whether the recommended regimens of penicillin are optimal in pregnancy. Several reports demonstrated worrisome instances of treatment failures despite adherence to recommended guidelines.^{335,352} A high maternal VDRL titer at the time of diagnosis, unknown duration of infection, treatment within 4 weeks of delivery, and ultrasound signs of fetal syphilis (e.g., hepatomegaly, fetal hydrops, placentomegaly) are associated with failure to prevent congenital syphilis.

Because of these reports demonstrating a high failure rate for treatment of syphilis in pregnancy, some experts recommend additional therapy.¹² A second dose of benzathine penicillin G (2.4 million units intramuscularly) may be given 1 week after the initial dose for pregnant women with primary, secondary, or early latent syphilis. During the second half of pregnancy, management of syphilis may be facilitated by sonographic assessment for evidence of congenital syphilis. Sonographic signs of fetal or placental syphilis (e.g., hepatomegaly,

ascites, hydrops, a thickened placenta) indicate a greater risk for fetal treatment failure.³⁵³

Syphilis can involve the CNS during any stage of disease. Therefore, any patient with syphilis who demonstrates clinical evidence of neurologic involvement should have a lumbar puncture to assess the CSF for evidence of neurosyphilis. Patients with neurosyphilis should be treated with high doses of aqueous penicillin G, as noted in Table 38-17.

Obstetric caregivers should be aware that women treated for syphilis during the second half of pregnancy are at risk for preterm labor or fetal distress if the Jarisch-Herxheimer reaction occurs. The Jarisch-Herxheimer reaction occurs commonly during the treatment of early syphilis; among 33 pregnant women, the reaction complicated therapy in 100% and 60% of patients treated for primary or secondary syphilis, respectively.³⁵⁴ The Jarisch-Herxheimer reaction characteristically includes fever, chills, myalgia, headache, hypotension, and transient worsening of cutaneous lesions. It commences within several hours after treatment and resolves by 24 to 36 hours. Among pregnant women, the most frequent findings are fever (73%), uterine contrac-

tions (67%), and decreased fetal movement (67%). Transient late decelerations were observed in 30% of monitored fetuses.

Because of these findings, sonographic assessment of the fetus before initiating therapy for early syphilis in the last half of pregnancy has been recommended.³⁵⁵ If the results are normal, ambulatory treatment may be initiated. If abnormal findings suggesting fetal infection are identified, hospitalization for treatment and fetal monitoring is recommended. Sanchez and Wendel³⁵² demonstrated that, in the presence of severe fetal compromise before treatment, early delivery with treatment of the mother and neonate after delivery may yield an improved outcome.

For primary and secondary syphilis, patients should be re-examined clinically and serologically at 6 months and 12 months after treatment. A two-dilution (fourfold) decline in the nontreponemal titer at 1 year after treatment is used to define response.³⁵⁶ Patients with signs or symptoms that persist or recur and those with a sustained fourfold increase in the nontreponemal test titer have probably failed treatment or become reinfected. They should be re-treated, be assessed for HIV infection, and undergo analysis of the CSF. For re-treatment, weekly injections of benzathine penicillin G 2.4 million units IM for 3 weeks is suggested.¹²

With latent syphilis, quantitative nontreponemal titers should be repeated at 6, 12, and 24 months. Patients with a normal CSF examination should be re-treated for latent syphilis if (1) titers increase fourfold, (2) an initially high titer ($\geq 1:32$) fails to decline at least fourfold (i.e., two dilutions) within 12 to 24 months after therapy, or (3) signs or symptoms of syphilis develop. There is limited information available concerning either clinical response or follow-up in patients treated for tertiary syphilis.¹²

In pregnant women treated for syphilis, the CDC recommends repeating serologic titers at 28 to 32 weeks' gestation, and again at delivery, and following the recommendations described earlier for the stage of disease. Alternatively, serologic titers can be checked monthly in women who are at high risk for reinfection or who live in a geographic area where the prevalence of syphilis is high.¹²

Congenital syphilis is unusual if the mother received adequate treatment with penicillin during pregnancy. Infants should be treated for presumed congenital syphilis if they were born to mothers in the following categories:

1. Mothers who have untreated syphilis at delivery
2. Mothers who have serologic evidence of relapse or reinfection after treatment (i.e., a rise in titer by at least fourfold)
3. Mothers who were treated for syphilis during pregnancy with nonpenicillin regimens
4. Mothers who were treated for syphilis less than 1 month before delivery
5. Mothers who do not have a well-documented history of treatment of syphilis
6. Mothers who do not demonstrate an adequate response (fourfold decrease) of nontreponemal antibody titers despite appropriate penicillin treatment
7. Mothers who were treated for syphilis appropriately before pregnancy but had insufficient serologic follow-up to ensure response to treatment.

Any child with symptomatic congenital syphilis should undergo a lumbar puncture, complete blood count, and long-bone radiography before treatment. If these results are normal, a single intramuscular dose of benzathine penicillin G (50,000 units/kg) should be given. With abnormal results or if compliance is not ensured, the infant

should be given a 10-day course of either aqueous crystalline penicillin G (50,000 units/kg IV every 12 hours for the first 7 days of life, and then every 8 hours for the next 3 days) or procaine penicillin (50,000 units/kg/day IM).¹²

Prevention

Serologic screening of all pregnant women during the early stages of pregnancy is recommended. In geographic areas with a high prevalence of syphilis and in patients at high risk, serologic testing should be repeated at 28 to 32 weeks' gestation and at delivery.¹²

Toxoplasmosis

Epidemiology and Pathogenesis

Toxoplasma gondii is a protozoan that has three distinct life forms: trophozoite, cyst, and oocyst. The life cycle of this organism is dependent on wild and domestic cats, which are the only known host for the oocyst. The oocyst is formed in the intestine of the cat and subsequently is excreted in feces. Mammals, such as cows, ingest the oocyst, which is disrupted in the animal's intestine, releasing the invasive trophozoite. The trophozoite then is disseminated throughout the body, ultimately forming cysts in brain and muscle.³⁵⁷

Human infection occurs when infected meat is ingested or oocysts are ingested via contamination by cat feces. Infection rates are highest in areas of poor sanitation and crowded living conditions. Stray cats and domestic cats that eat raw meat are most likely to carry the parasite. The cyst is completely destroyed by heating.

Approximately half of all adults in the United States have antibody to this organism. Immunity is usually long-lasting except in immunosuppressed patients. The prevalence of antibody is highest in lower socioeconomic classes. The frequency of seroconversion during pregnancy is approximately 5%, and about 3 in 1000 infants show evidence of congenital infection. Clinically significant infection occurs in only 1 in 8000 pregnancies. Clinical manifestations of infection are the result of direct organ damage and the subsequent immunologic response to parasitemia and cell death. Immunity to this infection is mediated primarily through T lymphocytes.³⁵⁷

Diagnosis

Most infections in humans are asymptomatic. Even in the absence of symptoms, however, patients may have evidence of multiorgan involvement, and clinically apparent disease can develop after a long period of asymptomatic infection. Symptomatic toxoplasmosis usually manifests as an illness similar to mononucleosis.

In contrast to infection in the immunocompetent host, toxoplasmosis can be a devastating infection in the immunosuppressed patient. In these individuals, dysfunction of the CNS is the most common manifestation of infection. Findings typically include encephalitis, meningoencephalitis, and intracerebral abscess. Pneumonitis, myocarditis, and generalized lymphadenopathy also occur commonly.

Routine screening for toxoplasmosis in pregnancy is not indicated. However, immunosuppressed patients, women who have contact with outdoor cats, and patients with suspicious symptoms should be tested. The diagnosis of toxoplasmosis in the mother is best confirmed by serology. Serologic tests suggestive of an acute infection include identification of IgM-specific antibody, demonstration of an extremely high IgG antibody titer, and documentation of IgG seroconversion

from negative to positive. Clinicians should be aware that serologic assays for toxoplasmosis are not well standardized. Therefore, if initial laboratory tests suggest an acute maternal infection, additional evaluation, as detailed in the following paragraphs, is indicated before concluding that the fetus is at risk for serious injury.^{357,358}

Approximately 40% of neonates born to mothers with acute toxoplasmosis have evidence of infection. Congenital infection is most likely to occur when maternal infection develops during the third trimester. The risk of injury to the fetus is greatest, however, when maternal infection occurs in the first trimester.

The usual clinical manifestations of congenital toxoplasmosis include a disseminated purpuric rash, enlargement of the spleen and liver, ascites, chorioretinitis, uveitis, periventricular calcifications, ventriculomegaly, seizures, and mental retardation. Chronic or latent infection in the mother is unlikely to be associated with serious fetal injury.

The most valuable test for confirmation of congenital toxoplasmosis is detection of toxoplasmic DNA in amniotic fluid using the PCR methodology. In an important initial investigation, Hohlfeld and associates³⁵⁹ identified 34 infants with confirmed congenital toxoplasmosis. Amniotic fluid specimens from all affected pregnancies were positive by PCR, and test results were available within 1 day after specimen collection. In a subsequent investigation, Romand and colleagues³⁶⁰ reported that the PCR test for toxoplasmic DNA had an overall sensitivity of 64% (CI, 53% to 75%). No false-positive results were noted, and the positive predictive value was 100%. Once amniocentesis has confirmed toxoplasmic infection, targeted ultrasound examination is indicated to look for specific findings suggestive of severe fetal injury.

Treatment

In the immunocompetent adult, toxoplasmosis usually is an asymptomatic or self-limited illness that does not require treatment. Immunocompromised patients should be treated with a combination of oral sulfadiazine (4-g loading dose followed by 1 g four times daily) plus pyrimethamine (50 to 100 mg initially, then 25 mg daily). Extended courses of treatment may be necessary to cure the infection.

When acute toxoplasmosis occurs during pregnancy, treatment is indicated, because maternal therapy reduces the risk of congenital infection and decreases the late sequelae of infection. Pyrimethamine is not recommended for use during the first trimester of pregnancy because of possible teratogenicity. Sulfonamides may be used alone, but single-agent therapy appears to be less effective than combination therapy. Spiramycin has been used extensively in European countries with excellent success. It is available in the United States through special permission from the CDC.³⁵⁸

Aggressive early treatment of infants with congenital toxoplasmosis is indicated and consists of combination therapy with pyrimethamine, sulfadiazine, and leucovorin for 1 year. Early treatment reduces, but does not eliminate, the late sequelae of toxoplasmosis such as chorioretinitis. Early treatment of the neonate appears to be comparable in effectiveness to in utero therapy.³⁶¹

In pregnant women, prevention of toxoplasmosis is of paramount importance. Pregnant women should be advised to avoid contact with cat litter if at all possible. If they must change the litter, they should wear gloves and wash their hands afterward. They should always wash their hands after preparing meat for cooking, and they should never eat raw or rare beef, fowl, or pork. Meat should be cooked thoroughly until the juices are clear. Fruits and vegetables also should be washed carefully to remove possible contamination by oocysts.

Varicella-Zoster Virus Infection

Epidemiology and Pathogenesis

The varicella-zoster virus (VZV) is a DNA organism that is a member of the herpesvirus family. The organism causes varicella (chickenpox) and herpes zoster infection (shingles). Varicella is of great importance in pregnancy because it poses risks to the mother, fetus, and neonate.³⁶² Herpes zoster infection can be a painful and somewhat debilitating condition, especially in an immunosuppressed patient. However, because it occurs in a patient who already has antibody against VZV, herpes zoster poses essentially no risk to the fetus or neonate and is not discussed further in this chapter.

Varicella occurs in approximately 1 to 5 cases per 10,000 pregnancies. The infection is transmitted by respiratory droplets and by direct contact with vesicular lesions. The incubation period of the organism is 10 to 14 days. Varicella is among the most highly contagious of any viral infection.³⁶³

Diagnosis

The typical clinical manifestation of varicella is a disseminated, pruritic, vesicular rash. The lesions typically occur in crops and evolve in sequential fashion from vesicle to pustule, eventually crusting over to form a dry scab. Varicella is almost always a mild, self-limited infection in children. However, approximately 20% of infected adults develop pneumonia, and approximately 1% develop encephalitis. Both of these complications can cause serious morbidity and even mortality. The diagnosis can be confirmed by identification of anti-VZV IgM antibody.³⁶³

Treatment

All pregnant women should be questioned about prior varicella at the time of their first prenatal appointment. If they have a well-defined history of infection, they should be reassured that second infections are extremely unlikely and that, should a second infection occur, the risk to the fetus is negligible. Women who are not certain of prior exposure should have an anti-VZV IgG assay. Approximately 75% of individuals who are uncertain about their prior history actually have definitive serologic evidence of immunity. Women who do not have antibody against varicella should be cautioned about the need to avoid exposure to people who have vesicular viral eruptions.^{364,365}

If a susceptible pregnant patient is exposed to someone with varicella, she should be treated within 72 to 96 hours with one of two agents to prevent active infection. The most extensively tested regimen is intramuscular varicella zoster immune globulin (VZIG), 1 vial per 10 kg of weight up to a maximum of 5 vials.³⁶⁶ However, the U.S. company that manufactured this agent has discontinued its production, and securing the product through international manufacturers is problematic. An alternative method of prophylaxis is to administer oral acyclovir (800 mg, five times daily for 7 days) or oral valacyclovir (1000 mg, three times daily for 7 days).³⁶⁷

Pregnant women who develop varicella despite immunoprophylaxis should be treated with oral acyclovir or valacyclovir in the same dose as outlined for prophylaxis. Patients who have evidence of pneumonia, encephalitis, or disseminated infection and those who are immunosuppressed should be hospitalized and treated with intrave-

nous acyclovir (10 mg/kg infused over 1 hour every 8 hours for 10 days).^{363,366,368}

Acute varicella infection during pregnancy has been associated with spontaneous abortion, intrauterine fetal death, and congenital anomalies. However, these complications are rare. Investigations, have shown that the frequency of fetal anomalies was less than 1% when maternal infection occurred in weeks 1 through 12 of pregnancy and 2% or less when infection occurred in weeks 13 through 20.^{369,370}

The most valuable test to identify fetal injury due to congenital varicella is targeted ultrasound examination. Possible findings include intrauterine growth restriction, microcephaly, ventriculomegaly, echogenic foci in the fetal liver, and limb anomalies.³⁶³

Neonatal varicella, as opposed to congenital varicella infection, occurs when the mother develops acute varicella during the period from 5 days before to 2 days after delivery. If infection occurs at this time, there is no opportunity for protective antibody to cross the placenta. The manifestations of neonatal varicella include disseminated mucocutaneous lesions, visceral infection, pneumonia, and encephalitis. In the absence of timely antiviral chemotherapy, up to 30% of infected infants die of complications of neonatal varicella. Infants born during this window of time must avoid contact with vesicular lesions on the mother's skin. These infants, and any infants with suspected exposure in the nursery or postpartum ward also should receive immunoprophylaxis with VZIG or treatment with antiviral agents such as acyclovir or valacyclovir.³⁶³

Prevention

In an effort to prevent the serious conditions noted here, all women of reproductive age should be vaccinated for varicella if they have not already acquired natural immunity. The varicella vaccine (Varivax) is a live virus vaccine that is highly immunogenic. Individuals aged 1 to 12 years should receive one dose of the vaccine subcutaneously. Individuals older than 12 years of age require two subcutaneous doses, administered 4 to 6 weeks apart. Contraindications to the vaccine include pregnancy, an immunodeficiency disorder, high-dose corticosteroid therapy, untreated tuberculosis, severe systemic illness, and an allergy to neomycin, which is one component of the vaccine.^{365,371,372} The CDC guidelines³⁶⁶ indicate that the vaccine may be considered in breastfeeding mothers, although there is little information about whether the vaccine virus is excreted in breast milk. Vaccine recipients pose minimal risk of transmitting infection to susceptible contacts if no rash develops after the vaccination. If a rash does develop, there is a very small risk of transmission to susceptible contacts.³⁶⁵

Viral Influenza

Epidemiology

Influenza is caused by an RNA virus of the myxovirus family. Three antigenically different influenza viruses have been identified.³⁷³ Type A influenza is responsible for most epidemics and is associated with severe clinical presentation. Type B influenza is less frequently associated with epidemics and tends to cause milder clinical disease. Type C is the least frequent type and, as a result, is not accounted for in the annual influenza vaccine.

Influenza is of major clinical importance, both in the United States and worldwide. In the United States, the disease causes 30,000 to 40,000 excess deaths and approximately 200,000 hospitalizations

annually.^{374,375} Pregnant women suffer disproportionate morbidity and mortality during influenza pandemics.³⁷⁶

Influenza virus is characterized by low-level alterations of the surface proteins of influenza A (hemagglutinin A and neuraminidase). This antigenic drift allows the virus to change enough to evade the host's immune system response and cause the yearly epidemics. At approximately 20- to 40-year intervals, a more profound change of the surface proteins occurs, possibly as a result of genetic recombination, and leads to a substantially different surface protein configuration. It is this antigenic shift that imparts the novel properties for a virulent strain of influenza virus associated with pandemics. The aggressive nature of pandemic influenza also results, in part, from the lack of relevant immunity in the population to this novel surface protein configuration.³⁷⁶

Three influenza pandemics occurred in the last century: 1918, 1957, and 1968. Of these, two were major in nature. The pandemic of 1918 was responsible for between 30 and 50 million deaths worldwide and 500,000 deaths in the United States. The Asian influenza pandemic of 1957-1958 also caused substantial morbidity and mortality.³⁷⁷

The influenza A strains responsible for all three of these great pandemics originated in Southeast Asia. Great concern has arisen that another pandemic of influenza will soon occur because of the emergence of a new influenza A strain (avian H5N1) in that region.³⁷⁸ According to the World Health Organization, this virus has caused almost 100 deaths and has a case mortality rate of 55%.³⁷⁹ Although cases in humans have been reported, to date efficient human-to-human transmission has not occurred. Given the natural history of genetic shifting and evolution of the influenza virus, the ease of rapid worldwide travel, and the crowded living conditions in many areas of the world, it may only be a matter of time before a pandemic on the scale of the 1918 influenza pandemic (or greater) occurs.³⁷⁶

Annually, in the United States, influenza is responsible for 82 million infections and health care costs estimated at billions of dollars.³⁸⁰ Epidemics in the United States occur during the winter months (November through March). The rates of infection are highest in children, who are a major reservoir for spread of infection to adults, including pregnant women. The rates of serious illness and death are highest among persons 65 years of age and older, children younger than 2 years of age, and people of any age who have medical conditions that place them at increased risk for complications of influenza.³⁸¹

Pathogenesis

The influenza virus is transmitted primarily by respiratory droplets and, to a limited extent, by direct contact. The incubation period is relatively short, 1 to 5 days. Influenza occurs most commonly in the late fall and winter, and epidemics recur with regularity because the virus mutates in important ways from year to year. Immunity to the strains that caused infection in one year does not necessarily provide protection against strains that circulate in subsequent years.

Influenza can range in severity from a mild respiratory infection to a life-threatening pneumonia. The illness typically begins abruptly with prodromal symptoms of malaise, myalgia, and headache in association with fever. Subsequently, the patient develops a dry, nonproductive cough, coryza, mild dyspnea, and sore throat. On physical examination, the temperature is elevated and the pharynx is inflamed; auscultation of the chest discloses rales and rhonchi. In some patients, a secondary bacterial pneumonia develops, and their cough then becomes productive of purulent sputum.³⁸²

Influenza virus infects the ciliated columnar epithelial cells of the respiratory tract, with resultant cellular necrosis and sloughing. Con-

sequently, either the upper or the lower respiratory tract may be a site of infection.

In pregnancy, the major concern is the increased risk for development of life-threatening pneumonia.^{373,376} Influenza virus has not been associated with an increased risk of spontaneous abortion, stillbirth, or congenital anomalies. However, an infant delivered to an acutely infected patient may develop neonatal influenza as a result of close personal contact with the mother after delivery. In addition, mothers with severe respiratory infections may have an increased risk of preterm labor. In previous reports of influenza pandemics, pregnant women experienced increased morbidity and mortality compared with nonpregnant patients.³⁸³⁻³⁸⁵

Neuzil and coauthors³⁸⁶ assessed the impact of influenza on pregnant women during nonpandemic “flu” seasons. They reported that the relative risk for hospitalization with cardiorespiratory complications in pregnant women, compared with nonpregnant women, was 1.4 at 14 to 20 weeks’ gestation, rising to 4.7 in weeks 37 through 42. Moreover, women in the third trimester had a hospitalization rate similar to that of nonpregnant women with high-risk medical conditions.

Diagnosis

The presence of the clinical manifestations described earlier is highly suggestive of influenza. The diagnosis can be confirmed by culture of the virus from respiratory secretions and by documentation of characteristic rises in serum antibody to influenza A and B. Chest radiography also may be of great value in assessing the severity of the pulmonary infection.

Treatment

The management of influenza in pregnant women is similar to that in nonpregnant persons, consisting of symptomatic relief, with bed rest, analgesia, liberal fluid intake, and fever control with acetaminophen (650 mg PO every 4 to 6 hours, maximum 4 g/24 hours). Patients should be reevaluated immediately if signs of worsening pneumonia or preterm labor develop. In addition, if they have disabling symptoms, they should be offered treatment with either zanamivir (10 mg twice daily for 5 days) or oseltamivir (75 to 150 mg PO twice daily for 5 days).³⁸⁷ Although amantadine is effective in nonpregnant patients, it has been associated with teratogenic effects in animals and is not recommended for use in pregnancy.³⁷³ If pneumonia occurs in a pregnant woman with influenza, prompt hospitalization with broad-spectrum antibiotic coverage for bacteria that cause superinfection (e.g., *S. aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*) is required. Respiratory support is indicated in the presence of inadequate oxygenation, retention of carbon dioxide, or excessively labored breathing.

Prevention

The key to the prevention of influenza is vaccination. Immunization is 70% to 90% effective in either preventing influenza or diminishing the severity of illness. The ACIP^{381,388} recommends annual vaccination for

1. Children aged 6 to 59 months
2. Women who will be pregnant during flu season
3. Persons aged 50 years or older
4. Children and adolescents (aged 6 months to 18 years) who are receiving long-term aspirin therapy

5. Adults and children with chronic disorders of pulmonary or cardiovascular systems
6. Adults and children who have required medical follow-up or hospitalization in the past year for chronic metabolic diseases (e.g., diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunodeficiency
7. Persons having any condition that compromises respiratory function or increases risk of aspiration
8. Residents of nursing homes and other chronic care facilities
9. Persons living with or caring for individuals at high risk for influenza-related complications
10. Health care workers

The vaccine contains killed, inactivated virus and is safe for use in pregnancy. Since 2004, the CDC has recommended universal vaccination for all pregnant women regardless of gestational age.³⁸¹ Roberts and colleagues³⁸⁸ recently demonstrated that universal vaccination with inactivated trivalent influenza vaccine is cost-saving in pregnant women. The recently available live, attenuated intranasal influenza vaccine is contraindicated during pregnancy.^{381,389}

Viral Hepatitis

Hepatitis A

Hepatitis A is the second most common form of viral hepatitis in the United States. The infection is caused by an RNA virus that is transmitted by fecal-oral contact. The incubation period ranges from 15 to 50 days. Infections in children are usually asymptomatic; infections in adults are usually symptomatic. The disease is most prevalent in areas of poor sanitation and close living.³⁹⁰

The typical clinical manifestations of hepatitis include low-grade fever, malaise, poor appetite, right upper quadrant pain and tenderness, jaundice, and acholic stools. The diagnosis is best confirmed by detection of IgM antibody specific for the hepatitis A virus.

Hepatitis A does not cause a chronic carrier state. Perinatal transmission virtually never occurs, and, therefore, the infection does not pose a major risk to either the mother or the baby. The exception is the development of fulminant hepatitis and liver failure in the mother, but such a situation is extremely rare.³⁹⁰

Hepatitis A can be prevented by administration of an inactivated vaccine. Two formulations of the vaccine are available: Vaqta and Havrix. Both vaccines require an initial intramuscular injection, followed by a second dose 6 to 12 months later. The vaccine should be offered to the following individuals in the following categories³⁹¹:

- International travelers
- Children in endemic areas
- Intravenous drug users
- Individuals who have occupational exposure (e.g., workers in a primate laboratory)
- Residents and staff of chronic care institutions
- Individuals with liver disease
- Homosexual men
- Individuals with clotting factor disorders

Standard immune globulin provides reasonably effective passive immunization for hepatitis A if it is given within 2 weeks after exposure. The standard intramuscular dose of immune globulin is 0.02 mg/kg.³⁹²

Hepatitis E

Hepatitis E is caused by an RNA virus. The epidemiology of hepatitis E is similar to that of hepatitis A. The incubation period averages 45 days. The disease is rare in the United States but is endemic in developing countries of the world. In these countries, maternal infection with hepatitis E often has an alarmingly high mortality rate, in the range of 10% to 20%. This is probably less the result of virulence of the microorganism and more related to poor nutrition, poor general health, and lack of access to modern medical care.³⁹⁰

The clinical presentation of acute hepatitis E is similar to that of hepatitis A. The diagnosis can be established with the use of electron microscopy to identify viral particles in the stool of infected patients. The most useful diagnostic test, however, is serology.

Hepatitis E does not cause a chronic carrier state. Perinatal transmission can occur but is extremely rare.³⁹³

Hepatitis B

Hepatitis B is caused by a DNA virus that is transmitted parenterally and via sexual contact. The infection also can be transmitted perinatally from an infected mother to her infant.

Acute hepatitis B occurs in 1 or 2 of every 1000 pregnancies in the United States. The chronic carrier state is more frequent, occurring in 6 to 10 of 1000 pregnancies. Worldwide, more than 400 million individuals are chronically infected with hepatitis B virus. In the United States alone, approximately 1.25 million people are chronically infected.³⁹⁰

Approximately 90% of patients who acquire hepatitis B mount an effective immunologic response to the virus and completely clear their infection. Fewer than 1% of infected patients develop fulminate hepatitis and die. Approximately 10% of patients develop a chronic carrier state. Some individuals with chronic hepatitis B infection ultimately develop severe chronic liver disease such as chronic active hepatitis, chronic persistent hepatitis, cirrhosis, or hepatocellular carcinoma. This sequela is particularly likely in patients who are coinfecting with hepatitis D or hepatitis C or both.³⁹⁰

The diagnosis of hepatitis B is best confirmed by serologic tests. Patients with acute hepatitis B are positive for the hepatitis B surface antigen and positive for IgM antibody to the core antigen. Patients with chronic hepatitis B are positive for the surface antigen and positive for IgG antibody to the core antigen. Acutely or chronically infected patients may or may not be positive for the hepatitis B e antigen. If this latter antigen is present, it denotes active viral replication and a high level of infectivity.³⁹⁴

In the absence of intervention, approximately 20% of mothers who are seropositive for hepatitis B surface antigen will transmit infection to their neonates. Approximately 90% of mothers who are positive for both the surface antigen and the e antigen transmit infection. Fortunately, excellent immunoprophylaxis for prevention of perinatal transmission of hepatitis B infection is now available. Infants delivered to seropositive mothers should receive hepatitis B immune globulin within 12 hours after birth. Before their discharge from the hospital, these infants also should begin the hepatitis B vaccination series. The CDC now recommends universal vaccination of all infants for hepatitis B. In addition, the vaccine should be offered to all women of reproductive age.^{394,395}

Hepatitis D (Delta Virus Infection)

Hepatitis D is an RNA virus that is dependent on coinfection with hepatitis B for replication. Therefore, the epidemiology of hepatitis D

is essentially identical to that of hepatitis B. Patients with hepatitis D may have two types of infection. Some have acute hepatitis D and hepatitis B (coinfection). These individuals typically clear their infection and have a good long-term prognosis. Others have chronic hepatitis D infection superimposed on chronic hepatitis B infection (superinfection). These women are particularly likely to develop chronic liver disease.³⁹⁰

The diagnosis of hepatitis D can be established by identifying the delta antigen in liver tissue or serum. However, the most useful diagnostic tests are detection of IgM and/or IgG antibody in serum.³⁹⁰

As noted, hepatitis D can cause a chronic carrier state in conjunction with hepatitis B infection. Perinatal transmission of hepatitis D occurs but is uncommon. Moreover, the immunoprophylaxis outlined for hepatitis B is highly effective in preventing transmission of hepatitis D.^{390,394}

Hepatitis C

Hepatitis C is caused by an RNA virus. The virus may be transmitted parenterally, via sexual contact, and perinatally. In many patient populations, hepatitis C is as common or more common than hepatitis B. Chronic hepatitis C infection now is the number one indication for liver transplantation in the United States.^{390,396-398}

Hepatitis C is usually asymptomatic, at least in its initial stages. The diagnosis is best confirmed by serologic testing. The initial screening test should be an EIA. The confirmatory test is a recombinant immunoblot assay (RIBA). Seroconversion may not occur for up to 16 weeks after infection. In addition, although these immunologic tests have been available for many years, they still do not consistently and precisely distinguish between IgM and IgG antibody.³⁹⁰

In patients who have a low serum concentration of hepatitis C RNA and who do not have coexisting HIV infection, the risk of perinatal transmission of hepatitis C is less than 5%. If the patient's serum concentration of hepatitis C RNA is high or she is coinfecting with HIV, or both, the perinatal transmission rate may approach 25%.^{399,400} Several small, nonrandomized, uncontrolled cohort studies (level II evidence) support a role for elective cesarean delivery before the onset of labor and rupture of membranes in selected women who have detectable hepatitis C virus RNA. For women who have undetectable serum concentrations of RNA, vaginal delivery appears to be a reasonable plan of management.^{401,402}

Hepatitis G

Hepatitis G is caused by an RNA virus that is related to the hepatitis C virus. Hepatitis G is more prevalent, but less virulent, than hepatitis C. Many patients who have hepatitis G are coinfecting with hepatitis A, B, C, and/or HIV. Coinfection with hepatitis G does not adversely affect the prognosis of these other infections.⁴⁰³⁻⁴⁰⁶

Most patients with hepatitis G are asymptomatic. The diagnosis is best established by detection of the virus on PCR and identification of antibody on ELISA testing.

Hepatitis G can cause a chronic carrier state, and perinatal transmission has been documented. However, the clinical effects of infection in both mother and baby appear to be minimal. Accordingly, patients should not routinely be screened for this infection, and no special treatment is indicated even if infection is confirmed.³⁹⁰

Table 38-20 summarizes the key features of each form of hepatitis.

TABLE 38-20 HEPATITIS IN PREGNANCY: SUMMARY OF KEY FEATURES

Infection	Mechanism of Transmission	Best Diagnostic Test	Carrier State	Perinatal Transmission	Vaccine	Remarks
Hepatitis A	Fecal-oral	Antibody detection	No	No	Yes	Passive immunization with immune globulin
Hepatitis E	Fecal-oral	Antibody detection	No	Rare	No	High maternal mortality in developing countries
Hepatitis B	Parenteral, sexual contact	Antigen detection	Yes	Yes	Yes	Passive immunization with hepatitis B immune globulin
Hepatitis D	Parenteral, sexual contact	Antibody detection	Yes	Yes	Prevented by hepatitis B vaccine	Virus cannot replicate in absence of hepatitis B infection
Hepatitis C	Parenteral, sexual contact	Antibody detection	Yes	Yes	No	Cesarean delivery for women with detectable serum hepatitis C virus RNA
Hepatitis G	Parenteral, sexual contact	Antibody detection	Yes	Yes	No	No clinical significance of infection

Chapter 39

Cardiac Diseases

Daniel G. Blanchard, MD, and Ralph Shabetai, MD

Diagnosis of Heart Disease in Pregnancy

Pregnant women with heart disease are at higher risk for cardiovascular complications during pregnancy and also have a higher incidence of neonatal complications.¹ However, the significant hemodynamic changes that accompany pregnancy make the diagnosis of certain forms of cardiovascular disease difficult. During normal pregnancies, women frequently experience dyspnea, orthopnea, easy fatigability, dizzy spells, and, occasionally, even syncope. On physical examination, dependent edema, rales in the lower lung fields, visible neck veins, and cardiomegaly are commonly found. Systolic murmurs occur in more than 95% of pregnant women, and internal mammary flow murmurs and venous hums are common. A third heart sound (S_3 gallop) is often present.² Nevertheless, certain findings indicate heart disease in pregnancy and should suggest the presence of a significant cardiovascular abnormality. These symptoms include severe dyspnea, syncope with exertion, hemoptysis, paroxysmal nocturnal dyspnea, and chest pain related to exertion. Physical signs of organic heart disease include a fourth heart sound (S_4 gallop), cyanosis, clubbing, diastolic murmurs, sustained cardiac arrhythmias, and loud, harsh systolic murmurs.³

If there is a strong suspicion of heart disease during pregnancy, confirmatory diagnostic tests should be initiated. The changes of normal pregnancy must be recognized so that the findings are not misinterpreted. For example, nonspecific ST segment and T-wave abnormalities and shifts in the electrical axis can occur.⁴ Pregnancy also produces changes in the echocardiogram, including alterations in cardiac dimensions and performance. The internal dimensions of all the cardiac chambers are increased, and slight regurgitation through the four valves is frequently observed. The ejection fraction (EF) and stroke volume are concomitantly larger, and the cardiac output is increased.⁵ A small pericardial effusion can be a normal finding in pregnant women.⁶ Both radiographic and radionuclide diagnostic procedures should be avoided during pregnancy unless the procedure is deemed essential for the health and safety of the mother.

Pre-Conception Counseling

If a woman plans to become pregnant but knows that she has heart disease, she and her physicians must be fully aware of several fundamental principles. The cardiovascular system undergoes specific adaptations to meet the increased demands of the mother and fetus during

pregnancy. The most important of these are increases in blood volume, cardiac output, and heart rate. These adaptations exacerbate the symptoms and clinical signs of heart disease and may necessitate significant escalation in treatment.

Cardiac risk varies among the specific forms of heart disease and also with severity. During prepregnancy counseling, the physician should describe the nature of the heart disease in terms comprehensible to the prospective parents. The risk to the woman, which can vary from negligible to prohibitive, should be spelled out as clearly as possible.⁷ On this basis, the patient may be advised either that the contemplated pregnancy is safe, will be uncomfortable and will necessitate treatment, carries a significantly increased risk, or would be extremely dangerous and should not be undertaken.

In the case of certain cardiac conditions, the patient should be strongly advised to undergo the necessary treatment before pregnancy and to allow several months to elapse before becoming pregnant. Examples in this category include the following:

- Large intracardiac shunt (atrial or ventricular septal defect) with mild to moderate pulmonary hypertension
- Patent ductus arteriosus (PDA) with mild to moderate pulmonary hypertension
- Severe coarctation of the aorta
- Severe mitral stenosis or regurgitation
- Severe aortic stenosis or regurgitation
- Tetralogy of Fallot
- Various congenital malformations and acquired heart diseases

Again, it is imperative that the palliative procedure be carried out before pregnancy is undertaken and that a year or so elapse before pregnancy occurs. Flexibility in clinical judgment is necessary, however. A woman with moderately severe valvular disease may require a prosthetic valve in the future. In such a case, the patient should be advised to have her family before valve replacement—with its associated anticoagulant risk—is required⁸ (see Pregnancy in Patients with Artificial Heart Valves, later). The valvular heart lesions associated with high and low maternal and fetal risk during pregnancy are listed in Tables 39-1 and 39-2.

As previously noted, some cardiac disorders are so serious in nature that the physiologic changes of a superimposed pregnancy pose prohibitive risks to the mother; they carry such a high maternal mortality risk that pregnancy is contraindicated. In such circumstances, patients must be strongly cautioned against becoming pregnant. If such a patient is seen for the first time when she is already pregnant, termination of the pregnancy is recommended. The most serious of the cardiac

TABLE 39-1 VALVULAR HEART LESIONS ASSOCIATED WITH HIGH MATERNAL AND/OR FETAL RISK DURING PREGNANCY

Severe AS with or without symptoms
 AR with NYHA functional class III-IV symptoms
 MS with NYHA functional class II-IV symptoms
 MR with NYHA functional class III-IV symptoms
 Aortic and/or mitral valve disease resulting in severe pulmonary hypertension (pulmonary pressure greater than 75% of systemic pressures)
 Aortic and/or mitral valve disease with significant LV dysfunction (EF < 40%)
 Mechanical prosthetic valve requiring anticoagulation
 Marfan syndrome with or without AR

AR, aortic regurgitation; AS, aortic stenosis; EF, ejection fraction; LV, left ventricular; MR, mitral regurgitation; MS, mitral stenosis; NYHA, New York Heart Association.

TABLE 39-2 VALVULAR HEART LESIONS ASSOCIATED WITH LOW MATERNAL AND FETAL RISK DURING PREGNANCY

Asymptomatic AS with low mean gradient (<25 mm Hg and aortic valve area >1.5 cm²) in the presence of normal LV systolic function (EF > 50%)
 NYHA functional class I or II AR with normal LV systolic function
 NYHA functional class I or II MR with normal LV systolic function
 MVP with no MR or mild to moderate MR with normal LV systolic function
 Mild MS (mitral valve area >1.5 cm², gradient <5 mm Hg) without severe pulmonary hypertension
 Mild to moderate pulmonary valve stenosis

AR, aortic regurgitation; AS, aortic stenosis; EF, ejection fraction; LV, left ventricular; MR, mitral regurgitation; MS, mitral stenosis; MVP, mitral valve prolapse; NYHA, New York Heart Association.

Reproduced with permission from Bonow RO, Carabello B, DeLeon AC, et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. Circulation 114:84, 2006.

disorders are those involving pulmonary hypertension, particularly those associated with a right-to-left shunt in cardiac blood flow (Eisenmenger syndrome). Low cardiac output states and entities in which there is an increased risk of aortic dissection (Marfan syndrome) also represent an extraordinarily high risk of maternal mortality. These high-risk maternal cardiovascular disorders are listed in Table 39-3.

In some women with specific dangerous cardiovascular diseases, pregnancy is contraindicated because of the substantial risk of maternal death.⁹ Examples include the following:

- Dilated cardiomyopathy or left ventricular dysfunction (EF < 40%) of any cause
- Severe pulmonary hypertension of any cause
- Marfan syndrome, especially with aortic root dilation (diameter > 4 cm)

TABLE 39-3 HIGH-RISK MATERNAL CARDIOVASCULAR DISORDERS

Disorder	Estimated Maternal Mortality Rate (%)
Aortic valve stenosis	10-20
Coarctation of the aorta	5
Marfan syndrome	10-20
Peripartum cardiomyopathy	15-60
Severe pulmonary hypertension	50
Tetralogy of Fallot	10

If a patient with one of these disorders presents when she is already pregnant, she should be strongly urged to consider early termination. A carefully planned suction curettage before 13 weeks' gestation would place such a patient at minimal risk. Termination of pregnancy beyond 13 weeks increases the risk to the mother, because many of the cardiovascular alterations that occur in pregnancy have taken place.

Infective endocarditis often causes rapid and serious deterioration of the cardiac status, posing a major threat to the life and health of the mother and, therefore, of the fetus as well. Scrupulous attention to prophylaxis against endocarditis is critical during pregnancy. Pregnant women must pay meticulous attention to their dental health; if they have cardiac lesions susceptible to infective endocarditis, neglect of antibacterial prophylaxis could have dire consequences. In general, women with valvular heart disease should have antibiotic prophylaxis at the time of delivery.^{10,11}

The prospective parents will want to know not only about the risk to the health and life of the future mother but also about the fetal risks. One of the most important questions is whether the mother's heart disease is hereditary and, if so, what is the risk that the infant will be born with the same defect. A detailed family cardiac history must be obtained before pregnancy, especially if the prospective mother has heart disease.

Some of the cardiomyopathies, especially hypertrophic forms, may be inherited in a mendelian manner.¹² Familial dilated cardiomyopathy has also been described. Approximately 20% of idiopathic dilated cardiomyopathy is inherited.¹³ There is a strong familial tendency in certain congenital malformations, such as PDA and arterial septal defect (ASD). Additionally, mothers with congenital heart disease may have children with unrelated congenital malformations: this risk appears to be approximately 5%.^{3,14} Also, pregnant women with advanced heart disease, especially those with low cardiac output or severe hypoxia, experience a greatly increased incidence of spontaneous abortion, stillbirths, and small or deformed children.⁹ For most pregnant women with heart disease, vaginal delivery (with a low threshold for forceps or vacuum assistance) is recommended. Elective cesarean section is recommended in cases of Marfan syndrome or aortic aneurysm of any cause.³

Today's prospective mother wants to know about the risks to her fetus of drugs, other therapies, and diagnostic tests that are used to treat heart disease. Echocardiography poses no threat to the fetus, but radiation incurred with radionuclide angiography, cardiac catheterization with contrast angiography, or computed tomography pose a potential hazard to the fetus. If these studies are required, they should be performed before pregnancy occurs; they should be repeated thereafter only if mandated for the safety of the mother, and pelvic shielding should be used.

Maternal infection with the virus that causes German measles (rubella) is associated with a high risk of congenital malformation of the fetal heart as well as PDA. If the patient has not had German measles as a child and has never been inoculated against it and her antibody titer confirms the absence of immunity, she should be vaccinated some months before becoming pregnant.

Every pregnant woman who is known or thought to have heart disease should, at a minimum, be evaluated once by a cardiologist who understands the cardiovascular adaptations to pregnancy. The cardiologist will prescribe necessary diagnostic studies and treatments and, of equal importance, will not allow unnecessary ones. The effects of heart disease can often be ameliorated by correcting coexisting medical problems, such as anemia, chronic infection, anxiety, thyroid dysfunction, hypertension, and arrhythmia.

Cardiovascular Adaptations to Pregnancy

Increased Blood Volume

The cardiovascular alterations observed in pregnancy are discussed in detail in Chapter 7 but are reviewed here briefly. It is worthwhile to reconsider and emphasize some of the most important cardiovascular changes that occur during pregnancy, because they may significantly alter the course of cardiac disease or may themselves be influenced by a specific disorder.

Blood volume and cardiac output increase during pregnancy.¹⁵ The uterus hypertrophies, endometrial vascularization is greatly increased, and the placenta becomes a highly vascular structure that functions to some extent as an arteriovenous shunt. In addition, generalized arteriolar dilation develops, mediated most probably by estrogen. These mechanisms combine to lower systemic vascular resistance and increase the pulse pressure. The total blood volume rises steadily during the first trimester and is increased by almost 50% by the 30th week, remaining more or less constant thereafter.¹⁶ Several mechanisms are responsible for increasing blood volume in pregnancy, including steroid hormones of pregnancy, elevated plasma renin activity, and elevated plasma aldosterone levels. Human placental lactogen, atrial natriuretic factor, and other peptides may also play significant roles in governing changes of blood volume in pregnancy. Hypervolemia also occurs with trophoblastic disease, indicating that a fetus is not essential for its development. Heart rate increases by 10 to 20 beats/min. In a normal pregnancy, blood pressure does not increase, because the increased intravascular volume is balanced by decreased peripheral vascular resistance mediated by the placenta. Plasma volume tends to increase more than the red blood cell mass, accounting for a “physiologic anemia” that is common in pregnancy. Treatment with iron corrects the anemia which, if left untreated, may become significant (hematocrit as low as 33% and hemoglobin 11 g/dL).

Cardiac Output

Cardiac output rises during the first few weeks of pregnancy and is 30% to 45% above the nonpregnant level by the 20th week, remaining there until term.¹⁵ The increase in cardiac output in the first trimester begins rapidly and peaks between the 20th and 26th week. Early in pregnancy, the dominant factor is elevated stroke volume; later, increased heart rate predominates.¹⁷ In late pregnancy, the enlarged uterus partially impedes venous return by compressing the inferior

vena cava, accounting for lower cardiac output. This is one reason why some obstetricians prefer to manage labor with the patient in the left decubitus position.

Cardiac Performance

Echocardiographic studies have shown increases in the left ventricular fiber shortening velocity and in EF. These changes do not necessarily indicate increased myocardial contractility but may simply be the result of decreased peripheral vascular resistance and increased preload. In any case, stroke volume is increased, and cardiac output is further augmented by the 10% to 15% increase in heart rate that characterizes normal pregnancy.¹⁸

Demands on the cardiovascular system increase significantly during labor and delivery. Pain increases sympathetic tone, and uterine contractions induce wide swings in the systemic venous return. With placental separation, autotransfusion of at least 500 mL takes place, placing an acute load on the diseased heart, unless offset by blood loss. These large shifts in blood volume can precipitate, on the one hand, shock, and on the other, pulmonary edema in women with severe heart disease.

If a chest radiograph is obtained in a pregnant woman, the cardiac silhouette often appears slightly enlarged owing to the combined effects of volume overload and elevation of the diaphragm. Routine echocardiographic studies have demonstrated that a small, silent pericardial effusion is quite common.⁶

Electrocardiographic Changes

The mean QRS axis may shift to the left¹⁹ as a result of the elevated diaphragm. In later pregnancy, the axis may shift to the right when the fetus descends into the pelvis. Minor ST segment and T-wave changes may be observed, usually in lead III but sometimes aVF as well. Less often, T inversions may appear transiently in the left precordial leads. Occasionally, small Q waves may accompany T-wave inversion in leads III and aVF. These changes are seldom of sufficient magnitude to raise the question of ischemic heart disease, which in any case is relatively uncommon in pregnancy, especially if the mother is young and free from symptoms. Extrasystoles and supraventricular tachycardia are more common during pregnancy. Symptoms of palpitations are common during pregnancy but only rarely signify the presence of organic heart disease.

General Guidelines for Management

During treatment of all pregnant patients with heart disease, priority must be given to maternal health, but all possible therapeutic measures should also be taken to protect the developing fetus. The aspects of management are outlined in Table 39-4.

Because pregnancy increases the demands on the heart, physical exertion frequently must be restricted, especially if it causes symptoms. Some women with certain forms of cardiac disease, such as significant mitral stenosis and cardiomyopathy, tolerate pregnancy poorly and cannot endure physical exertion. They may require strict bed rest for the duration of the pregnancy, particularly during the last trimester. Women with heart disease have a limited ability to increase cardiac output to meet increased metabolic demands and should minimize the demands placed on the heart from physical activity.

Cardiovascular drugs

Cardiovascular Drugs

Some of the drugs commonly used in the management of cardiovascular disease have potentially harmful effects on the developing embryo and fetus. For example, there is no question that oral anticoagulants are potential teratogens when administered in the first trimester (see Chapter 20 and later discussion in this chapter). The “warfarin embryopathy syndrome,” consisting of nasal hypoplasia, optic atrophy, digital abnormalities, and mental impairment, occurs in a minority of cases. The actual risk of warfarin embryopathy is difficult to estimate and has ranged from 4% to 67% in various reports.^{20,21} A risk of 4% to 10% seems more reasonable.²² There is some evidence that embryopathy is less likely if the warfarin dose is 5 mg/day or less.²³ The fetal risks continue beyond the first trimester, because warfarin increases the possibility of both fetal and intrauterine bleeding.

Anticoagulation presents a significant practical problem in the management of atrial fibrillation, systemic or pulmonary embolism, thrombophlebitis, and pulmonary hypertension in pregnancy. The most vexing problem arises in the setting of prosthetic heart valves^{10,11} (discussed later). In the case of mechanical valve prostheses, warfarin appears to be superior to heparin in preventing valvular thrombosis. Although heparin is safer for the fetus, there is probably an increased risk for the mother.^{20,24} This is a complex medical issue, and no randomized trial to determine the optimal anticoagulant therapy for women with a prosthetic valve has been conducted. Therefore, recommendations are based on smaller studies and on clinical judgment.^{10,11} No single regimen is likely to be applicable to all such cases, because the issue is complicated by the type and generation of the prosthetic valve, the cardiac rhythm, and the size and contractility of the cardiac chambers.

β -Adrenergic blocking agents, used for the treatment of hypertension and tachyarrhythmia, have been associated with neonatal respiratory depression, sustained bradycardia, and hypoglycemia when administered late in pregnancy or just before delivery. However, if they are used judiciously in selected cases (e.g., in women with cardiomyopathy and heart failure), β -blockers are usually well tolerated.

The thiazide diuretics are another class of drugs that can produce harmful effects on the fetus—especially if they are used in the third trimester or for extended periods—and may impair normal expansion of plasma volume. Rarely, severe neonatal electrolyte imbalance, jaundice, thrombocytopenia, liver damage, and even death have been reported.

There have been numerous reports of fetal and neonatal renal complications after the use of angiotensin-converting enzyme (ACE)

inhibitors during pregnancy.^{25,26} These complications suggest a profound and deleterious effect on fetal renal function, leading to decreased renal function and oligohydramnios, as well as neonatal renal failure. ACE inhibitors are absolutely contraindicated during pregnancy. Another class of antihypertensive drugs, the angiotensin receptor blockers, also may affect fetal renal function and are likewise absolutely contraindicated in pregnancy.

The indications and possible adverse effects of commonly prescribed cardioactive drugs during pregnancy are summarized in Table 39-5.

Team Approach to Medical Care

Medical care for pregnant women with heart disease is best provided through the cooperative efforts of a cardiologist who is familiar with the hemodynamic changes of pregnancy and an obstetrician. Frequent visits to both specialists, along with open consultations, can provide the patient with consistent advice and reassurance and can circumvent the worry and anxiety created by confusing and conflicting information. In addition, the anesthesiologist needs to be consulted during the antepartum period to outline the anticipated approach to intrapartum management, a time of maximum risk for most of these women. The role of the anesthesiologist and the approach to women with pregnancies complicated by cardiac disease are summarized in Chapter 56.

Congenital Heart Disease

A number of simple congenital malformations are compatible with a normal or nearly normal pregnancy. Congenital malformations previously associated with high maternal morbidity and mortality and fetal wastage now frequently end with a satisfactory outcome because of palliative or corrective surgery. Despite recent advances, however, women with congenital heart disease who become pregnant still have a significant risk of miscarriage, cardiac complications, and premature delivery.²⁷

The care of adults with congenital heart malformation is an important and growing branch of cardiology^{7,28,29} that requires the cooperative efforts of medical and pediatric cardiologists, cardiac surgeons, and, in the case of pregnancy, obstetricians and anesthesiologists.^{30,31}

Left-to-Right Shunt

Atrial Septal Defect

ASD may be undiscovered before pregnancy, because symptoms are often absent and the physical findings are not blatant. Other causes of left-to-right shunt, such as PDA and ventricular septal defect (VSD), are more likely to be discovered and treated in infancy or childhood. Physicians should be alert to the higher possibility of uncorrected defects in women who have immigrated from an undeveloped country.

Closure of uncomplicated large ostium secundum ASD is straightforward and safe and usually is curative. Therefore, the procedure should be done before pregnancy. Many ASDs can now be closed percutaneously, using a “clamshell” or “umbrella” device inserted via a transvenous catheter.³² If the patient is unwilling to undergo ASD closure, she can be advised that the lesion is unlikely to complicate pregnancy and labor, provided that pulmonary hypertension is not present.³

TABLE 39-5 INDICATIONS FOR AND POSSIBLE ADVERSE EFFECTS OF COMMONLY PRESCRIBED CARDIOACTIVE DRUGS ON MOTHER AND FETUS

Drug	Use in Pregnancy	Potential Side Effects	Breastfeeding	Risk Category*
Adenosine	Maternal and fetal arrhythmias	No side effects reported; data on use during first trimester are limited	Data NA	C
Amiodarone	Maternal arrhythmias	IUGR, prematurity, congenital goiter, hypothyroidism and hyperthyroidism, transient bradycardia, prolonged QT in the newborn	Not recommended	C
ACEIs and angiotensin receptor blockers	Hypertension	Oligohydramnios, IUGR, prematurity, neonatal hypotension, renal failure, anemia, death, skull ossification defect, limb contractures, patent ductus arteriosus	Compatible	X
β-Blockers	Hypertension, maternal arrhythmias, myocardial ischemia, mitral stenosis, hypertrophic cardiomyopathy, hyperthyroidism, Marfan syndrome	Fetal bradycardia, low placental weight, possible IUGR, hypoglycemia; no information on carvedilol	Compatible; monitoring of infant's heart rate recommended	Acebutolol: B Labetalol: C Metoprolol: C Propranolol: C Atenolol: D
Digoxin	Maternal and fetal arrhythmias, heart failure	No evidence for unfavorable side effects on the fetus	Compatible	C
Diltiazem	Myocardial ischemia, tocolysis	Limited data; increased incidence of major birth defects	Compatible	C
Disopyramide	Maternal arrhythmias	Limited data; may induce uterine contraction and premature delivery	Compatible	C
Diuretics	Hypertension, congestive heart failure	Hypovolemia leads to reduced uteroplacental perfusion, fetal hypoglycemia, thrombocytopenia, hyponatremia, hypokalemia; thiazide diuretics can inhibit labor and suppress lactation	Compatible	C
Flecainide	Maternal and fetal arrhythmias	Limited data; 2 cases of fetal death after successful treatment of fetal SVT reported, but relation to flecainide uncertain	Compatible	C
Heparin	Anticoagulation	None reported	Compatible	C
Hydralazine	Hypertension	None reported	Compatible	C
Lidocaine	Local anesthesia, maternal arrhythmias	No evidence for unfavorable fetal effects; high serum levels may cause CNS depression at birth	Compatible	C
Nifedipine	Hypertension, tocolysis	Fetal distress related to maternal hypotension reported	Compatible	C
Nitrates	Myocardial infarction and ischemia, hypertension, pulmonary edema, tocolysis	Limited data; use is generally safe; few cases of fetal heart rate deceleration and bradycardia have been reported	Data NA	C
Procainamide	Maternal and fetal arrhythmias	Limited data; no fetal side effects reported	Compatible	C
Propafenone	Fetal arrhythmias	Limited data; fetal death reported after direct intrauterine administration in fetuses with fetal hydrops	Data NA	C
Quinidine	Maternal and fetal arrhythmias	Minimal oxytocic effect, high doses may cause premature labor or abortion; transient neonatal thrombocytopenia and damage to eighth nerve reported	Compatible	C
Sodium nitroprusside	Hypertension, aortic dissection	Limited data; potential thiocyanate fetal toxicity, fetal mortality reported in animals	Data NA	C
Sotalol	Maternal arrhythmias, hypertension, fetal tachycardia	Limited data; 2 cases of fetal death and 2 cases of significant neurologic morbidity in newborns reported, as well as bradycardia in newborns	Compatible; monitoring of infant's heart rate recommended	B
Verapamil	Maternal and fetal arrhythmias, hypertension, tocolysis	Limited data; other than 1 case of fetal death of uncertain cause, no adverse fetal or newborn effects reported	Compatible	C
Warfarin	Anticoagulation	Crosses placental barrier; fetal hemorrhage in utero, embryopathy, CNS abnormalities	Compatible	X

ACE, angiotensin-converting enzyme inhibitor; CNS, central nervous system; IUGR, intrauterine growth retardation; NA, not available; SVT, supraventricular tachycardia.

*U.S. Food and Drug Administration classification of drug risk. B: Either animal reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women, or animal reproduction studies have shown an adverse effect that was not confirmed in controlled studies in women. C: Either studies in animals have revealed adverse effects on the fetus and there are no controlled studies in women, or studies in women and animals are not available. Drug should be given only if the potential benefits justify the potential risks to the fetus. D: There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk. X: Studies in animals or human beings have demonstrated fetal abnormalities. The risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

In Zipes DP, Libby P, Bonow RO, Braunwald E (eds): Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine, 7th ed. Philadelphia: Elsevier, 2005, p 1965.)

Metcalf and colleagues³³ reported one maternal death among 219 pregnancies in 113 women with ASD. Peripheral vasodilation, if anything, reduces the left-to-right shunt.¹⁷ Because ASD in young women is not associated with heart failure, diuretics and extreme limitation of intravenous infusion are not warranted. A small percentage of patients with ASD have atrial flutter or fibrillation, which usually is paroxysmal. This arrhythmia can be managed along conventional lines, often with digoxin if necessary. The prospective mother should be informed that closure of the defect does not prevent atrial fibrillation once the arrhythmia has occurred.

ASD can be difficult to diagnose during pregnancy. The murmur associated with ASD may be inconspicuous, being a pulmonary ejection systolic murmur and therefore not unlike the physiologic murmur of pregnancy. However, the second heart sound is widely split and may be fixed throughout the respiratory cycle, a distinctly abnormal finding. The electrocardiogram (ECG) shows incomplete right bundle branch block and, in the case of the much more common ostium secundum defect, marked left axis deviation accompanies incomplete right bundle branch block. The chest radiograph shows right atrial and right ventricular enlargement, prominent pulmonary arteries, and plethoric lung fields. Echocardiography establishes or confirms the diagnosis (Fig. 39-1), obviating the need for cardiac catheterization in many cases.

Complicated Atrial Septal Defect

If atrial arrhythmias recur frequently—and especially if the heart rate is difficult to control—catheter ablation is successful in restoring normal sinus rhythm without the need for antiarrhythmic drugs. In most cases, this procedure should not be done until after delivery because of the extensive radiation exposure that is needed. In rare instances, pregnancy and labor may be associated with a paradoxical systemic embolus resulting from a thrombus migrating from the inferior vena cava across the ASD into the left atrium.

In the uncommon event that the patient is more than 35 years old and has an uncorrected large ASD, the likelihood of chronic atrial fibrillation, right ventricular dysfunction, and pulmonary hypertension rises significantly. Pregnancy is not advised if any of these sequelae is present. If the patient insists on going through with the pregnancy, prolonged bed rest will be required, and vigorous treatment of heart failure may be needed. The maternal risk is increased, and there is significant risk of fetal loss. Although warfarin is generally recommended for chronic atrial fibrillation, its use is best avoided (especially in the first trimester); aspirin would be a reasonable compromise. Severe pulmonary hypertension is an uncommon feature of an ostium secundum ASD but is a contraindication to pregnancy. The ostium primum ASD, which is associated with Down syndrome and poses a risk of endocarditis, is more often associated with severe pulmonary hypertension. Infective endocarditis rarely, if ever, complicates a simple ostium secundum ASD; therefore, prophylaxis during labor is not warranted.

Ventricular Septal Defect

The clinical spectrum and risk of VSD may range from so mild that it has little or no effect on pregnancy to so high that maternal or fetal death can occur. Small defects in the muscular ventricular septum frequently close spontaneously during childhood. However, these defects occasionally persist, allowing a small left-to-right shunt, manifested by a loud pansystolic murmur along the left sternal border accompanied by a coarse thrill. The chest radiograph is often normal, as is the ECG. The echocardiogram is usually diagnostic (Fig. 39-2).

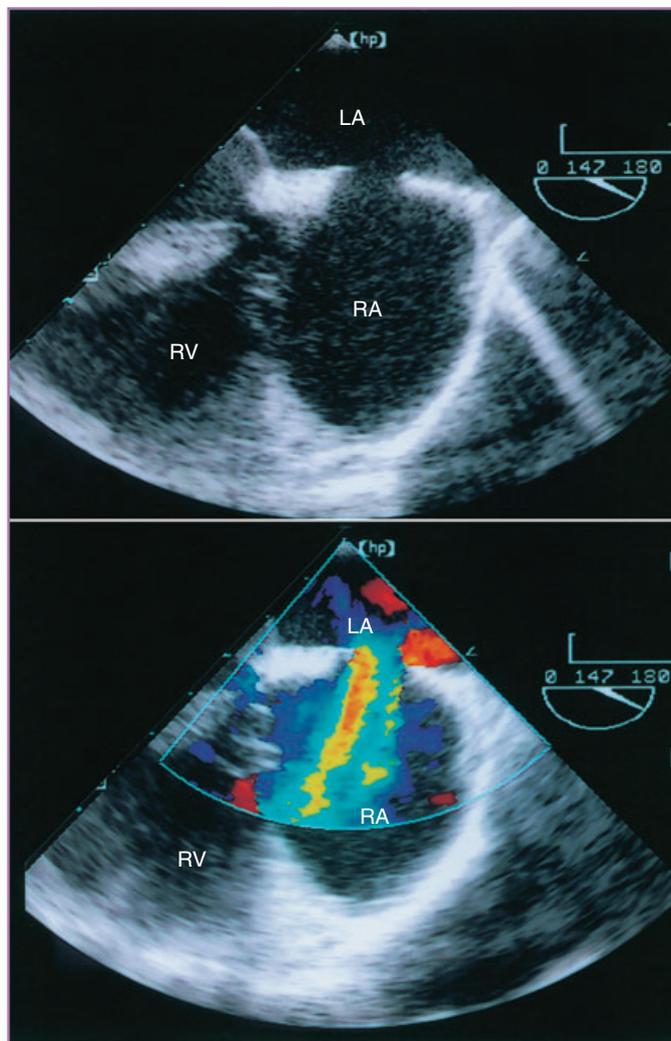

FIGURE 39-1 Transesophageal echocardiographic image of atrial septal defect (ostium secundum). In the upper panel, a large defect in the interatrial septum is present. In the lower panel, the blue/yellow color represents blood flow from the left atrium (LA) into the right atrium (RA). RV, right ventricle.

These findings constitute the *maladie de Roger*. Prophylaxis against infective endocarditis is indicated, but otherwise this lesion has no effect on pregnancy or labor.

When the defect is in the membranous septum, spontaneous closure is rare. In the absence of significant pulmonary vascular disease, the same pansystolic murmur and thrill are found. If the shunt is large, however, the lung fields are plethoric on chest radiography, and the heart and pulmonary arteries are enlarged. The classic ECG shows a pattern of biventricular hypertrophy. In such cases, flow through the pulmonary vascular bed is usually at least twice the systemic cardiac output. Patients with a relatively large, uncomplicated left-to-right shunt through a VSD tolerate pregnancy well and, in this respect, are comparable to patients with ASD. However, prophylaxis against endocarditis is essential in cases of VSD.

Here it is appropriate to detour from clinical description to pathophysiology. Pulmonary vascular resistance is calculated as the pressure drop across the pulmonary vascular bed divided by the flow through it:

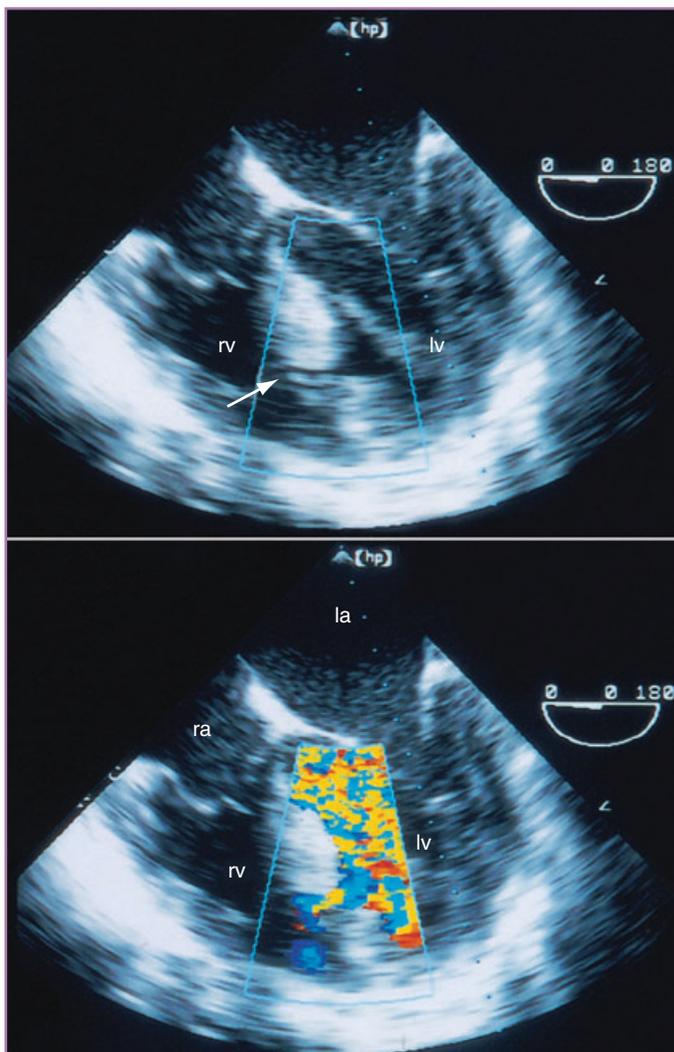

FIGURE 39-2 Transesophageal echocardiographic image of a small muscular ventricular septal defect. In the upper panel, a small communication is seen (arrow) between the right ventricle (rv) and left ventricle (lv). In the lower panel, color imaging confirms blood flow between the two chambers. la, left atrium; ra, right atrium.

$$R = (\text{MPAP} - \text{MPCWP}) / Q_{\text{pulm}}$$

where R is pulmonary vascular resistance in Wood units; MPAP and MPCWP (in mm Hg) are the mean pulmonary arterial and capillary wedge pressures, respectively; and Q_{pulm} is total flow through the right heart and pulmonary circulation (i.e., cardiac output plus left-to-right shunt) in liters per minute.

Resistance can be described in Wood units or in $\text{dyne}\cdot\text{s}/\text{cm}^5$. The Wood unit has the merit of simplicity and is derived from clinical units of pressure and flow. The more fundamental but less friendly $\text{dyne}\cdot\text{s}/\text{cm}^5$ can be obtained by multiplying Wood units by 80. Normal pulmonary vascular resistance is 0.5 to 1.5 units. When a clinician is faced with a pregnant woman with pulmonary hypertension, the key to her risk during pregnancy lies in the pulmonary vascular resistance. High flow, by itself, can be the mechanism for pulmonary hypertension without dangerous elevation in the resistance. This mechanism can be appreciated by rewriting the resistance equation to read

$$P = Q \cdot R$$

where P is the pressure drop and Q is the flow across the pulmonary vascular bed.

A patient at one extreme may have a large shunt with pulmonary flow of 20 L/min and an R of 3 units, yielding an MPAP of 55 mm Hg (assuming a normal MPCWP of 5 mm Hg). At the other extreme, a patient with pulmonary vascular disease may have a pulmonary blood flow of 7 L/min and an R of 7 units, yielding an MPAP of 44 mm Hg. The higher the pulmonary vascular resistance (R), the greater the maternal risk. The risk is prohibitive when R reaches the systemic level (approximately 15 Wood units). In borderline cases (e.g., patients with R between 5 and 8 units), a pulmonary arteriolar vasodilating agent is sometimes administered to determine whether the increased resistance is partially reversible or completely irreversible. An increase in pulmonary vascular resistance of 3 to 4 units is considered mild, 5 to 7 units is moderate, and more than 8 units is severe.

VSD may be associated with considerable increase in pulmonary vascular resistance, reflecting occlusive disease of the small pulmonary arteries and arterioles. This development, if it is to occur, usually does so in childhood; unless corrected, it leads to the Eisenmenger syndrome (discussed later). However, a small number of adults may survive with VSD and pulmonary vascular resistance that is significantly elevated but falls short of the Eisenmenger syndrome. Such patients are at high risk for death during pregnancy or labor, and there is a high risk of fetal impairment or loss. The patient should be told that early therapeutic abortion would be the safest option, and that later pregnancy would be hazardous and would require intensive care, with physical exercise strictly curtailed and prolonged bed rest enforced. The combination of decreased physical activity, pulmonary hypertension, and pulmonary vascular disease would constitute a sound rationale for instituting anticoagulation, which is another reason why pregnancy is better avoided or terminated.

Some authorities strongly advise that delivery be effected prematurely by means of cesarean section and urge sterilization at the same operation. The dangers must be thoroughly understood by women in this category who insist on continuing pregnancy.

Patent Ductus Arteriosus

The loud, continuous or machinery murmur of typical PDA with a large left-to-right shunt and no pulmonary vascular disease is so striking that the lesion is almost invariably detected and corrected in infancy or childhood. Occasionally, however, women of childbearing age or pregnant women from underdeveloped countries may present with a PDA. If the left-to-right shunt is large, the circulation is hyperdynamic, with a wide arterial pulse pressure, low arterial diastolic pressure, and hyperactive precordium. The heart may be somewhat enlarged to clinical and radiologic examination, and the ECG may show left ventricular hypertrophy. The echocardiogram is useful for demonstrating a shunt between the two great vessels (Fig. 39-3). The signs of hyperdynamic circulation resulting from the PDA are exaggerated by pregnancy.

Because the murmur of PDA is systolic-diastolic, it is commonly referred to as a “continuous” murmur, although it usually peaks late in systole. Because of its characteristics, the murmur is also referred to as a “machinery” murmur. It is maximal in the left infraclavicular region. It must be distinguished from a venous hum, which is loudest in the neck rather than the infraclavicular area. Venous hum is common in pregnant women, and it changes dramatically with changes in the position of the head.

Division or occlusion of the PDA should be accomplished before pregnancy is undertaken. Currently, most PDAs can be closed by the insertion of an occluder device delivered via a percutaneous intravas-

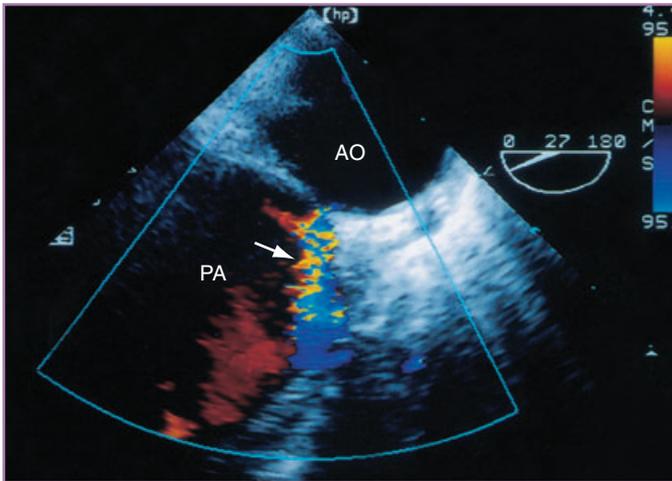

FIGURE 39-3 Transesophageal echocardiographic image of a patent ductus arteriosus. A communication is present between the proximal portion of the descending aorta (AO) and the pulmonary artery (PA). Color imaging (arrow) confirms blood flow from the aorta into the PA.

cular catheter.³⁴ If a patient does become pregnant before PDA occlusion, an uncomplicated left-to-right shunt can be managed safely. Endocarditis is a risk in patients with PDA, and antibiotic prophylaxis is required. Embolic complications of infective endocarditis and endarteritis secondary to PDA may take the form of infected pulmonary emboli. The patient becomes febrile with respiratory symptoms, and the chest radiograph shows multiple opacities and infiltrates.

The leading cause of Eisenmenger syndrome is a large VSD, followed in prevalence by a large PDA. As with VSD, individuals with PDA may sustain severe increases in pulmonary vascular resistance with the corresponding pulmonary hypertension and right ventricular hypertrophy, yet fall short of Eisenmenger physiology. The maternal risk during pregnancy is high in this situation, similar to that encountered in VSD with equivalent pathology. Treatment is the same as in VSD with Eisenmenger syndrome. When the pulmonary pressure rises, the aortopulmonary shunt decreases, and the murmur becomes progressively quieter and shorter, until it finally disappears.

In general, the woman with uncomplicated PDA tolerates pregnancy well. If pulmonary hypertension supervenes, the risk to the mother becomes significant. Therefore, if pulmonary hypertension is suspected and documented, termination of pregnancy is strongly recommended.

Eisenmenger Syndrome

Eisenmenger syndrome is characterized by a congenital communication between the systemic and pulmonary circulations and increased pulmonary vascular resistance, either to systemic level (so that there is no shunt across the defect) or exceeding systemic (allowing right-to-left shunting). As mentioned, the most common underlying defect is a large VSD, followed in prevalence by a large PDA. Eisenmenger pathophysiology is less common in ASD. Occasionally, this type of pathophysiology develops in other, less common defects. By the time the syndrome is fully developed, it is often difficult clinically to diagnose the underlying defect. For this discussion, the VSD serves as a good model (Fig. 39-4).

Eisenmenger pathophysiology develops only if the defect is large and is not restrictive, resulting in equal systolic pressure in the two

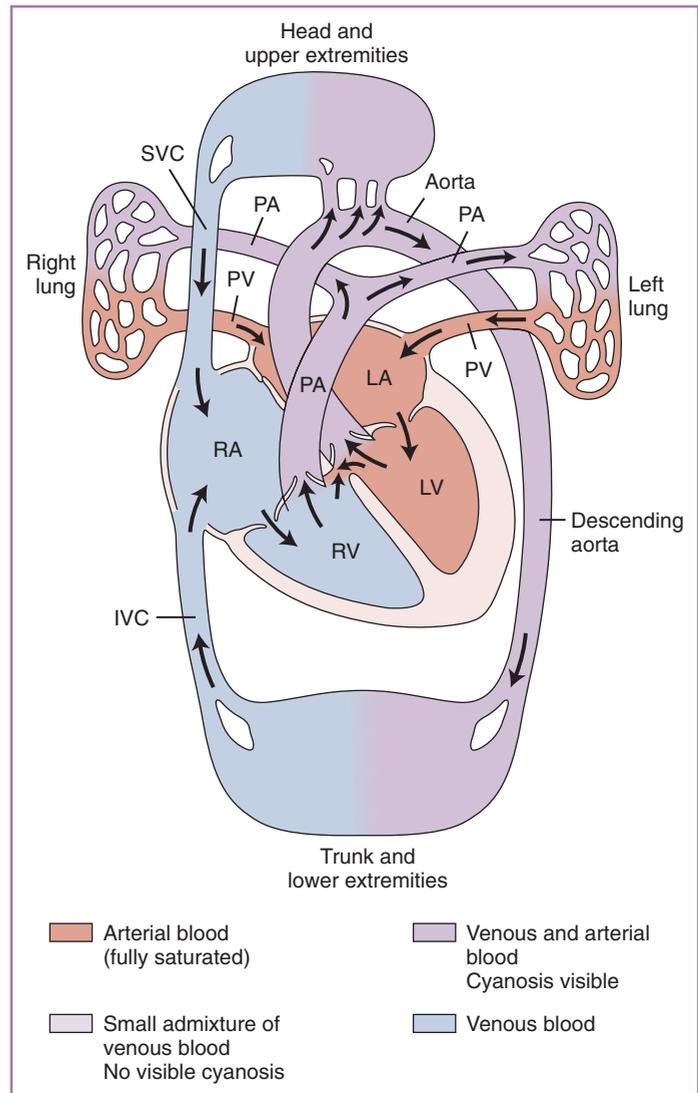

FIGURE 39-4 Eisenmenger complex. Here the cause of right-to-left shunt across the ventricular septal defect is increased pulmonary vascular resistance arising in the small pulmonary arteries and arterioles. IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava. Copyright © 1960 by the Commonwealth Fund by the President and Fellows of Harvard College.)

ventricles. It is more common in girls and develops at a young age. Therefore, when increased pulmonary vascular resistance is detected in a child with a large VSD, operative closure must be done as soon as possible to prevent the development of Eisenmenger pathophysiology. Once this has appeared, pulmonary hypertension is irreversible, and the VSD is consequently inoperable (unless lung transplantation is performed as well).

The major clues that pulmonary vascular resistance is increasing are (1) diminution of evidence of a left-to-right shunt and (2) the appearance of progressively severe pulmonary hypertension. The pansystolic murmur of VSD or the continuous murmur of PDA is replaced by a short ejection systolic murmur. The lungs are no longer plethoric

but show large central pulmonary arteries and small peripheral arteries characteristic of severe pulmonary hypertension. Because the shunt has disappeared, the radiographic cardiothoracic ratio returns to normal but the main pulmonary segment is prominent. There is usually a striking right ventricular heave, a loud and palpable pulmonary valve closure sound, and an ejection sound in early systole. When concentric ventricular hypertrophy gives way to dilatation and right-sided heart failure, evidence of tricuspid regurgitation appears. Until then, the mean venous pressure is normal but the amplitude of the a wave may be increased, reflecting decreased right ventricular diastolic compliance.

If pulmonary vascular resistance is significantly higher than systemic levels, right-to-left shunting of blood occurs and causes cyanosis and clubbing of the fingers and toes. This shunting of deoxygenated blood into the systemic circulation leads to hypoxemia and triggers a reactive erythrocytosis as the system attempts to increase peripheral oxygen delivery. This increases blood viscosity and can cause sludging and decreased flow of blood, especially in small vessels. A high hematocrit value, however, is not an automatic indication for serial phlebotomy, because this approach can lead to iron deficiency and microcytosis. Tissue hypoxia may then actually worsen, a particularly undesirable result in pregnancy. Phlebotomy is reserved for patients without evidence of iron deficiency on laboratory testing who have symptoms of hyperviscosity, including headache, dizziness, visual disturbance, myalgia, and bleeding diathesis. Quantitative volume replacement is necessary during phlebotomy.

Attempted surgical correction of a congenital cardiac shunt after Eisenmenger syndrome is present usually results in the death of the patient.³⁵ Many patients ultimately die of right-sided heart failure, pulmonary hypertension, or pulmonary hemorrhage.³⁶

The woman with Eisenmenger syndrome must be informed that pregnancy carries a mortality risk of about 50%.³⁷ Even if the mother survives, the outcome for the fetus is likely to be poor, because the fetal mortality rate exceeds 50% in cyanotic women with Eisenmenger syndrome.³⁶ Sudden death may occur at any time, but labor, delivery, and particularly the early puerperium seem to be the most dangerous periods.³⁸ Any significant fall in venous return, regardless of cause, impairs the ability of the right heart to pump blood through the high, fixed pulmonary vascular resistance. Hypotension and shock can occur quickly and are often unresponsive to medical therapy.

The major physiologic difficulty in pulmonary hypertension is maintenance of adequate pulmonary blood flow. Any event or condition that decreases venous return, such as vasodilation on the systemic side of the circulation from epidural anesthesia or pooling of blood in the lower extremities from vena caval compression, decreases preload to the right ventricle and pulmonary blood flow. Therefore, management during pregnancy centers on the maintenance of pulmonary blood flow. If the patient insists on continuing her pregnancy, limitation of physical activity is essential, as is the use of pressure-graded elastic support hose, low-flow home oxygen therapy, and monthly monitoring of blood and platelet counts. Because of the precarious physiologic balance, a planned delivery should be performed with intensive care monitoring, including a Swan-Ganz catheter and provisions for skilled obstetric anesthesia care. Anesthetic considerations for this entity are discussed in Chapter 56.

On a more optimistic note, a report published in 1995 described 13 pregnancies in 12 women with Eisenmenger syndrome who elected not to accept advice to terminate pregnancy.³⁹ Mean systolic pulmonary arterial pressure was 113 mm Hg. Three spontaneous abortions, one premature labor, and two maternal deaths occurred. The seven patients who reached the end of the second trimester were hospitalized

until term, treated with oxygen and heparin, and delivered by cesarean section. One patient died a month after delivery. Most of the infants were small, and one died. Despite this better-than-average outcome, pregnancy should not be encouraged in women with Eisenmenger syndrome or in those with a systemic level of pulmonary hypertension of any cause.

Primary Pulmonary Hypertension

Severe idiopathic (“primary”) pulmonary hypertension, like the Eisenmenger syndrome, carries a high risk in pregnancy, and the same principles apply to its management. Pregnancy is not advised in women with this condition, because the mortality rate approaches 50%.⁴⁰

Severe pulmonary hypertension can result from taking appetite-suppressing drugs. The fenfluramine-phentermine regimen (“fen-phen”) was a notorious culprit⁴¹ and was withdrawn from the market. Treatment strategies include vasodilators, sometimes by chronic intravenous infusion, and nitric oxide inhalation. In some 25% of cases, pulmonary arterial pressure is lowered by prostacyclin infusion.⁴² This response predicts a favorable response to chronic oral nifedipine administration and a good prognosis. Balloon atrial septostomy,^{43,44} through the foramen ovale or via transseptal puncture, can be used, in extreme cases of pulmonary hypertension, to relieve right heart pressure, usually as a bridge to transplantation.

Congenital Obstructive Lesions

Some congenital cardiac malformations are characterized by obstruction to left or right ventricular outflow. The more common examples include pulmonary stenosis, aortic stenosis, and coarctation of the aorta. The hypoplastic left heart syndrome seldom allows survival to childbearing age, and those who do survive usually have undergone a major palliative procedure, such as construction of a ventriculoaortic conduit with a prosthetic valve, that would constitute a strong contraindication to pregnancy.

Mitral Stenosis

Congenital mitral stenosis is a rare malformation. When it is associated with an ASD, it constitutes the Lutembacher syndrome. Survival to childbearing age is usual. Both lesions tend to promote atrial fibrillation. Ideally, the mitral valve and the atrial defect should be repaired before pregnancy.

Aortic Stenosis

(see also the later section on aortic stenosis under Aortic Valve Disease)

Bicuspid aortic valve is one of the more common congenital malformations that may lead to aortic stenosis, regurgitation, or both (Fig. 39-5). Often, aortic stenosis is not present during early life but progresses over time because of valve calcification and gradual restriction in leaflet motion. The bicuspid valve may occur as an isolated defect or in combination with other congenital anomalies, most commonly aortic coarctation. Congenital aortic stenosis, on the other hand, can be severe at birth and may cause severe left ventricular hypertrophy

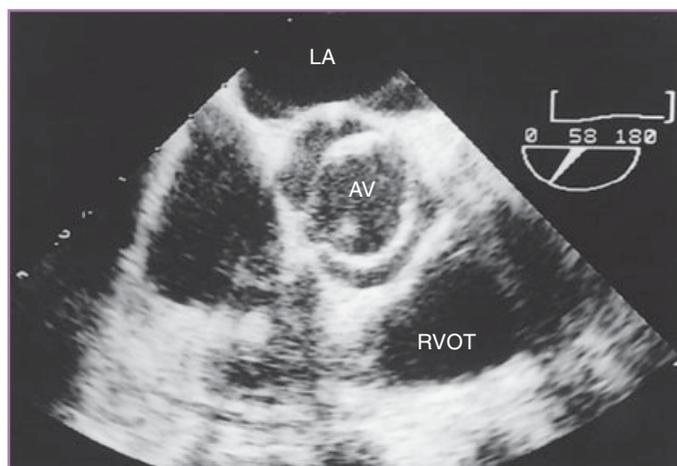

FIGURE 39-5 Transesophageal echocardiographic image of a bicuspid aortic valve. During systole, only two aortic valve (AV) leaflets are seen. LA, left atrium; RVOT, right ventricular outflow tract.

that limits the ability of the heart to respond to demands for increased cardiac output.

In the syndrome of severe congenital aortic stenosis, the pulses are of slow upstroke and diminished amplitude. Unlike adults with acquired aortic stenosis, children and young adults with congenital aortic stenosis have an abnormally loud aortic valve closure sound. Left ventricular ejection is prolonged, so that the aortic valve closure sound may occur after the pulmonary valve closure sound. Therefore, splitting of the second heart sound is paradoxical and is heard in expiration instead of inspiration. Often a loud ejection sound is heard in early systole. The duration of the ejection murmur and the time to its peak intensity increase with worsening severity of aortic stenosis.

The ECG shows severe left ventricular hypertrophy. The chest radiograph is characterized by poststenotic dilatation of the aorta. Although some patients complain of dyspnea, chest pain, and syncope, others remain asymptomatic. The lesion can be recognized and its severity assessed by Doppler echocardiography.

Critical calcific aortic stenosis is usually treated by aortic valve replacement in older patients, but aortic valve repair is often possible in younger women of childbearing age with congenital aortic stenosis. If aortic stenosis is severe—and especially if it is symptomatic—the woman should be advised against becoming pregnant. She should be advised that, if the aortic valve must be replaced, pregnancy and labor would be difficult and dangerous because of the need for anticoagulant treatment after a mechanical prosthesis is implanted. Maternal mortality rates as high as 17% have been reported,⁴⁵ although more recent data have suggested a somewhat lower risk. However, these studies also emphasize the adverse effects of severe maternal aortic stenosis on fetal outcomes, including increased rates of preterm delivery and intrauterine growth restriction.⁴⁶ If aortic stenosis is moderate in severity, the patient should be advised to complete her pregnancies before the aortic valve is replaced. Labor can be managed in such cases without a high maternal or fetal risk, but assisted shortening of the second stage of labor is recommended.⁴⁷

Strict limits on physical exertion and prolonged periods of bed rest may be required. Left ventricular failure may appear and may necessitate the use of diuretic agents and digitalis. Rarely, even in the presence of severe aortic stenosis, heart failure may be due to another cause (e.g., peripartum cardiomyopathy).⁴⁸ Prophylaxis against bacterial endocarditis at delivery is recommended.

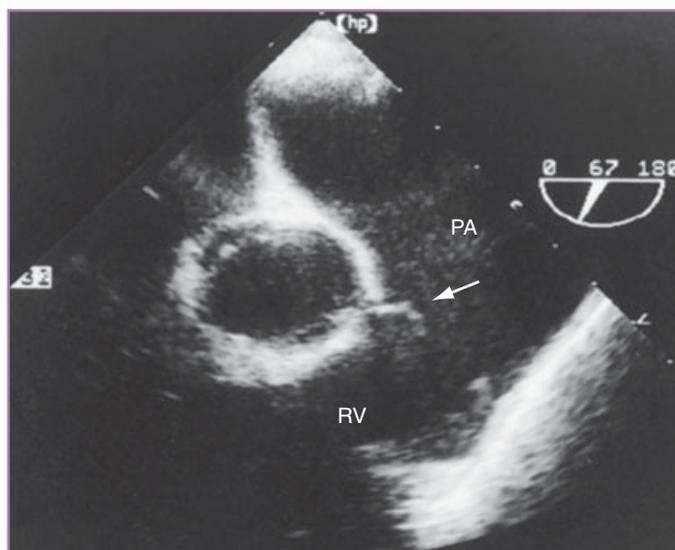

FIGURE 39-6 Transesophageal echocardiographic image of pulmonic stenosis. The pulmonic valve leaflets exhibit characteristic doming (arrow). PA, pulmonary artery; RV, right ventricle.

Vasodilators, helpful in patients with heart failure of other etiology, are dangerous in patients with aortic stenosis, because the impeded left ventricle may not be able to fill the dilated peripheral vascular bed. It should be remembered that the lowered systemic vascular resistance of pregnancy adversely affects aortic stenosis. The obstructed left ventricle is limited in its ability to fill the dilated peripheral bed, a situation that can lead to syncope or more serious manifestations of limited, relatively fixed cardiac output.

Pulmonic Stenosis

The murmur of pulmonic stenosis is loud and is often accompanied by a thrill. The lesion is usually detected in early childhood and is likely to have been corrected before the childbearing age. Expectant mothers who have not had adequate health supervision in childhood may have unrecognized pulmonary stenosis.

The diagnosis is suggested by a long, harsh systolic murmur over the upper left sternal border that is usually preceded by an ejection sound. The venous pressure is normal, but there are striking waves in the jugular venous pulse. The pulmonary valve closure sound is usually too soft to hear when pulmonary stenosis is severe. Severe pulmonary stenosis causes massive concentric right ventricular hypertrophy; this is manifested by a left parasternal heave and by tall R waves and deeply inverted T waves in the right precordial leads of the ECG. Tall, pointed P waves are also present, denoting right atrial enlargement.

Right ventricular enlargement and poststenotic dilatation of the main and left pulmonary arteries are seen on the chest radiograph, which also may show slightly diminished peripheral pulmonary vasculature. Echocardiography demonstrates limited opening of the pulmonic valve leaflets (Fig. 39-6), right ventricular hypertrophy, and abnormally high velocity of blood flow in the pulmonary artery. Doppler echocardiography also allows calculation of the right ventricular pressure and the systolic pressure gradient across the valve. These pressures can also be measured directly in the hemodynamics laboratory (Fig. 39-7).

FIGURE 39-7 Pressure tracings in severe pulmonary stenosis. Pulmonary pressure is extremely low and appears damped. Right ventricular pressure is suprasystemic. (From Shabetai R, Adolph RJ: *Principles of cardiac catheterization*. In Fowler NO [ed]: *Cardiac Diagnosis and Treatment*. Hagerstown, MD: Harper & Row, 1980, p 106.)

Pulmonic stenosis is generally well tolerated so that neither pregnancy nor labor poses a significant threat.⁴⁹ Prophylaxis against infective endocarditis is necessary. More severe pulmonary stenosis requires treatment. Unlike aortic stenosis, however, critical pulmonary stenosis does not require valve replacement or open repair. Most cases are treated successfully with transvenous balloon valvuloplasty.⁵⁰ Ideally, this should be carried out before pregnancy is undertaken; if a woman does become pregnant and develops intractable right-sided heart failure, the procedure can still be safely performed (but at some risk to the fetus). Extreme pulmonary stenosis (right ventricular systolic pressure > systemic systolic pressure) is a contraindication to pregnancy until the lesion is adequately treated.

Right-to-Left Shunt without Pulmonary Hypertension (Tetralogy of Fallot)

The congenital cyanotic heart diseases discussed so far have been associated with a communication between the pulmonary and systemic circulations and pulmonary vascular resistance sufficiently high to cause a right-to-left shunt. However, cyanosis occurs in other congenital malformations, in which there is a defect between the right and left sides of the heart but also right ventricular outflow obstruction (Figs. 39-8 and 39-9). Examples include the tetralogy of Fallot and tricuspid atresia.

Tetralogy of Fallot is used to illustrate this class of congenital malformation of the heart, because it is by far the most common form of cyanotic congenital heart disease encountered in pregnancy. Moreover, the offspring of a mother with tetralogy of Fallot has a 2% to 13% chance of inheriting the condition.⁵¹ The syndrome includes (1) a large defect high in the ventricular septum; (2) pulmonary stenosis, which may be at the valve itself but more commonly is in the infundibulum of the right ventricle; (3) dextroposition of the aorta so that the aortic orifice sits astride the VSD and overrides, at least in part, the right ventricle; and (4) right ventricular hypertrophy (Fig. 39-10).

A wide spectrum of clinical presentations may be present, depending on the relative size of the VSD and the degree of right ventricular

FIGURE 39-9 Transthoracic echocardiographic image of tetralogy of Fallot. A large ventricular septal defect is present, and the aorta (AO) overrides the interventricular septum. LV, left ventricle; MV, mitral valve; RV, right ventricle.

outflow obstruction that diverts blood flow through the VSD. In the typical case, right and left ventricular systolic pressures are equal but the pulmonary artery pressure is exceedingly low. A loud, long systolic murmur is audible along the left sternal border. The murmur is caused by an abnormal flow pattern through the obstructed right ventricular outflow tract. The pulmonary valve closure sound is usually inaudible. Patients are usually cyanotic and often have significant clubbing of the fingers and toes. The hematocrit value is greatly elevated because of the severe erythrocytosis. Phlebotomy is not indicated to treat the hematocrit level per se but is indicated if symptoms of hyperviscosity occur. Ignoring this important therapeutic principle leads to a microcytic anemia that further complicates pregnancy. The ECG shows severe right ventricular hypertrophy. The chest radiograph is characterized by a normal-sized heart and a concavity in the region where the pulmonary artery should be (Fig. 39-11). As in all malformations of this general type, the lung fields are oligemic, showing small vessels throughout.

Most adults born with the tetralogy of Fallot and lesions with similar pathophysiology have undergone surgical treatment before reaching young adulthood. Children raised in undeveloped countries are an important exception. Many patients have had surgery to close

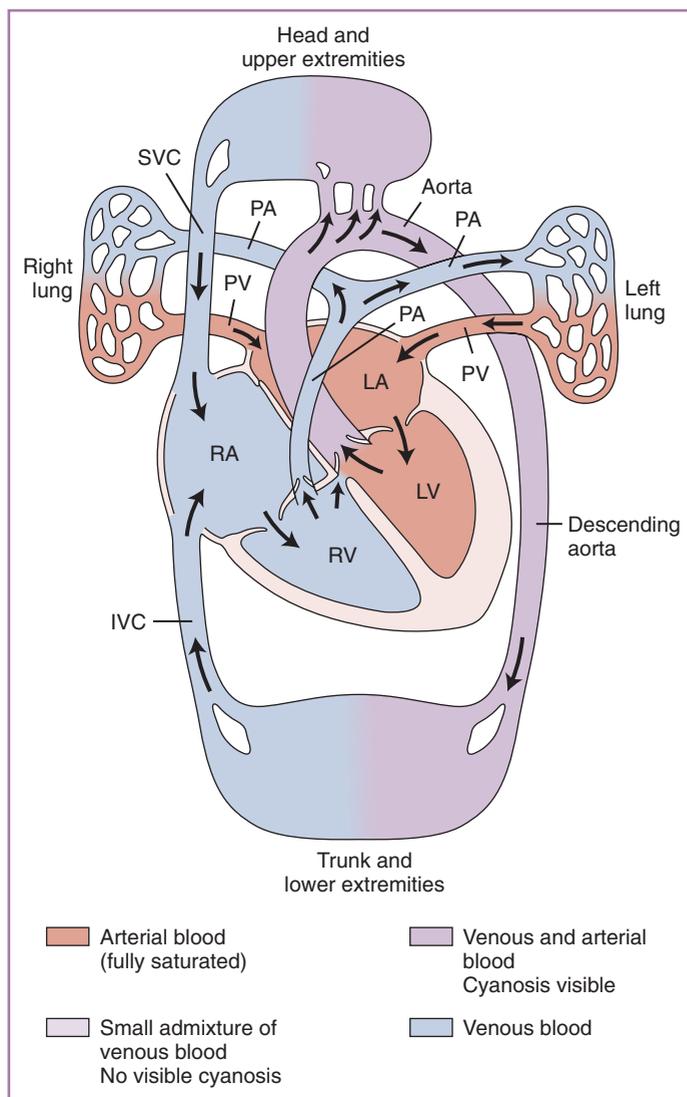

FIGURE 39-10 Tetralogy of Fallot. Blood shunts from left to right through the ventricular septal defect because its flow to the lungs is impeded by pulmonary stenosis; this results in cyanosis. the VSD and relieve the pulmonary stenosis, constituting virtual “total repair” and rendering them potentially safe candidates for pregnancy and delivery. However, the operation is not curative. Significant arrhythmia and conduction defects that may eventually lead to the need for electronic cardiac pacing or an implantable defibrillator may occur years after an apparently successful operation. Other sequelae and residua include only partial relief of the right ventricular outflow obstruction and pulmonic regurgitation. This latter problem is usually well tolerated early but may lead to right-sided heart failure, necessitating reoperation. In addition, women with repaired tetralogy of Fallot and significant pulmonic regurgitation have a higher risk of decompensation during pregnancy.⁵²

The cyanotic patient with tetralogy of Fallot has special problems during pregnancy. The reduced systemic vascular resistance of pregnancy causes more blood to shunt from right to left, leaving less to flow to the pulmonary circulation. This intensifies hypoxemia and can lead to syncope or death. Maintenance of venous return is crucial. The most dangerous times for these women are late pregnancy and the early puerperium, because venous return is impeded by the large gravid uterus near term and by peripheral venous pooling after delivery. Pressure-graded elastic support hose are recommended. Blood loss during labor may compromise venous return, and blood volume must be promptly and adequately restored. Anesthetic considerations during delivery are discussed in detail in Chapter 56. Antibiotic prophylaxis should be used in these susceptible patients at delivery.

Because of the combined high maternal risk and high incidence of fetal loss, pregnancy is discouraged in women with uncorrected tetralogy of Fallot. The prognosis is particularly bleak in those women with a history of repeated syncopal episodes, a hematocrit level greater than 60%, or a right ventricular systolic pressure greater than 120 mm Hg. If a young woman with untreated tetralogy of Fallot requests pregnancy counseling, she should be advised to undergo surgical correction before pregnancy. Pregnancy does not represent a significantly increased risk for patients in whom the VSD has been patched and the pulmonary stenosis corrected.

Coarctation of the Aorta

Coarctation of the aorta is a congenital defect in the area of the aorta where the ligamentum arteriosum and the left subclavian artery insert (the distal portion of the aortic arch). The malformation may be simple or complex, and it is either isolated or associated with PDA and other malformations, notably aortic stenosis and aortic regurgitation secondary to a bicuspid aortic valve. It may also occur in women with Turner syndrome. The lesion should be detected and treated surgically or by balloon dilation in infancy or childhood, but it may be present in women who are, or want to become, pregnant.

Typical features include the following:

- Upper extremity hypertension but lower extremity hypotension
- Visible and palpable collateral arteries in the scapular area
- A late systolic murmur, usually loudest over the interscapular region
- Femoral pulses that lag behind the carotid pulses and are of diminished amplitude
- Notching of the inferior rib borders seen on the chest radiograph and resulting from erosion by arterial collaterals that bridge the coarctation

Electrocardiographic evidence of severe left ventricular hypertrophy strongly suggests associated aortic stenosis. Surgical grafting or percutaneous intravascular balloon dilation reduces the upper extremity hypertension, but blood pressure does not always return to normal, and hypertension may recur in later life.

Whenever possible, the operation should be performed before pregnancy; otherwise, the maternal mortality rate is approximately 3%. Coarctation is associated with congenital berry aneurysm of the circle of Willis and hemorrhagic stroke. The risk of stroke may increase during labor because of transient elevations in blood pressure. Patients are at risk for aortic dissection and infective endocarditis involving an abnormal aortic valve; these risks increase during pregnancy.⁵³ Hypertension often worsens as well.⁵⁴ Coarctation is also associated with an increased frequency of preeclampsia.³¹ The operation does not

(From Shabetai R, Adolph RJ: Principles of cardiac catheterization. In Fowler NO [ed]: Cardiac Diagnosis and Treatment. Hagerstown, MD: Harper & Row, 1980, p 106.)

require cardiopulmonary bypass and can be carried out with safety for the mother and with less fetal risk than accompanies open heart surgery with cardiopulmonary bypass. Although transvascular balloon dilation of aortic coarctation is a viable option for children and infants with coarctation, its use in adults is controversial.⁵⁵ The procedure is well accepted for treatment of postsurgical renarrowing of the coarctation, but de novo balloon angioplasty carries a risk of aortic

dissection and rupture. A number of centers are now performing balloon dilation with stent implantation for adults with unoperated aortic coarctation, but large, multicenter studies are currently not available.⁵⁶

If delivery must be undertaken in cases of unoperated coarctation, blood pressure can be titrated with β -adrenergic-blocking agents delivered by intravenous drip.

Other Congenital Cardiac Malformations

Ebstein Anomaly

Ebstein anomaly is a malformation of the tricuspid valve in which the septal leaflet is displaced apically and the anterior leaflet is abnormally large in size. The deformed tricuspid valve apparatus may be significantly incompetent or stenotic, depending on the location of the anomalously placed cusps of the valve. In some cases, the malformation causes impediment to right ventricular outflow.

The clinical features are easily recognized by a cardiologist, and the echocardiogram is characteristic and reliable (Fig. 39-12). This syndrome is frequently associated with anomalous atrioventricular conduction pathways and with the Wolff-Parkinson-White syndrome. Patients may also have an ASD with right-to-left shunting and cyanosis. Supraventricular arrhythmias are also common.

The most favored treatment is reconstruction of the tricuspid valve, for which satisfactory techniques have now been developed. The operation should be performed before pregnancy is undertaken. Interruption of anomalous conduction pathways also can be performed during surgery.

The Mayo Clinic group⁵⁷ reported on 111 pregnancies in 44 women with Ebstein anomaly resulting in 95 live births, although most of the infants had low birth weight. Vaginal delivery was performed in 89% and cesarean section in 9%; 23 deliveries were premature. Nineteen pregnancies ended with spontaneous abortion, and seven ended with therapeutic abortion. Congenital heart disease occurred in 6% of the children of mothers with Ebstein anomaly.

Congenital Atrioventricular Block

Congenital atrioventricular block differs somewhat from heart block in adults. The pacemaker is usually junctional, and therefore the QRS complex is normal or only slightly widened and the ventricular rate is

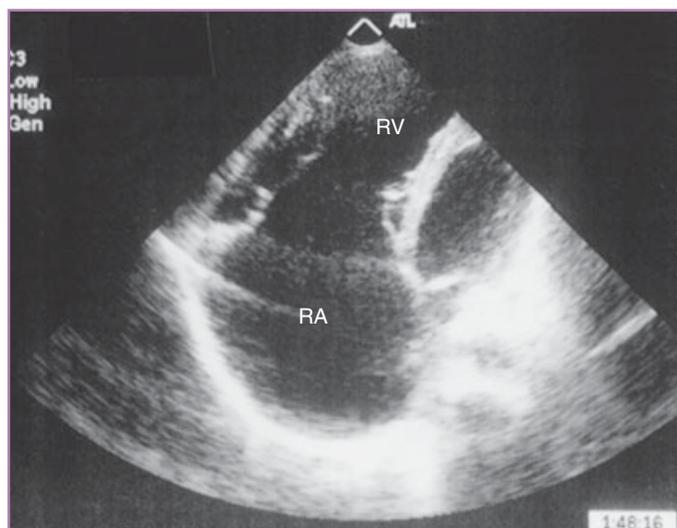

FIGURE 39-12 Ebstein anomaly. The right atrium (RA) and right ventricle (RV) are markedly dilated, and the tricuspid valve is displaced toward the cardiac apex.

more rapid than in acquired complete atrioventricular block. Although these patients appear to do well during childhood and young adulthood, the lesion is associated with an unexpectedly high mortality rate. Therefore, treatment with a pacemaker is indicated in many of the cases.⁵⁸ The pacemaker used should be dual-chamber and rate-responsive, so that normal cardiovascular dynamics at rest and exercise will be preserved. Patients who are untreated or who have received a pacemaker are at slight to no increased risk during pregnancy.

Additional Malformations

A number of other malformations may be present in women of child-bearing age, including

- Other left-to-right or right-to-left shunts
- Transposition of the great vessels
- Truncus arteriosus
- Single-ventricle double-outlet right ventricle
- Various obstructive lesions

The malformations may be multiple and complex. Survival to adulthood depends on at least partial correction, which may have been furnished by surgical operation or may be part of the malformation. For example, in D-type transposition of the great vessels, the aorta arises from the right ventricle and the pulmonary artery from the left. Survival requires a shunt at some level (ASD, VSD, or PDA) so that oxygenated blood can enter the systemic circulation.

Some of these women with untreated and delicately balanced lesions bear children, but usually this is not wise to attempt. Transposition of the great vessels is now treated by anastomosis of the aorta to the morphologic left ventricle and of the pulmonary artery to the morphologic right ventricle. Lesions such as single ventricle may be palliated by the Fontan procedure, in which venous return is connected directly to the pulmonary circulation, bypassing the right side of the heart. Neither procedure constitutes a cure, but successful pregnancy can occur.

In summary, patients should be evaluated and tracked by a cardiologist who is experienced in congenital heart disease and by a maternal-fetal medicine specialist with knowledge and experience in managing pregnancy in women with congenital cardiac lesions.^{7,31}

Rheumatic Heart Disease

Rheumatic Fever

Rheumatic fever is now distinctly uncommon in the United States, Canada, Western Europe, and Great Britain, but it is still prevalent in less economically developed countries. Young female immigrants to the Western world constitute a large proportion of the patients with a history of rheumatic fever. These women are at risk of developing rheumatic valvular heart disease 10 to 20 years after the initial episode of rheumatic fever.

Chronic Rheumatic Heart Disease

In the United States, acute rheumatic fever with carditis has been uncommon for many years, and chronic rheumatic heart disease, which manifests years to decades after the episode of acute rheumatic fever, is becoming uncommon among the native childbearing population. Control of rheumatic fever has largely shifted the burden of

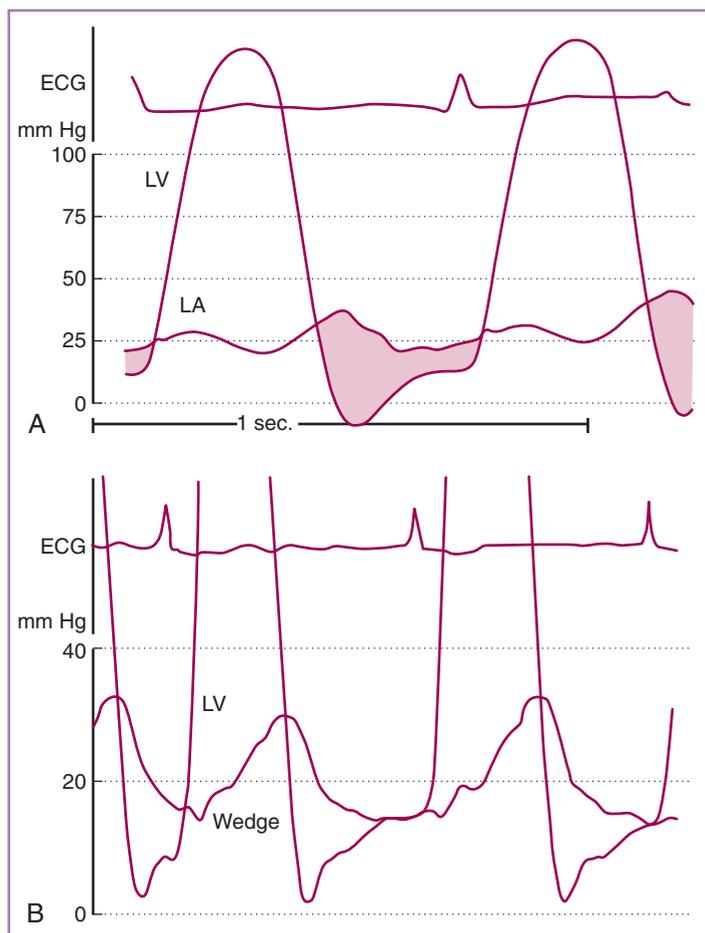

FIGURE 39-13 Hemodynamics of mitral valve disease. **A**, Mitral stenosis. The diastolic pressure gradient (shaded area) between the left atrium (LA) and left ventricle (LV) persists to end-diastole. **B**, Mitral regurgitation. Note the large systolic pressure wave of the pulmonary wedge pressure tracing. The diastolic pressure gradient is limited to early diastole. ECG, electrocardiogram.

rheumatic heart disease from teenagers to women in the third and fourth decades of life.

The characteristic lesion of rheumatic heart disease is mitral stenosis, and the next most common manifestation is the combination of mitral stenosis with aortic regurgitation. The mitral valve may become both stenotic and incompetent, and the valve may calcify. Pure mitral regurgitation is almost always nonrheumatic, except in young people with acute carditis. Similarly, aortic valve disease without mitral involvement is seldom rheumatic. Tricuspid regurgitation is a late secondary manifestation that occurs secondary to pulmonary hypertension and right ventricular enlargement.

Mitral Stenosis

The principal features are enlargement of the left atrium and right ventricle, a diastolic murmur at the cardiac apex, and pulmonary hypertension. Inflow to the left ventricle is impeded by the narrowed valve and can be accomplished only by an increased level of pressure in the left atrium (Figs. 39-13 and 39-14). The faster the heart rate, the less time in diastole, and the less time for ventricular filling. Left atrial pressure therefore is further elevated by tachycardia. Atrial fibrillation

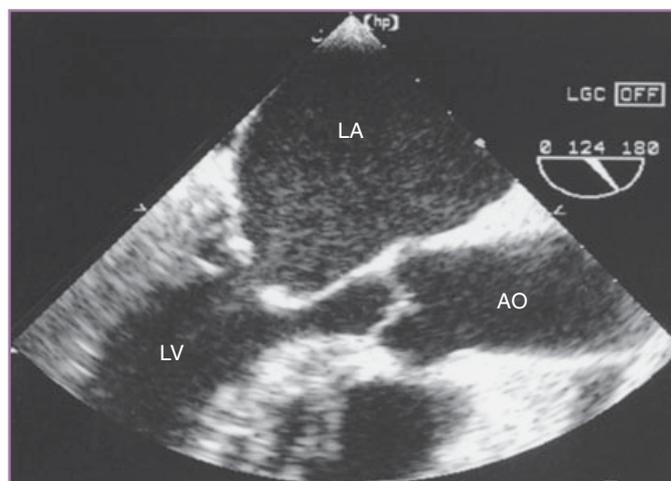

FIGURE 39-14 Transesophageal echocardiographic image of mitral stenosis. During diastole, opening of the mitral valve is restricted by scarring and fusion of the leaflet tips. Characteristic doming of the leaflet is also present. AO, aorta; LA, left atrium; LV, left ventricle.

eventually supervenes, causing a fall in cardiac output and escalation of left atrial hypertension, especially if the ventricular rate is not controlled. Atrial fibrillation substantially increases the probability of thrombus in the left atrial appendage and the threat of a subsequent embolic stroke.

Effect of Pregnancy

Pregnancy drastically stresses the circulation in women with severe mitral stenosis. The increased blood volume, heart rate, and cardiac output raise left atrial pressure to a level that causes severe pulmonary congestion, leading to progressive exertional dyspnea, orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema. Women who have not been receiving antenatal care often present initially with severe pulmonary edema during pregnancy. In long-standing cases, severe right-sided heart failure develops. Infective endocarditis, pulmonary embolism, and massive hemoptysis may also occur. The maternal risk for death is highest in the third trimester and in the puerperium.^{10,11}

Significant Mitral Stenosis without Heart Failure

Patients who have mitral stenosis without heart failure should be advised to undergo percutaneous balloon mitral valvuloplasty and to postpone pregnancy until after full recovery from the procedure. If they do not follow this advice and do become pregnant, one reasonable course in the first trimester may be pregnancy termination, followed by mitral valve operation and subsequent pregnancy planning. If this is not acceptable, the patient can be advised to remain under frequent close supervision by the cardiologist and obstetrician and to accept long periods of rest, prohibition of strenuous activity, salt restriction, and diuretic treatment. If this type of regimen is followed closely and is expertly supervised, maternal mortality is low.^{10,11} Atrial fibrillation signals the need for digitalis, a β -adrenergic blocking agent, or a calcium channel blocking agent to maintain a normal heart rate. More than one of these drugs may be needed to achieve the desired result without side effects. For patients with atrial fibrillation and significant mitral stenosis, anticoagulant treatment is recommended.

Depending on her course, the woman may have to spend many weeks in bed and should be admitted to the hospital well in advance

of labor. The supine posture should be avoided as much as possible, and delivery in the left lateral decubitus position is desirable. The lithotomy position, with the patient on her back and her feet elevated in stirrups, is an invitation to pulmonary edema. The crisis of pulmonary edema may appear despite good management. Sedation (to drop the heart rate and promote cardiac filling and output) and diuretic treatment must then be followed by prompt delivery if the fetus is viable.

Percutaneous balloon valvuloplasty is a nonsurgical means to dilate mitral stenosis and is the current treatment of choice for most patients with symptomatic mitral stenosis.^{59,60} The procedure can be done during pregnancy if heart failure is severe, and it appears to be safer for the fetus than open mitral commissurotomy.⁶¹ Lead shielding should be used, because fluoroscopy is required to guide the balloon into the mitral orifice. Balloon valvuloplasty should be used with caution during pregnancy, and it should be reserved for women who are unresponsive to aggressive medical therapy.^{10,11} If possible, the procedure should be put off at least until after the first trimester. Patients with confirmed mitral stenosis and right-sided heart failure with severe pulmonary congestion should avoid pregnancy until after the valvular disease is corrected, because the risk of maternal mortality is high.

Mitral Valve Prolapse

In the past, a degree of prolapse of the mitral valve was considered so prevalent in the general population,⁶² particularly among young women, that authorities differed as to whether mitral valve prolapse (MVP) should be considered a normal variant or abnormal. More exacting echocardiographic criteria have yielded more realistic and much lower estimates of the prevalence of MVP (perhaps 1% of the female population).⁶³

True MVP occurs because portions of the mitral valve apparatus are redundant and, therefore, the leaflets balloon into the left atrium during systole. The leaflets may remain coapted during systole, or they may separate, causing a variable degree of mitral regurgitation. More severe prolapse may be caused by myxomatous degeneration of the mitral leaflets. These abnormalities of connective tissue may be isolated to the mitral valve, or they may be a part of Marfan syndrome (see later discussion). MVP (and sometimes tricuspid valve prolapse) may be associated with congenital malformations, notably ASD.

Mitral regurgitation may be absent, intermittent, or permanent and may be of any degree of severity. Severe mitral regurgitation greatly enlarges the left atrium (Fig. 39-15) and ventricle and eventually leads to left ventricular failure and pulmonary hypertension, the latter less severe than with mitral stenosis.

Past reports have associated MVP with a number of disorders, including stroke, dysautonomia, panic attacks, anxiety, and transient ischemic attacks,^{64,65} but more recent studies^{66,67} have discounted almost all of these associations. The syndrome of myxomatous mitral valve degeneration with prolapse and mitral regurgitation is quite uncommon, and many women who were diagnosed with MVP more than 10 years ago do not have any actual pathology. For this reason, it may be prudent to order an echocardiogram for any woman who was diagnosed with MVP a number of years ago if she has no symptoms or signs of mitral regurgitation. This may prevent needless and repeated exposure to antibiotics (e.g., before dental procedures).

Some women with MVP complain of chest pain, which can be suggestive of angina pectoris. Although the coronary arteriogram is normal, T-wave inversions, especially in leads II, III, and aVF, are found

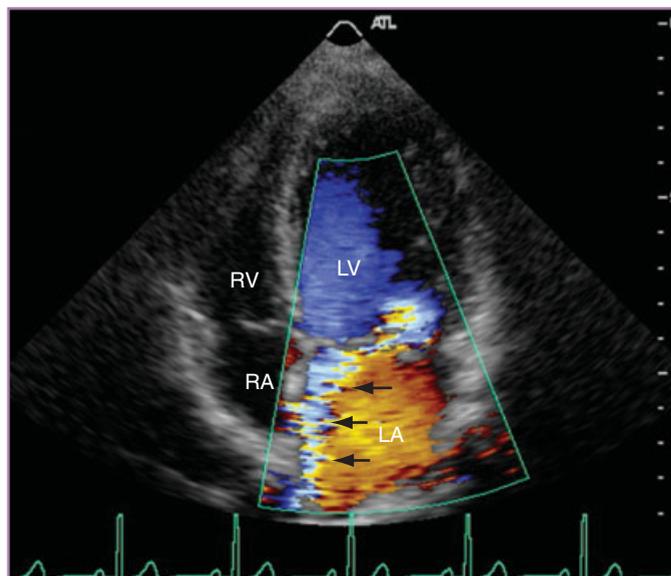

FIGURE 39-15 Transthoracic echocardiographic image of severe mitral regurgitation. During systole, the mitral valve does not coapt properly, and an eccentric jet of mitral regurgitation is present (arrows). LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

in a small proportion, and the treadmill exercise test may induce ST-segment depression, indistinguishable from ischemia.⁶⁸

In most cases, the diagnosis of MVP is made by the physician providing pre-conception counseling and antenatal care. The examination reveals a systolic click occurring between the first and second heart sounds. The click may or may not be followed by a midsystolic or late systolic murmur. The click and murmur vary with the patient's posture and hydration status. In most patients, no other abnormality is found on clinical examination. Unless significant mitral regurgitation is present, the patient should be told that pregnancy, labor, and delivery will be safe and unaffected by the prolapse.

Patients with MVP and significant mitral regurgitation are far fewer in number than those with simple prolapse. The murmur is louder, longer, and may become pansystolic. Clinical and laboratory evidence of enlargement of the left atrium and ventricle increases with increasing severity and duration of regurgitation. Even modest impairment of left ventricular function, especially if it is progressive, indicates that pregnancy may well precipitate heart failure and cannot be lightly undertaken. More obvious left ventricular dysfunction (e.g., EF < 40%) indicates that the woman should be strongly advised to avoid pregnancy. She should then be referred for complete cardiologic evaluation² and surgery to address the mitral regurgitation. In most cases of MVP, the valve can be repaired rather than replaced. It is important to appreciate that left ventricular function deteriorates after mitral valve replacement but may improve after mitral valve repair.⁶⁹ Thereafter, if the result is good and ventricular function is significantly improved, pregnancy may be undertaken successfully.

Chest pain and arrhythmias are best managed with β -adrenergic blockers such as atenolol or metoprolol. If symptoms are unusually pronounced, thyroid function tests should be checked as well. Because the gravid uterus and vasodilation may add to postural hypotension, the patient should be informed that she may experience lightheadedness, dizziness, or fainting with prolonged standing during pregnancy.

Mitral Regurgitation Not Caused by Prolapse

In younger women, mitral regurgitation may be a result of rheumatic or congenital disease. In older women, mitral regurgitation is more often a manifestation of hypertension, ischemia, idiopathic myocardial disease, or infective endocarditis.

Most of the information regarding mitral regurgitation in prolapse also applies here. In older women, the valve is more likely to be calcified; fewer of the valves are amenable to repair and must be replaced. The problems posed by prosthetic valves in pregnant women are discussed later in this chapter; the hemodynamics are illustrated in Figure 39-13, and echocardiography is illustrated in Figure 39-15.

In patients with far-advanced left ventricular dysfunction or failure who have severe mitral regurgitation, it can be difficult to determine which is the cause and which the result. In either case, the patient with a greatly enlarged and hypokinetic ventricle must be advised against becoming pregnant. Most of the pregnancy would be spent in bed, the course would be punctuated by episodes of uncompensated congestive heart failure (any of which could prove fatal or require therapeutic abortion), and the risk to the fetus would exceed 50%.

Pregnancy in patients with mild or moderate mitral regurgitation can be managed safely with a conservative regimen of reduced physical activity, salt restriction, and low doses of a diuretic agent. Low-dose digoxin may be helpful if atrial fibrillation supervenes. As mentioned previously, severe mitral regurgitation indicates a need for repair or replacement of the valve when symptoms and/or early evidence of declining ventricular function appear.^{2,70} Clearly, surgical treatment is best undertaken before pregnancy. If the woman is already pregnant, the physician should make every effort to help her to carry the pregnancy to term using strict medical measures. This course is particularly important if clinical, radiologic, and echocardiographic criteria suggest that the valve is irreparable and would require replacement.

Aortic Valve Disease

Aortic Stenosis

(see also the earlier section on aortic stenosis under Congenital Obstructive Lesions)

The etiologic mechanism of aortic stenosis commonly is degeneration, often of a congenitally bicuspid valve. The problem may be encountered in women a decade or more older than those with rheumatic or congenital aortic valve disease. The combination of aortic and mitral stenosis is usually caused by rheumatic heart disease. Critical aortic stenosis leads to severe left ventricular hypertrophy and, eventually, to left ventricular failure. Before overt heart failure develops, syncope or even sudden death may occur.

The characteristic findings include an ejection systolic murmur that is harsher and longer and peaks later than the normal ejection murmur of pregnancy. It is usually loudest at the second right intercostal space. If aortic stenosis is severe, the pulse upstroke is slow, and left ventricular hypertrophy is evident on the ECG. The echocardiogram is a more sensitive and more specific marker of left ventricular hypertrophy. Doppler echocardiographic measurement of blood flow velocity through the aortic valve permits reliable estimation of the systolic pressure drop across the valve, as well as calculation of the valve area. The hemodynamics are illustrated in Figure 39-16. The left ventricle in women remodels differently than in men. The concentric hypertro-

Rights were not granted to include this figure in electronic media. Please refer to the printed publication.

FIGURE 39-16 Hemodynamic data in aortic stenosis. Left ventricular pressure is 250/40 mm Hg (normal, 120/10 mm Hg). Aortic systolic pressure is 130 mm Hg lower than the left ventricular pressure and shows a slow upstroke and vibrations representing the systolic thrill. The record above the aortic pressure tracing is a phonocardiogram showing the systolic murmur. Also shown is the pulmonary wedge pressure (lowest pressure tracing), which is elevated to equal the left ventricular diastolic pressure. The bottom tracing is the electrocardiogram. (From Shabetai R, Adolph RJ: Principles of cardiac catheterization. In Fowler NO [ed]: Cardiac Diagnosis and Treatment. Hagerstown, MD: Harper & Row, 1980, p 106.)

phy is more pronounced, the cavity is smaller, and systolic function is supranormal.

The left ventricle does not dilate until the ventricle fails, and so a dilated ventricle in aortic stenosis is an ominous sign that calls for rapid intervention. In general, aortic valve replacement is preferred to percutaneous balloon aortic valvuloplasty, but open heart surgery presents a high risk to the fetus. For this reason, some have advised balloon aortic valvuloplasty for treatment of aortic stenosis during pregnancy,⁷¹ but valve replacement will almost certainly have to be done soon after delivery.

Hemodynamic monitoring is recommended during labor in patients with moderate to severe aortic stenosis. Vaginal delivery is preferred, with assisted second stage of labor. If cesarean section is performed, some have suggested that general anesthesia is preferred.⁷² See Chapter 56 for more details regarding anesthesia management.

Pregnancy in women with a mechanical aortic valve replacement must be undertaken with great caution and meticulous management, because continuous anticoagulation is necessary (see Pregnancy in Patients with Artificial Heart Valves, later).

Aortic Regurgitation

The etiologic mechanism of aortic regurgitation is commonly rheumatic heart disease, in which case mitral stenosis often coexists. Other diseases, such as Marfan syndrome, bicuspid aortic valve, infective endocarditis, and systemic lupus erythematosus, also may cause severe aortic regurgitation. This valvular lesion imposes a volume rather than a pressure overload on the heart and, as such, is usually well tolerated in pregnancy and labor.¹⁵

The diagnosis is usually based on the finding of a typical, high-pitched, blowing diastolic murmur and can be quantified by Doppler echocardiography. Both pregnancy and aortic regurgitation contribute to hypervolemia and peripheral vasodilatation. A prolonged course without decompensation is characteristic of chronic aortic regurgitation; once heart failure appears, however, the course may progress rapidly downhill.

Traditionally, aortic valve replacement is not recommended until symptoms of heart failure (most notably exertional dyspnea) occur or left ventricular dysfunction/enlargement is seen on echocardiography. Repair of aortic regurgitation is much less successful than repair of mitral regurgitation. For a woman who is contemplating pregnancy, the need for aortic valve replacement constitutes the grounds on which the medical advisor should caution against pregnancy and make the patient fully understand the consequences of choosing otherwise. If left ventricular dysfunction and heart failure are absent, carefully supervised pregnancy is in order, and the woman should be encouraged to complete her family before cardiac dysfunction and the need for valve replacement arise.

In many cases, the cause of aortic regurgitation is unclear. Special care must be taken to rule out aortic aneurysm or dissection, especially if aortic regurgitation is associated with Marfan syndrome or coarctation of the aorta, because these conditions can result in aortic rupture and constitute strong reasons to advise against pregnancy.

Drug-Induced Valvular Heart Disease

A recently recognized cause of deformity and regurgitation of the cardiac valves is ingestion of the drug combination, fenfluramine-phenentermine. The revelation of this side effect led to withdrawal of this drug combination from the market in the late 1990s. The mechanism of the effect of these drugs is unclear, and there is evidence that valvular lesions may sometimes gradually improve after discontinuation of the drugs.⁷³ In some cases, however, valve surgery has been necessary.⁷⁴

Cardiomyopathy

Cardiomyopathy is a disorder of myocardial structure or function. A number of forms exist, and several types that are seen in pregnant women are discussed here.

Dilated Cardiomyopathy

In dilated cardiomyopathy, the cardiac chambers are severely dilated and the left ventricle is diffusely hypokinetic. Left ventricular wall tension is increased, and systolic pump function progressively declines. Consequently, cardiac output falls and filling pressures increase; both of these changes cause progressive dyspnea, edema, and fatigue. Serious ventricular arrhythmia develops in most cases.

Despite advances in treatment, the 5-year survival rate in patients with dilated cardiomyopathy and symptomatic heart failure approaches 50%. In some cases, however, improvement or even return to normal has been noted. Both ACE inhibitors and β -adrenergic blocking agents (most notably carvedilol) have been shown to slow the deterioration of left ventricular function in patients with congestive heart failure and occasionally to actually improve the left ventricular EF.⁷⁵ In addition, some of the patients who recover may have had unrecognized myocar-

ditis that did not progress to cardiomyopathy. Dilated cardiomyopathy may be the outcome of an autoimmune response to a myocardial injury, most commonly viral myocarditis. The exact role of alcohol is unclear, but it is at least a major aggravating factor in some cases.

Patients may have symptoms and signs of heart failure for which no cause can be found on clinical and laboratory examination. Weight is increased, the jugular venous pressure is elevated, and the heart is enlarged. An S_3 gallop is often present, frequently accompanied by the murmurs of mitral and tricuspid regurgitation, which develop as a consequence of cardiac dilatation. The ECG is usually abnormal, often showing left ventricular hypertrophy or left bundle branch block. Echocardiography shows enlargement and hypocontractility of the ventricles. The patients are subject to mural thrombus in the cardiac chambers with a consequent risk of stroke or pulmonary embolism. Established dilated cardiomyopathy, even when heart failure is compensated, is a contraindication to pregnancy.

It was formerly thought that dilated cardiomyopathy was sporadic and not familial, but inherited cases have now been observed. It is estimated that 20% of cases are genetic in origin.¹³ Therefore, if an extensive family history of heart failure is present, the prospective mother and father should be informed of the potential risk of genetic transmission.

In a young woman with severe dilated cardiomyopathy, manifested by greatly impaired ventricular function and drastically reduced exercise capacity, cardiac transplantation should be considered. Successful pregnancy has been reported in women who have undergone heart or heart-lung transplantation.⁷⁶⁻⁷⁸

Peripartum Cardiomyopathy

Peripartum cardiomyopathy is a form of dilated cardiomyopathy that occurs in the last month of pregnancy or during the first 5 months after delivery, in the absence of previous heart disease.⁷⁹ The incidence in the United States is 1 case per 3000 to 4000 live births. Additional diagnostic criteria include a left ventricular EF of less than 45% and, most importantly, the absence of other identifiable causes of heart failure.⁸⁰ Whether the peripartum or postpartum state somehow constitutes the original myocardial insult or is an aggravating factor in individuals susceptible to cardiomyopathy for other reasons is not known.⁸¹ It has been suggested that some cases are caused by active myocarditis,⁸² but other investigators have reported that the incidence of myocarditis is the same in idiopathic and peripartum cardiomyopathy.⁸³ It is also possible that the stress of pregnancy may “unmask” an underlying cardiomyopathic process that might otherwise have manifested later in life.⁸⁴ This devastating disease can affect previously healthy young women and can cause unexpected sudden death.⁸⁵

The clinical course of peripartum cardiomyopathy is frustratingly variable and difficult to predict.⁸⁶ About 20% of patients have a dramatic and fulminant downhill course and can be saved only with cardiac transplantation. Others, perhaps 30% to 50%, have partial recovery with persistence of some degree of cardiac dysfunction. The rest show remarkable recovery.⁸¹ Apparently, the initial degree of left ventricular dysfunction does not predict the long-term outcome.⁸⁷ A recent study showed that cardiac function improved gradually over a 5-year period.⁸⁸

Women who recover from peripartum cardiomyopathy must be informed that cardiomyopathy may recur with a subsequent pregnancy. For some time, this risk has been believed to be 50%.⁸⁷ However, one report of four women who had peripartum cardiomyopathy with a previous pregnancy but whose hearts remained normal clinically and by echocardiography in a subsequent pregnancy indicated that the risk

may be less.⁸⁹ The largest study to date of patients with a history of peripartum cardiomyopathy who subsequently became pregnant⁹⁰ showed that heart failure recurred in 20% of those patients whose EF had normalized after the previous pregnancy. None of these patients died during the study period. However, heart failure recurred in 40% of the patients who had persistent left ventricular dysfunction after their previous pregnancy, and the maternal mortality in this group was 19%. A study from Haiti of 15 women with peripartum cardiomyopathy showed a recurrence rate of almost 50% during a subsequent pregnancy.⁹¹ Therefore, the risk of recurrent heart failure is high in women with peripartum cardiomyopathy, especially in those who do not have complete recovery of left ventricular function.

Treatment is similar to that for other patients with heart failure. Because ACE inhibitors are contraindicated during pregnancy hydralazine is the vasodilator of choice. If cardiac dysfunction is severe, anticoagulation is usually recommended, given the prothrombotic tendency of pregnancy. Low-molecular-weight heparin (LMWH) is probably preferred to unfractionated heparin (warfarin is not recommended).⁸⁶

Idiopathic Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy, which is usually inherited as an autosomal dominant trait with variable penetrance but sometimes is caused by a spontaneous mutation, is being recognized with increasing frequency. The phenotypes vary greatly. Left ventricular outflow tract obstruction may or may not be present, and the hypertrophy may be either symmetrical or asymmetrical. The chief symptoms are angina, dyspnea, arrhythmia, and syncope. Sudden death is a feature mostly confined to patients in whom the diagnosis is established in childhood or youth, patients with a history of syncope or ventricular arrhythmia, and patients with a family history of hypertrophic cardiomyopathy and sudden death. Recent research has shown that certain specific genetic defects place patients at great risk for sudden death.

When the disease is first detected in older adults, the course is more benign and sudden death is rare. Left ventricular hypertrophy is often apparent on clinical examination and ECG and is invariably present on the echocardiogram. The echocardiographic findings are often diagnostic and include marked thickening of the ventricular septum, usually with less thickness of the other walls of the left ventricle (asymmetrical hypertrophy), and abnormal systolic anterior movement of the mitral valve (Fig. 39-17). The internal dimensions of the left ventricle are normal to small, and its contractility is increased.

An important feature in many cases is obstruction of the space between the ventricular septum and the anterior leaflet of the mitral valve. This space constitutes the left ventricular outflow tract. Outflow obstruction by the anterior mitral valve leaflet is worsened by increased inotropy, decreased heart size, and diminished peripheral vascular resistance. The normal fall in peripheral vascular resistance that accompanies pregnancy tends to increase outflow tract obstruction, although this effect may be compensated for by the physiologic increase in blood volume. In addition, vena caval obstruction in late pregnancy and blood loss at delivery, both of which may result in hypotension, can have a similar deleterious effect. Outflow tract obstruction may also be worsened by the increases in circulating catecholamine levels frequently encountered during labor and delivery. The Valsalva maneuver during the second stage of labor may greatly diminish heart size and increase outflow tract obstruction. Despite all these problems, however, most pregnant women with hypertrophic cardiomyopathy do tolerate labor and delivery.⁹²

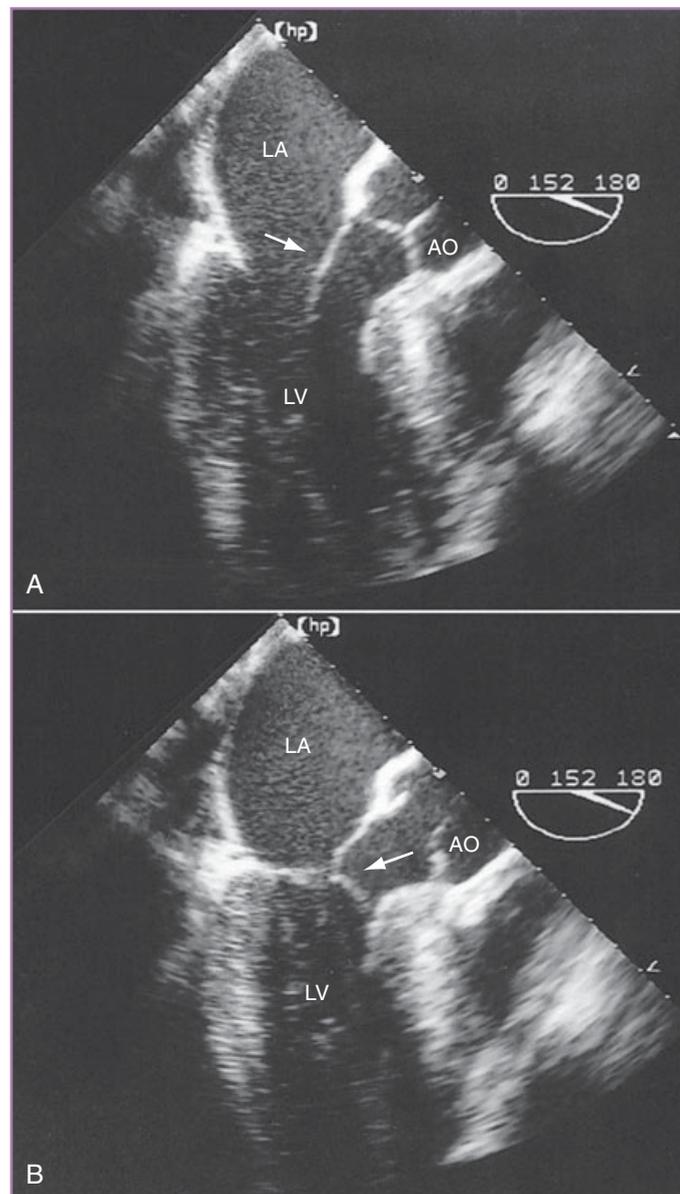

FIGURE 39-17 Transesophageal echocardiographic images of hypertrophic cardiomyopathy. **A**, During diastole the anterior leaflet of the mitral valve (*arrow*) is in a normal position. **B**, During systole the leaflet (*arrow*) is pulled by Venturi forces into the left ventricular outflow tract, causing obstruction to outflow. AO, aorta; LA, left atrium; LV, left ventricle.

There is a complex interplay between the hemodynamics of the cardiomyopathy and those of pregnancy, neither of which is constant. Exacerbation of symptoms⁹³ and even sudden death⁹⁴ have been reported during pregnancy in women with obstructive cardiomyopathy. Treatment is aimed at avoiding hypovolemia, maintaining venous return, and diminishing the force of myocardial contraction by avoiding anxiety, excitement, and strenuous activity.

Because left ventricular diastolic compliance can be greatly reduced in this disease, excessive or too rapid volume repletion can induce pulmonary edema. β -Adrenergic blockade is considered first-line pharmacologic therapy for symptomatic hypertrophic cardiomyopathy and can be continued or instituted during pregnancy. The dose

should be the minimal effective dose needed to avoid excessive slowing of the fetal heart.

Esmolol can be given intravenously if the patient first presents with severe symptoms. Volume replacement and vasopressor therapy may be needed, along with β -adrenergic blockers. Calcium channel blockers, such as verapamil, have been shown to be effective in reducing symptoms, but they must be used cautiously because they can cause pulmonary edema in severe cases. Nifedipine, because of its vasodilator properties, is best avoided.

Vaginal delivery is almost always appropriate in the absence of an obstetric indication for abdominal delivery. Impaired venous return is highly undesirable in hypertrophic cardiomyopathy and can be ameliorated by managing the second stage of labor with the patient in the left lateral decubitus position.

Acquired Immunodeficiency Syndrome

Myocarditis or cardiomyopathy is frequently discovered on postmortem examination of patients with acquired immunodeficiency syndrome (AIDS).^{95,96} Symptomatic myocardial disease, although considerably less common, also occurs. If patients with full-blown AIDS are screened for cardiac involvement (e.g., by echocardiography), cardiac or pericardial involvement is found in almost 75% of the cases.⁹⁷ In some cases, these abnormalities are transient.⁹⁸ Myocarditis is usually caused by opportunistic infection, but in some cases hybridization studies have proved direct AIDS infection. Clinical findings range from occult ventricular dysfunction to severe uncompensated heart failure. Rarely, even Kaposi sarcoma has been detected in the heart or pericardium. Pericardial effusion, often occult, is one of the more common cardiac manifestations and suggests a worse prognosis.⁹⁹ Malignant lymphoma involving the myocardium and endocardium has been reported as well. In the current era of highly-active antiretroviral therapy (HAART), myocardial involvement has become considerably less common in patients with human immunodeficiency virus (HIV) infection. However, some classes of antiretroviral drugs appear to cause dyslipidemia, and this can lead to an increased risk of coronary artery disease (CAD) and subsequent myocardial infarction.¹⁰⁰

Cardiac failure ranks low on the list of problems faced by the physician managing pregnancy complicated by AIDS. Nevertheless, physicians need to be on guard lest severe dilated cardiomyopathy, myocarditis, or cardiac tamponade develop, and the pregnant woman must be treated appropriately to prevent transmission of HIV to her offspring (see Chapter 38.)

Coronary Artery Disease

Because premenopausal women enjoy substantial protection against coronary atherosclerosis,¹⁵ ischemic heart disease is rarely relevant to obstetric practice. However, CAD may be found in women of child-bearing age when other risk factors, such as insulin-dependent diabetes, smoking, or severe dyslipidemia, overwhelm the natural protection they should normally enjoy. Lupus erythematosus, especially when treated with steroidal agents, may precipitate premature CAD. Coronary atherosclerosis appears in a significant proportion of patients who have received a cardiac transplant¹⁰¹ and may be observed in familial lipid disorders. In the latter instance, the exact nature of the lipid disorder must be defined by detailed analysis of the patient's lipid chemistry and lipoproteins to enable the physician to provide an accurate forecast of the risk that the infant would inherit the lipid

disorder and premature CAD. In women with CAD or severe dyslipidemia, oral contraceptives may be detrimental.¹⁰² In addition, spasm of anatomically normal coronary arteries leading to myocardial infarction has been reported.¹⁰³ Finally, as mentioned earlier, women with HIV infection may develop dyslipidemia on HAART, which can increase the risk of CAD.¹⁰⁰

Spontaneous coronary artery dissection is quite rare and occurs chiefly in young women during or soon after pregnancy.^{104,105} Treatment has included placement of a stent, emergency coronary bypass operation, and thrombolysis.¹⁰⁶⁻¹⁰⁹ Although coronary artery dissection is very uncommon, it is extremely important to consider this diagnosis whenever a woman presents with severe chest pain in the peripartum period. If the coronary artery dissection remains undetected, massive myocardial infarction and even death can occur. If the diagnosis is made expediently, however, outcome appears to be quite good, and long-term survival is expected.¹¹⁰

Management of Stable Angina Pectoris

Women with CAD who experience angina pectoris only at high levels of exertion should be treated with β -adrenergic blocking drugs, aspirin, and lipid-lowering agents. In this setting, the likelihood of significant complications during pregnancy, labor, or delivery is low. If there is any question regarding the severity of myocardial ischemia, however, stress testing should be performed before pregnancy is attempted. Similarly, a woman who previously sustained a myocardial infarction but recovered without heart failure, significant left ventricular dysfunction, or unstable angina pectoris can also be advised that her pregnancy and labor should be relatively uncomplicated.

The major indications that pregnancy and labor would pose a significant risk to a woman with ischemic heart disease are the presence of overt heart failure, significant enlargement or dysfunction of the left ventricle, and ischemia at rest or provoked by mild exertion.

Severe Myocardial Ischemic Syndromes: Unstable Angina

The diagnosis of severe ischemia may be confirmed if angina occurs at rest or with mild exertion. This unstable angina frequently, but not necessarily, follows a period of classic stable angina pectoris. Unstable angina is a clear warning of the imminence of a major ischemic event, such as acute myocardial infarction or a fatal ventricular arrhythmia. Starting a pregnancy under these circumstances is not advisable, and aggressive treatment (including coronary angiography followed by percutaneous coronary intervention or coronary artery bypass surgery) is recommended. If the outcome is satisfactory, pregnancy can then be considered.

In some women with CAD, the clinical picture is less dramatic but a treadmill exercise test demonstrates that profound and dangerous ischemia can be precipitated by minimal exertion. If the treadmill test provokes an abnormal response at a low level of exercise, and particularly if this response is accompanied by either angina pectoris or a fall in blood pressure, the woman is at high risk for a serious and possibly fatal myocardial ischemic event and must not undertake pregnancy unless the myocardium can be revascularized.

Pregnant women who develop unstable ischemia require aggressive treatment in an intensive care unit. If the ischemia proves intractable, percutaneous coronary intervention (e.g., stenting) or bypass graft surgery will be necessary.¹¹¹ If possible, the coronary bypass operation

should be performed without cardiopulmonary bypass to help decrease the risk to the fetus.¹¹²

Myocardial Infarction

Acute myocardial infarction complicates about 1 in 10,000 pregnancies.¹¹³ The highest incidence appears to occur in the third trimester and in older (>33 years) multigravidas. The maternal mortality rate is high (about 20%), and death usually occurs at the time of infarction or during labor and delivery.¹¹⁴ Coronary angiography in this population demonstrated atherosclerosis in about 40% of cases, coronary thrombosis without atherosclerosis in 20%, and coronary dissection in 16%, but 30% had normal coronary arteries.¹¹⁴ Treatment of acute myocardial infarction during pregnancy should include use of heparin and β -blockers (unless acute heart failure is present). The use of thrombolytics in pregnancy is controversial, because there is increased risk of maternal hemorrhage. Therefore, percutaneous coronary intervention (with stenting) is probably the procedure of choice. Obviously, this exposes the fetus to radiation, and so extensive lead shielding should be used.

A remote myocardial infarction, followed by recovery without angina, major left ventricular dysfunction, or heart failure, should have little influence on pregnancy or labor. Patients should wait a year after an infarction before undertaking pregnancy. In many cases, coronary arteriography should be done first so that, if critical coronary stenoses are found, myocardial revascularization can be performed. Severe left ventricular damage and heart failure are contraindications to pregnancy.

For remote myocardial infarction without evidence of ischemia, heart failure, or severe left ventricular dysfunction, simple electrocardiographic monitoring suffices during labor. If a large myocardial infarction has occurred during pregnancy, then arterial blood pressure, central venous pressure, pulmonary arterial and pulmonary wedge pressure, and cardiac output should be monitored invasively. Monitoring should be continued until after the completion of labor, because maternal preload abruptly increases with the birth, after which substantial loss of blood can accompany delivery of the placenta.

Heart Failure

Chronic heart failure is a syndrome that develops when the heart cannot meet the metabolic requirements of the normally active individual. It may be defined as ventricular dysfunction causing dyspnea, fatigue, and sometimes arrhythmia. The lesion may be an intrinsic myocardial abnormality. Examples include myocarditis, the various cardiomyopathies, ischemic heart disease, other specific myocardial disorders (e.g., amyloidosis), and metabolic abnormalities (e.g., myxedema). The myocardial response to chronic pressure overload is concentric hypertrophy with increased thickness of the ventricular walls; the response to chronic volume overload is dilation (eccentric hypertrophy). Contractile power is eventually diminished with either type of overload, resulting in decreased pump function of the heart. Causes include valvular disease, systemic and pulmonary hypertension, and congenital malformations. The clinical manifestations result in part from the abnormal loading conditions and in part from the damaged myocardium.

Manifestations

The principal manifestations of heart failure are caused by increased left and right ventricular diastolic pressure, which engenders pulmo-

nary and systemic congestion, and reduced cardiac output (during exercise or, in severe cases, at rest as well). The combined effects of inadequate cardiac output and congestion are dyspnea, fatigue, and edema. In the later stages of heart failure, these changes lead to progressive dysfunction of vital organs, principally the liver and kidneys. The prognosis of severe uncorrectable heart failure is quite poor, and pregnancy is absolutely contraindicated.

The critical clinical features that enable physicians to diagnose and monitor the course of heart failure are body weight, jugular venous pressure, the S_3 , cardiac size, radiologic evidence of pulmonary congestion, pulmonary rales, and peripheral edema. Echocardiography is an extremely useful tool for evaluating left ventricular function and prognosis in heart failure¹¹⁵ and should be performed without delay if heart failure is suspected. Circulating B-type natriuretic peptide (BNP) is increased in congestive heart failure. Serum BNP levels provide an effective, inexpensive, and quickly available test for heart failure. The degree of BNP increase correlates with the severity of heart failure.¹¹⁶

The presence of heart failure greatly limits physical activity and warrants several or all of the following treatments:

- Continuous, usually escalating courses of diuretic drugs
- β -Adrenergic receptor blockers
- ACE inhibitors (or, if these are not well tolerated, angiotensin receptor blockers)—note that these agents are contraindicated during pregnancy and should be replaced by hydralazine
- Salt restriction
- Digoxin

If heart failure is first discovered during pregnancy, episodes of cardiac decompensation that do not respond to adjustment of orally administered medicine necessitate admission to an intensive care unit. There, the effects of treatment on cardiac output, pulmonary arterial pressure, systemic venous pressure, and pulmonary wedge pressure, along with the maternal and fetal ECGs, can be monitored. If the hemodynamic parameters and clinical condition indicate continuing deterioration despite maximal medical therapy, emergency abdominal delivery may be necessary.

Asymptomatic Left Ventricular Dysfunction

There is a remarkable lack of correlation between symptoms of heart failure and objective evidence of left ventricular dysfunction.¹¹⁷ For example, patients with chronic heart disease after myocardial infarction may have a considerably enlarged and extremely hypokinetic ventricle and yet be relatively free from symptoms. For this reason, any woman who has sustained myocardial damage should have left ventricular function assessed by echocardiography before deciding on pregnancy.

Cardiac Transplantation

Some women with advanced heart failure become successful recipients of a cardiac transplant. Successful pregnancy and delivery in patients with cardiac transplantation have been reported.⁷⁸ Medical treatment after transplantation is complex because of the immunosuppressive drug regimen, the frequent endomyocardial biopsies, and the uncertain long-term prognosis. Women should delay pregnancy for at least 1 year after cardiac transplantation, by which time the risk of acute rejection and the intensity of immunosuppression and biopsy surveys are considerably less.

Disturbances of Cardiac Rhythm

Isolated supraventricular and ventricular extrasystoles are very common, and no treatment is necessary. Pre-conception counseling is simplified by a clear appreciation of several general principles.

Arrhythmia that occurs in the absence of organic heart disease is almost always benign and is therefore not an indication for pharmacologic treatment unless the woman finds the symptoms intolerable. Reassuring her of the benign nature of this symptom is often all that is required. Sustained symptomatic arrhythmia, however, requires treatment, which can be pharmacologic or procedural (e.g., transcatheter ablation of an anomalous conduction pathway, insertion of an implantable cardiac defibrillator).

Pregnancy and labor should be safe except in the group with sustained ventricular arrhythmia, with its attendant risk of cardiac arrest and need for vigorous treatment. Pharmacologic treatment for serious arrhythmia is likely to include newly introduced agents, such as amiodarone or sotalol, for which there is at best limited knowledge of potentially unfavorable effects on the fetus. Ideally, pregnancy should be postponed until the arrhythmia has been eliminated or at least controlled, preferably by nonpharmacologic means. If antiarrhythmic drugs must be used, whenever possible they should be those that have been used for several decades, allowing prediction of the fetal risk.

High-grade atrioventricular conduction disturbance, especially if it is symptomatic, is treated by artificial pacing, which should not influence pregnancy, labor, or the fetus. Electrical cardioversion or defibrillation of the mother's heart does not disturb or damage the fetal heart.¹¹⁸

It is clearly desirable to evaluate disturbances of cardiac rhythm and conduction before pregnancy, proceeding to full electrophysiologic testing if indicated. This plan avoids exposing a fetus to potentially toxic antiarrhythmic agents and the radiation associated with electrophysiologic investigation.

Marfan Syndrome

Marfan syndrome is variably expressed and inherited as an autosomal dominant trait. If it is left untreated, life expectancy is reduced by half in those who exhibit the classic syndrome. The basic defect is one of connective tissue, particularly fibrillin, and connective tissue weakness in the aorta causes the dangerous complications, most notably aortic dissection.¹¹⁹

Symptoms and signs may include dyspnea and chest pain, an aortic diastolic murmur, and a midsystolic click. The best diagnostic test, and apparently the most critical one for determining the outcome of pregnancy, is the echocardiogram. More than 90% of patients have evidence of MVP, and 60% have echocardiographic evidence of aortic root dilatation.¹²⁰

Pregnancy is particularly dangerous for patients with this syndrome, because there appears to be a high risk of aortic rupture and dissection, especially if dilatation of the aortic root is present.⁴⁷ Women with an aortic diameter exceeding 40 mm are at greatest risk of death during pregnancy.¹²¹ The physician should also make sure the woman understands the 50% risk of genetic transmission of Marfan syndrome to her children.

FIGURE 39-18 Aortic aneurysm. Aortogram showing an aneurysm of the ascending aorta (AO) with regurgitation of contrast through an incompetent aortic valve (*arrows*) into the left ventricle (LV). (From Shabetai R, Adolph RJ: Principles of cardiac catheterization. In Fowler NO [ed]: Cardiac Diagnosis and Treatment. Hagerstown, MD: Harper & Row, 1980, p 106.)

Deficiency of elastic tissue is the cause of myxomatous degeneration of the aortic and mitral valves and cystic medial necrosis of the aorta (Figs. 39-18 and 39-19). This abnormality translates to large aneurysms of the aortic root, multiple aneurysms elsewhere along the course of the aorta and great vessels, and severe aortic and mitral regurgitation with resulting heart failure. Surgery is indicated for rapidly expanding aneurysm or if dissection is evident. Pregnancy is poorly tolerated under these conditions, and labor may precipitate rupture of an aneurysm or aortic dissection.

If a woman with Marfan syndrome chooses to become pregnant, therapy is directed at markedly limiting physical activity, preventing hypertensive complications, and decreasing the pulsatile forces on the aortic wall with the use of a β -blocker. Long-acting β -blockers are indicated before, during, and after pregnancy in women with Marfan syndrome.¹²² Once the aortic root diameter reaches 50 to 55 mm, most authorities recommend prophylactic aortic valve and root replacement because of the high risk of aortic dissection. Abdominal delivery is recommended to avoid the hemodynamic stress of labor.

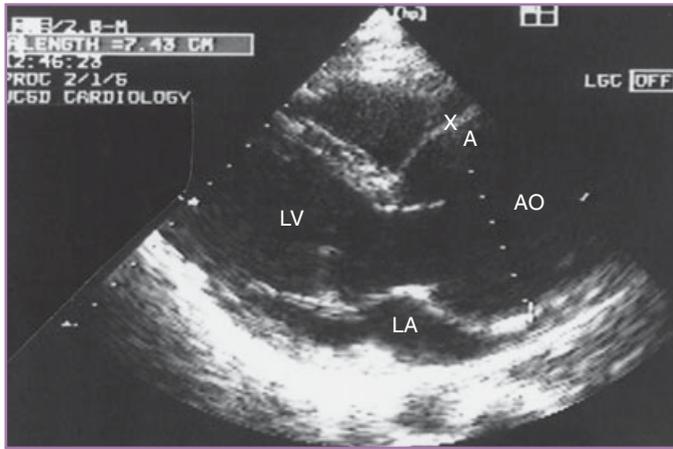

FIGURE 39-19 Marfan syndrome. The echocardiogram shows a markedly dilated aortic root, measuring 7.4 cm in diameter (normal, ≤ 3.5 cm). A, annulus diameter (7.43 cm); AO, aorta; LA, left atrium; LV, left ventricle.

Pregnancy in Patients with Artificial Heart Valves

Pregnancy in women with artificial heart valves is one of the most complex and challenging areas where cardiology and obstetrics intersect, and it could be the topic of an entire chapter itself. The discussion here covers three basic groups of patients:

1. Women contemplating pregnancy who are likely to need a valve replacement in the medium- to long-term future, such as women with moderate aortic or pulmonic stenosis, severe but asymptomatic mitral or aortic regurgitation with normal myocardial function, or mild to moderate mitral stenosis
2. Women who wish to become pregnant but have severe valve disease that must be addressed expediently, including those with severe aortic or mitral stenosis, severe mitral regurgitation with cardiac dysfunction, or severe aortic regurgitation with cardiac dysfunction
3. Women with mechanical valve replacements who become pregnant.

The only group for whom no management controversy exists is the first.¹²³ Without question, women who are likely to need valve surgery in several years should be strongly encouraged to complete their child-bearing as quickly as possible—so that they will not become members of the second or third group.

Women in the second group require valve replacement before pregnancy. In most adult patients younger than 70 years of age (but not in women who wish to become pregnant), mechanical prosthetic valves would be favored over biologic prostheses, because biologic valves have a shorter life span and deteriorate much more quickly than mechanical valves. This difference appears even more pronounced in younger patients; it was once thought that pregnancy itself hastened biologic valve deterioration, but this does not appear to be true.¹²⁴ In any case, younger patients with biologic valves will almost certainly require repeat surgery. With mechanical valves, however, the patient faces the

requirement for lifelong anticoagulation and the resultant small increase in risk of bleeding.

It is important to note that the anticoagulant of choice with a mechanical valve is warfarin, not heparin. Although heparin is clearly safer for the fetus,¹²⁵ it is not equivalent to warfarin in preventing thromboembolic complications (especially during the prothrombotic state of pregnancy). This has been shown in several studies and appears to be most striking in the case of single tilting-disk mechanical prostheses.^{8,24} Therefore, many experts agree that women who require valve surgery before pregnancy should receive a bioprosthetic valve—even though repeat surgery will be necessary in the future—because these valves have a much lower thromboembolic risk and do not usually require systemic anticoagulation. Women with normally functioning biologic valve replacements tolerate pregnancy well.

Management of the last group (i.e., women with mechanical cardiac valves who become pregnant) is the most difficult. A woman with a mechanical prosthetic heart valve should be counseled strongly that pregnancy is risky, primarily because of the risk of embolic phenomena. If the patient decides to proceed with pregnancy, warfarin is superior to heparin for preventing thromboemboli with mechanical valves. However, warfarin is teratogenic and carries a 4% to 10% risk of warfarin embryopathy.^{126,127} This risk appears to be dose dependent as well.²³ For these reasons, the U.S. manufacturer of Coumadin (warfarin) states that the drug is absolutely contraindicated during pregnancy. Although warfarin is used during pregnancy in Europe (after the first 12 weeks) and is recommended until the 35th week of pregnancy, American physicians face a particularly difficult dilemma because of the manufacturer's contraindication (even though this contradicts guidelines from acknowledged expert panels).^{2,10,11} In addition, many pregnant women would prefer to put themselves rather than the fetus at risk. Therefore, subcutaneous or intravenous heparin is used during pregnancy in many American women with mechanical heart valves, even though thromboembolic risk is higher.^{127,128} During treatment with heparin or LMWH, the activated partial thromboplastin time (or anti-Xa heparin levels) must be monitored frequently. In addition, the dose must be adjusted as the patient gains weight during pregnancy. There is some evidence that LMWH is superior to unfractionated heparin in nonpregnant patients with mechanical prostheses,¹²⁹ and this approach has been used successfully in a number of pregnant patients.^{130,131} However, in a recent small study of enoxaparin in pregnant women with prosthetic heart valves, two of eight patients developed prosthetic valve thrombosis leading to maternal and fetal death.¹³² It is unclear but possible that these women did not receive adequate dosing of enoxaparin. Randomized trials have not been performed, and more information is needed before LMWH can be recommended over unfractionated heparin in this setting.¹³³

Tables 39-6 and 39-7 show two currently proposed protocols for anticoagulation in the pregnant woman with a mechanical heart valve. Most authorities recommend using heparin through the first trimester, although continuous use of warfarin until week 35 is an option in high-risk patients (those with first-generation tilting-disk prostheses in the mitral position).^{10,11} The joint American College of Cardiology (ACC)/American Heart Association (AHA) Guidelines for the Management of Patients with Valvular Heart Disease² stress the importance of discussing the risks and benefits of various anticoagulation approaches with the patient, because she must be a full partner in her medical care. She must be informed that if she chooses to change from warfarin to heparin during the first trimester (or for the entire pregnancy), she has a higher risk of both thrombosis and bleeding, and any risk to her jeopardizes the baby as well. Table 39-6, from Elkayam and

TABLE 39-6 RECOMMENDED APPROACH FOR ANTICOAGULATION PROPHYLAXIS IN WOMEN WITH PROSTHETIC HEART VALVES (PHV) DURING PREGNANCY

Higher Risk*	Lower Risk†
Warfarin (INR 2.5-3.5) for 35 wk <i>followed by</i> UFH (mid-interval aPTT >2.5) or LMWH (pre-dose anti-Xa ≈ 0.7) + ASA 80-100 mg qd OR UFH (aPTT 2.5-3.5) or LMWH (pre-dose anti-Xa ≈ 0.7) for 12 wk <i>followed by</i> Warfarin (INR 2.5-3.5) to 35th wk <i>then</i> UFH (mid-interval aPTT >2.5) or LMWH (pre-dose anti-Xa ≈ 0.7) + ASA 80-100 mg qd	SC UFH (mid-interval aPTT, 2.0-3.0) or LMWH (pre-dose anti-Xa ≈ 0.6) for 12 wk <i>followed by</i> Warfarin (INR 2.5-3.0) for 35 wk <i>then</i> SC UFH (mid-interval aPTT 2.0-3.0) or LMWH (pre-dose anti-Xa ≈ 0.6) OR SC UFH (mid-interval aPTT 2.0-3.0) or LMWH (pre-dose anti-Xa ≈ 0.6) throughout pregnancy

aPTT, activated partial thromboplastin time; ASA, acetylsalicylic acid; INR, international normalized ratio; LMWH, low-molecular-weight heparin; SC, subcutaneous; UFH, unfractionated heparin.

*First-generation PHV (e.g., Starr-Edwards, Bjork-Shiley) in the mitral position, atrial fibrillation, history of thromboembolism on anticoagulation.

†Second-generation PHV (e.g., St. Jude Medical, Medtronic-Hall) and any mechanical PHV in the aortic position.

TABLE 39-7 RECOMMENDATIONS OF THE SEVENTH ACCP CONSENSUS CONFERENCE ON ANTITHROMBOTIC THERAPY FOR PROPHYLAXIS IN PATIENTS WITH MECHANICAL HEART VALVES

1. Aggressive adjusted-dose UFH, q12h SC throughout pregnancy; mid-interval aPTT time maintained at >2× control levels, or anti-Xa heparin level maintained at 0.35 to 0.70 IU/mL
- OR**
2. LMWH throughout pregnancy, in doses adjusted according to weight or as necessary to maintain a 4-h postinjection anti-Xa heparin level of about 1.0 IU/mL
- OR**
3. UFH or LMWH, as above, until the 13th week; then change to warfarin until the middle of the third trimester, then restart UFH or LMWH therapy until delivery

ACCP, American College of Chest Physicians; aPTT, activated partial thromboplastin time; LMWH, low-molecular-weight heparin; SC, subcutaneous; UFH, unfractionated heparin.

Data from Bates SM, Greer IA, Hirsh J, Ginsberg JC: Use of antithrombotic agents during pregnancy: The seventh ACCP conference on antithrombotic and thrombolytic therapy. *Chest* 126:627S, 2004.

Bitar,¹¹ stratifies treatment options by risk of thrombosis and recommends consideration of continuing warfarin throughout the pregnancy (until week 35) for patients with first-generation valves in the mitral position, atrial fibrillation, or a history of previous embolic events. The treatment options in Table 39-7, from the American College of Chest Physicians¹³⁴ are simpler, but they do not differentiate on the basis of the type of mechanical valve or its position (aortic versus mitral). Consultation and close follow-up during pregnancy with an experienced cardiologist is strongly recommended, as well as meticulous attention to blood coagulation testing. Because preterm labor occurs frequently in this group,²⁴ warfarin should be replaced by therapeutic doses of subcutaneous heparin beginning at the 35th week of

gestation. If labor occurs while a patient is taking warfarin, cesarean section is recommended to avoid fetal cerebral hemorrhage during vaginal delivery.²

All patients with prosthetic heart valves require antibiotic prophylaxis for dental and surgical procedures and at delivery. Prevention of prosthetic valve endocarditis is essential, because the mortality rate can reach 40%. The patient who experiences endocarditis with a prosthetic valve must receive aggressive antibiotic therapy and often will require valve replacement. Obviously, the risk to the fetus is exorbitant.

Cardiac Surgery during Pregnancy

Whenever possible, any woman who requires cardiac surgery should undergo the procedure before becoming pregnant. Nevertheless, as explained previously, in rare instances a patient may require surgery during pregnancy. Valvular surgery has been performed successfully during pregnancy for many years, and patients have also undergone coronary artery bypass surgery and emergency aortic dissection repair. Cardiac surgery during pregnancy does not appear to increase the maternal mortality risk.^{135,136} There is, however, a 10% to 15% risk of fetal mortality because of the nonpulsatile blood flow and hypotension associated with conventional cardiopulmonary bypass. Therefore, whenever possible, cardiac surgery should be performed without cardiopulmonary bypass. In addition, hypothermia should be avoided, because this appears to be especially dangerous to the fetus. In one study, fetal mortality was decreased by half when normothermic perfusion was used instead of hypothermic perfusion.¹³⁶ Hypothermia stimulates uterine contractions and impairs oxygen delivery to the fetus, mandating careful monitoring of the uterus and the fetal heart. The deleterious effect of hypothermia on umbilical blood flow has been documented by transvaginal ultrasonography.¹³⁷

Experimental studies suggest that fetal survival can be improved by the use of pulsatile perfusion, but results are not yet clear. If bypass is required for cardiac surgery at an immature gestational age, high-flow high-pressure normothermic perfusion should be instituted.¹³⁸ If pos-

sible, surgery should be postponed until the third trimester, when the fetal risk is considerably reduced. Fetal bradycardia is often seen during surgery and may require rapid treatment, usually with intravenous nitroprusside. In addition, preterm labor occurs more frequently in women undergoing cardiac surgery.

During surgery and in the immediate postoperative period, these patients should be monitored very closely. In general, use of intra-arterial and Swan-Ganz catheters and electrocardiographic monitoring of the woman and the fetus is recommended. Transesophageal echocardiography is also helpful in some cases and provides direct assessment of valvular and ventricular function. Maintenance of acceptable arterial oxygen levels and normal blood pressure, plus avoidance of hypothermia, are of utmost importance to the fetus.

The Use of Prophylactic Antibiotics to Prevent Infective Endocarditis in Pregnant Women with Heart Disease

The most recent recommendations from the American Heart Association (AHA) regarding the use of prophylactic antibiotics represent a major departure from previous guidelines and are summarized here because of the importance of this information to those caring for women with heart disease. The most prominent aspect of the new guidelines is that antibiotics to prevent infective endocarditis (IE) are now recommended *only* for those patients deemed to be at the highest risk. These high risk cardiac conditions include:

1. Prosthetic heart valve or prosthetic material used for cardiac valve repair
2. Previous IE
3. Congenital heart disease (CHD)
 - Unrepaired CHD, including palliative shunts and conduits
 - Completely repaired congenital heart defect with prosthetic material or device, whether replaced by surgery or by catheter intervention, during the first 6 months after the procedure (during the process of endothelialization)
 - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
4. Cardiac transplantation recipients who develop cardiac valvulopathy

The reader is referred to the AHA publication for additional details and the consensus panel's rationale.¹³⁹

Chapter 40

Coagulation Disorders in Pregnancy

Charles J. Lockwood, MD, and Robert M. Silver, MD

Disorders of the hemostatic system can lead to both hemorrhage and thrombosis. The former can result from inherited and acquired defects in hemostasis and platelets, and the latter is greatly increased in the presence of inherited and acquired defects in the endogenous anticoagulant system.^{1,2} In addition to their association with thrombosis, the leading cause of maternal death in the United States, inherited and acquired thrombophilias as well as certain bleeding dyscrasias, have also been associated with adverse pregnancy outcomes. This chapter reviews the hemostatic system and its modulators and then discusses the various common inherited and acquired disorders of platelet function, coagulation, and anticoagulation and their impact on both mother and fetus.

The Hemostatic System

The hemostatic system is designed to ensure that hemorrhage is avoided in the setting of vascular injury while the fluidity of blood is maintained in the intact circulation. After vascular injury, activation of the clotting cascade and simultaneous platelet adherence, activation, and aggregation are required to form the optimal fibrin-platelet plug and thus avoid bleeding. The system is held in check by a potent series of anticoagulant proteins as well as a highly regulated fibrinolytic system. Pregnancy presents an additional challenge to this system, because the risk of hemorrhage during placentation and in the third stage of labor is high, and the risk of thrombosis in the highly vulnerable uteroplacental and intervillous circulations is also great. Through a series of local and systemic adaptations, the vast majority of pregnant women are able to balance these paradoxical requirements and achieve uncomplicated pregnancies.

Platelet Plug Formation

After vascular injury, platelets rolling and flowing in the bloodstream are arrested at sites of endothelial disruption by the interaction of collagen with von Willebrand factor (vWF). Attachment to collagen exposes sites on the vWF molecule that permit it to bind to the platelet glycoprotein Ib/IX/V complex (GpIb-IX-V) receptor.³ Abnormal platelet adhesion and bleeding can result from mutations in GpIb-X-V (e.g., Bernard-Soulier disease) or from defects in the vWF gene (von Willebrand disease [vWD]). Platelets can also adhere to subendothelial collagen via their GpIa-IIa ($\alpha_2\beta_1$ integrin) and GpVI receptors. Deficiencies in either receptor cause mild bleeding diatheses.

Adherent platelets are activated by collagen after binding to the GpVI receptor.⁴ This triggers receptor phosphorylation, leading to acti-

vation of phospholipase C, which causes the generation of inositol triphosphate and 1,2-diacylglycerol. The former triggers a calcium flux, and the latter activates protein kinase C, which, in turn, triggers platelet secretory activity and activates various signaling pathways. Such signaling promotes activation of the GpIIb-IIIa ($\alpha_{IIb}\beta_3$ integrin) receptor, a crucial step in subsequent platelet aggregation (see later discussion). Thus, collagen serves to promote both platelet adhesion and platelet activation. However, maximal platelet activation requires binding of thrombin to platelet type 1 and 4 protease-activated receptors (PAR-1, PAR-4).⁵ Platelet activation is also mediated by receptor binding to thromboxane A₂ (TXA₂) and adenosine diphosphate (ADP), which are released by adjacent activated platelets. Collagen and these circulating agonists induce calcium-mediated formation of platelet pseudopodia, promoting further adhesion.

Platelet secretory activity includes the release of α -granules containing vWF, vitronectin, fibronectin, thrombospondin, partially activated factor V, fibrinogen, β -thromboglobulin, and platelet-derived growth factor. These factors either enhance adhesion or promote clotting. Secretory activity also includes the release of dense granules containing ADP and serotonin, which enhance, respectively, platelet activation and vasoconstriction in damaged vessels. Calcium flux promotes the synthesis of TXA₂ by the sequential action of phospholipase A₂, cyclooxygenase-1 (COX-1) and TXA₂ synthase and its passive diffusion across platelet membranes to promote both vasoconstriction and, as noted, activation of adjacent platelets.⁴ Inherited disorders of α -granule homeostatic and release proteins result in gray platelet syndrome, whereas deficiencies in dense granule-related genes are associated with Wiskott-Aldrich, Chediak-Higashi, Hermansky-Pudlak, and thrombocytopenia-absent radius syndrome. Inhibition of COX-1-mediated TXA₂ synthesis by nonsteroidal anti-inflammatory drugs (NSAIDs) also can also impair platelet function.

Platelet aggregation follows activation-induced conformational changes in the platelet membrane GpIIb-IIIa receptor, so-called inside-out signaling. The receptor forms a high-affinity bond to divalent fibrinogen molecules. The same fibrinogen molecule is also able to bind to adjacent platelet GpIIb-IIIa receptors.⁶ Because these receptors are abundant (40,000 to 80,000 copies), large platelet rosettes quickly form, reducing blood flow and sealing vascular leaks.⁴ Mutations in the GpIIb-IIIa gene cause the bleeding dyscrasia known as Glanzmann thrombasthenia. Figure 40-1 presents a schematic review of platelet function.

Platelet activation and aggregation are prevented in intact endothelium via the latter's elaboration of prostacyclin, nitric oxide, and ADPase as well as by active blood flow. Cyclic adenosine monophosphate (cAMP) inhibits platelet activation, and this is the basis for the

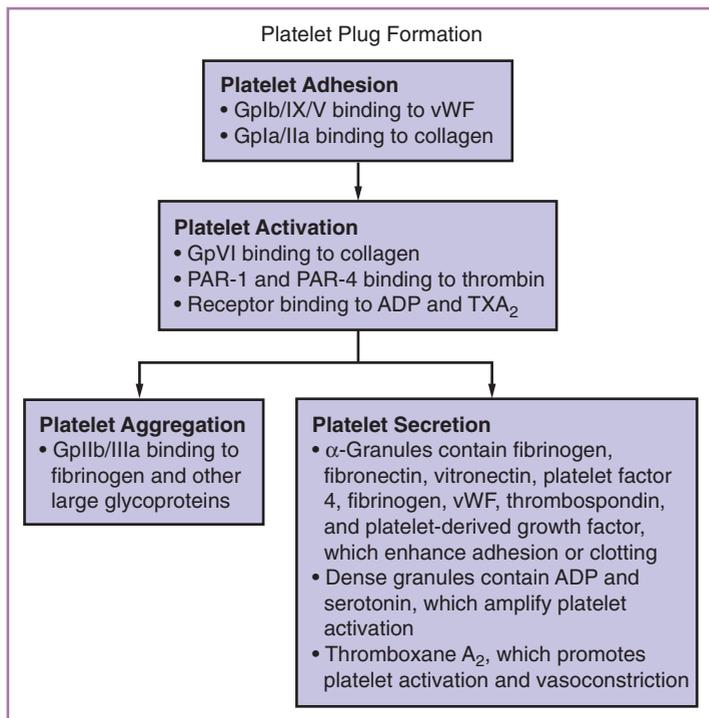

FIGURE 40-1 Schematic review of platelet function. ADP, adenosine diphosphate; Gp, glycoprotein; PAR, protease-activated receptor; TXA₂, thromboxane A₂; vWF, von Willebrand factor.

therapeutic effects of dipyridamole. Normal pregnancy is associated with a modest decline in platelet number⁷ and with evidence of progressive platelet activation.⁸

Fibrin Plug Formation

Effective hemostasis requires the synergistic interaction of the clotting cascade with platelet activation and aggregation. This synergism is in part mechanical, because fibrin and platelets together form an effective hemostatic plug after significant vascular disruption. However, biochemical synergism also occurs, because activated platelets contribute clotting factors and form an ideal surface for clot propagation. Conversely, optimal platelet activation and subsequent aggregation require exogenous thrombin generation (see Fig. 40-1). Therefore, the avoidance of hemorrhage ultimately depends on the interplay between platelets and the coagulation cascade.

Understanding of the coagulation component of hemostasis has evolved rapidly in the past two decades. Clotting is no longer thought of as a seemingly infinite cascade of enzymatic reactions occurring in the blood but rather as a highly localized cell surface phenomenon.⁹ Clotting is initiated when subendothelial (extravascular) cells expressing tissue factor (TF), a cell membrane-bound glycoprotein, come into contact with circulating factor VII. Intrauterine survival is not possible in the absence TF.¹⁰ TF is primarily expressed on the cell membranes of perivascular smooth muscle cells, fibroblasts, and tissue parenchymal cells, but not on healthy endothelial cells. However, TF also circulates in the blood in very low concentrations, as part of cell-derived microparticles or in a truncated soluble form.^{8,11}

After vascular disruption and in the presence of ionized calcium, perivascular cell TF comes into contact with plasma factor VII on negatively charged (anionic) cell membrane phospholipids. Factor VII

is unique in that it has low intrinsic clotting activity. In addition, it may autoactivate after binding to TF or be activated by thrombin or factors IXa or Xa.¹² Activation of factor VII to VIIa increases its catalytic activity more than 100-fold, and its promiscuous activation potential ensures that factor VIIa will be readily available to initiate clotting.

The complex of TF and factor VII(a) can activate both factor X and factor IX. Factor Xa remains active as long as it is bound to TF-VIIa in the cell membrane-bound prothrombinase complex. However, when factor Xa diffuses away from the site of vascular injury, it is rapidly inhibited by tissue factor pathway inhibitor (TFPI) or antithrombin (AT). This serves to prevent inappropriate propagation of the clot throughout the vascular tree.⁹ Factor Xa ultimately binds to its cofactor, Va, which is generated from its inactive form by the action of factor Xa itself or by thrombin. Partially activated factor Va can also be delivered to the site of clot initiation after its release from platelet α -granules (Fig. 40-2A).⁸ The Xa/Va complex catalyzes the conversion of prothrombin (factor II) to thrombin (factor IIa). Thrombin, in turn, converts fibrinogen to fibrin, and, as noted, activates platelets (see Fig. 40-2A).

Following this initial TF-mediated reaction, the clotting cascade is amplified by clotting reactions that occur on adjacent activated platelets.⁹ Locally generated factor IXa diffuses to adjacent activated platelet membranes, or to perturbed endothelial cell membranes, where it binds to factor VIIIa. This cofactor is not only directly activated by thrombin but is released from its vWF carrier molecule through the action of thrombin.⁹ The factor IXa/VIIIa complex can then generate factor Xa at these sites to further drive thrombin generation (see Fig. 40-2B). The significant hemorrhagic sequelae of hemophilia underscore the vital role played by platelet surface factor IXa-VIIIa-mediated factor Xa generation in ensuring hemostasis.⁹

The clotting cascade can also be amplified via the activation of factor XI to XIa by thrombin on activated platelet surfaces; factor XIa also activates factor IX (see Fig. 40-2C). The lack of significant hemorrhagic sequelae in patients with factor XI deficiency emphasizes that this mechanism is of lesser importance in the maintenance of hemostasis. Factor XIa has been described as serving a “booster function” in coagulation.⁹

A third, theoretical coagulation amplification pathway may be mediated by circulating TF-bearing microparticles that bind to activated platelets at sites of vascular injury through the interaction between P-selectin glycoprotein ligand-1 on the microparticles and P-selectin on activated platelets (see Fig. 40-2C).¹³ Taken together factor IXa, factor XIa, and TF-platelet surface events lead to additional factor Xa generation and thence to enhanced production of thrombin and fibrin. They also reflect the synergism that exists between platelet activation and the coagulation cascade.

The stable hemostatic plug is finally formed only when fibrin monomers self-polymerize and are cross-linked by thrombin-activated factor XIIIa (see Fig. 40-2D). This last reaction highlights the dominant role that thrombin plays in the coagulation cascade: Thrombin activates platelets, generates fibrin, and activates the crucial clotting cofactors V and VIII, as well as the key clotting factors VII, XI, and XIII. This accounts for the primacy of antithrombin factors in preventing inappropriate intravascular clotting (i.e., thrombosis).

Prevention of Thrombosis: The Anticoagulant System

As noted, the hemostatic system not only must prevent hemorrhage after vascular injury but also must maintain the fluidity of the circula-

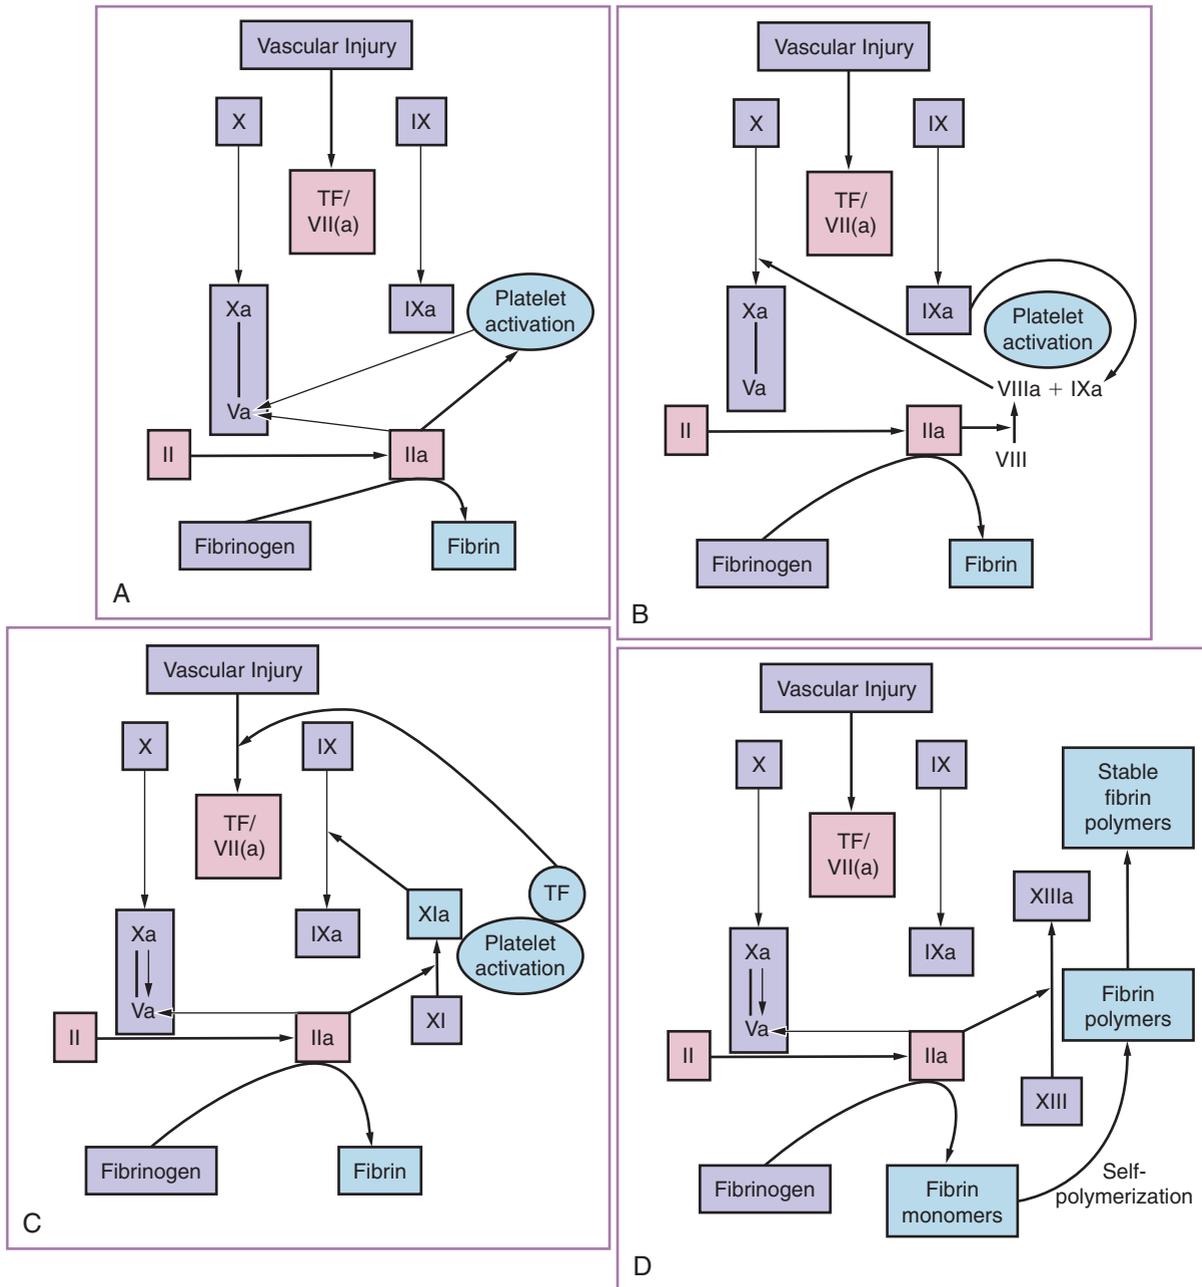

FIGURE 40-2 Fibrin plug formation. **A**, After vascular disruption, plasma factor VII binds to tissue factor (TF) to form the TF/VII(a) complex, which activates both factor X and factor IX. Factor Xa binds to factor Va, which has been activated by thrombin (factor IIa) or released from platelet α -granules. The Xa/Va complex catalyzes the conversion of prothrombin (factor II) to thrombin, which, in turn, converts fibrinogen to fibrin and activates platelets. **B**, The clotting cascade is amplified by clotting reactions that occur on adjacent activated platelets. Locally generated factor IXa binds to factor VIIIa, which is activated by thrombin. The factor IXa/VIIIa complex then generates factor Xa. **C**, Coagulation is further boosted by the thrombin-mediated activation of factor XI to factor XIa, which also activates factor IX. Circulating TF-bearing microparticles may also bind to activated platelets at sites of vascular injury. **D**, The stable hemostatic plug is finally formed when fibrin monomers self-polymerize and are cross-linked by thrombin-activated factor XIIIa.

tion in an intact vasculature. Indeed, thrombotic disease is a consequence of inappropriate and/or excess thrombin generation. As was the case with avoiding hemorrhage, avoidance of thrombosis is again dependent on the synergistic interaction of platelets and the coagulant system. As noted earlier, clotting is initiated locally at sites of vascular injury and amplified by the arrival, adherence, and activation of plate-

lets. This local coagulation reaction is relatively protected from the dampening effects of circulating endogenous anticoagulants, both because of its intensity and because it is shielded by the initial layer of adherent and activated platelets. However, maximal platelet activation occurs only after stimulation by both subendothelial collagen and thrombin, so, as additional platelets aggregate on top of the initial layer

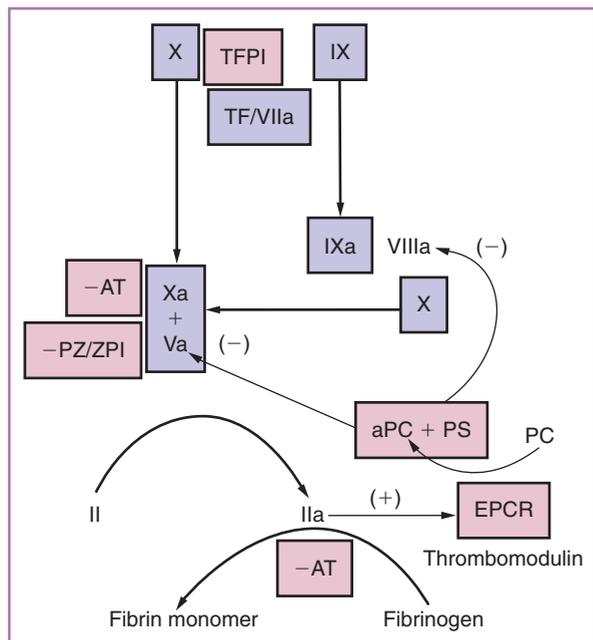

FIGURE 40-3 The anticoagulant system. Tissue factor pathway inhibitor (TFPI) binds with tissue factor (TF), factor VIIa, and factor Xa to form the prothrombinase complex. Thrombin, after binding to thrombomodulin, can activate protein C (PC) when bound to the endothelial protein C receptor (EPCR). Activated protein C (aPC) then binds to its cofactor, protein S (PS), to inactivate factors VIIIa and Va. Factor Xa is inhibited by the protein Z-dependent protease inhibitor (ZPI) when complexed to its cofactor, protein Z (PZ). Antithrombin (AT) potently inhibits both factor Xa and thrombin.

of platelets, they become progressively less activated, and their clotting reaction becomes more susceptible to the action of circulating inhibitors, thus attenuating the clotting cascade.⁹

Prevention of disseminated intravascular coagulation (DIC) ultimately requires the presence of inhibitor molecules (Fig. 40-3). The first inhibitory molecule is TFPI which forms a complex with TF, VIIa, and Xa (the prothrombinase complex).¹⁴ As noted earlier, TFPI is most effective distal to the initial site of clotting, and it can be bypassed by the generation of factors IXa and XIa.

Paralleling its pivotal role in initiating the hemostatic reaction, thrombin also plays a central role in initiating the anticoagulant system. Thrombin binds to thrombomodulin, and the resultant conformational change permits thrombin to activate protein C (PC) when bound to damaged endothelium or the endothelial protein C receptor (EPCR). Activated protein C (aPC) then binds to its cofactor, protein S (PS), to inactivate factors VIIIa and Va. However, this process is far less efficient at blocking thrombin generation on activated platelets, possibly because platelet-derived, partially activated factor Va is resistant to aPC/PS inactivation.¹⁵ Therefore, additional anticoagulant reactions are required. Factor Xa can be efficiently inhibited by the protein Z-dependent protease inhibitor (ZPI) when complexed to its cofactor, protein Z (PZ).¹⁶ ZPI also inhibits factor XIa in a process that does not require PZ. Deficiencies of PZ can promote both intracerebral bleeding and systemic thrombosis, the latter predominating in the setting of coexistent inherited thrombophilias.

The most potent inhibitor of both factor Xa and thrombin is antithrombin (AT, previously known as antithrombin III or ATIII) (see Fig. 40-3). Antithrombin bound to vitronectin can bind thrombin or factor

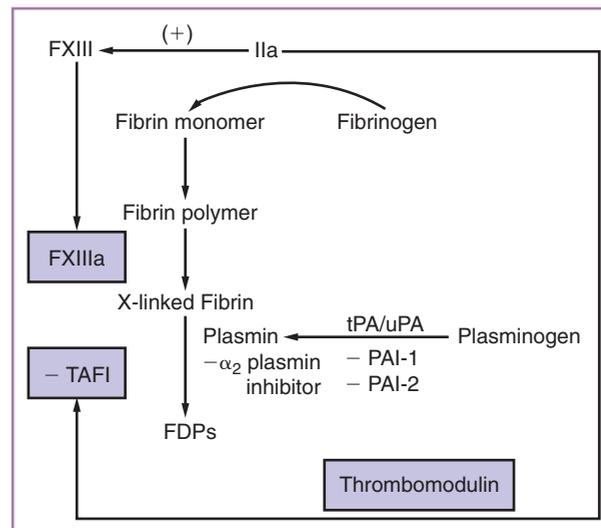

FIGURE 40-4 Fibrinolysis. The cross-linked fibrin polymer (X-linked Fibrin), which was stabilized by thrombin (factor IIa)-activated factor XIIIa, is degraded to fibrin degradation products (FDPs) by the action of plasmin, which is generated by the proteolysis of plasminogen via tissue-type plasminogen activator (tPA) and urokinase-type plasminogen activator (uPA). To prevent excessive fibrinolysis, plasmin is inhibited by α_2 -plasmin inhibitor, and tPA and uPA are inhibited by plasminogen activator inhibitor type 1 (PAI-1) and type 2 (PAI-2). In addition, thrombin-activated fibrinolytic inhibitor (TAFI), which is activated by the thrombin-thrombomodulin complex, cleaves terminal lysine residues from fibrin to render it resistant to plasmin.

Xa. The resultant conformational change facilitates AT binding to endothelial surface heparanoids or exogenous heparin, which augments thrombin inactivation more than 1000-fold.¹⁷ Although thrombin generated at the initial site of vascular injury is relatively “protected” from AT, thrombin produced more distally on the surface of activated platelets is readily susceptible.⁹ Similar inhibitory mechanisms utilize heparin cofactor II and α_2 -macroglobulin.

Restoration of Blood Flow: Fibrinolysis

Fibrinolysis permits the restoration of circulatory fluidity and serves as another barrier to thrombosis (Fig. 40-4). The cross-linked fibrin polymer is degraded to fibrin degradation products (FDPs) by the action of plasmin embedded in the fibrin clot.¹⁸ Plasmin is, in turn, generated by the proteolysis of plasminogen via tissue-type plasminogen activator (tPA), which is also embedded in fibrin. Endothelial cells also synthesize a second plasminogen activator, urokinase-type plasminogen activator (uPA), whose primary function is cell migration and extracellular matrix remodeling.

Fibrinolysis is, in turn, modulated by a series of inhibitors. Plasmin is inhibited by α_2 -plasmin inhibitor, which, like plasmin and plasminogen, is bound to the fibrin clot, where it is positioned to prevent premature fibrinolysis. Platelets and endothelial cells release type-1 plasminogen activator inhibitor (PAI-1) in response to thrombin binding to PARs. The PAI-1 molecule inhibits both tPA and uPA. In pregnancy, the decidua is also a very rich source of PAI-1,¹⁹ and the placenta can synthesize another antifibrinolytic molecule, PAI-2. Fibrinolysis can also be inhibited by thrombin-activated fibrinolytic inhibitor (TAFI). This carboxypeptidase cleaves terminal lysine residues from fibrin to render it resistant to plasmin. TAFI is activated by the

thrombin-thrombomodulin complex.²⁰ In the initial stages of clotting, platelets and endothelial cells release PAI-1, but, after a delay, endothelial cells release tPA and uPA to promote fibrinolysis. This biologic process permits sequential clotting followed by fibrinolysis to restore vascular patency.

The fibrinolytic system can also interact with the coagulation cascade. FDPs inhibit the action of thrombin, and this is a major source of hemorrhage in DIC. Moreover, PAI-1 bound to vitronectin and heparin also inhibits thrombin and factor Xa activity.²¹

The Effect of Pregnancy on Hemostasis

As noted, pregnancy and delivery present unique and paradoxical challenges to a woman's hemostatic system. They also present one of the greatest risks for venous thromboembolism (VTE) that most young women will face. Profound alterations in both local uterine and systemic clotting, anticoagulant, and fibrinolytic systems are required to meet this enormously complex challenge. The uterine decidua is ideally positioned to regulate hemostasis during placentation and the third stage of labor. Progesterone augments expression of TF²² and PAI-1¹⁹ on perivascular decidualized endometrial stromal cells. The crucial importance of the decidua in the maintenance of puerperal hemostasis is highlighted by the massive hemorrhage that accompanies obstetric conditions associated with impaired decidualization (e.g., ectopic and cesarean scar pregnancy, placenta previa, and accreta). That decidual TF plays the primary role in mediating puerperal hemostasis is demonstrated by the observation that transgenic TF knockout mice rescued by the expression of low levels of human TF have a 14% incidence of fatal postpartum hemorrhage despite far less invasive placentation.²³

The extraordinarily high level of TF expression in human decidua can also serve a pathologic function if local hemostasis proves inadequate to contain spiral artery damage and hemorrhage into the decidua occurs (i.e., abruption). This bleeding results in intense generation of thrombin and occasionally in frank hypofibrinogenemia and DIC. However, thrombin can also bind to decidual PAR-1 receptors to promote production of matrix metalloproteinases and cytokines, contributing to the tissue breakdown and inflammation associated with abruptio placenta and preterm premature rupture of the membranes.²⁴⁻²⁷

Pregnancy also induces systemic changes in the hemostatic system. It is associated with a doubling in concentration of fibrinogen and increases of 20% to 1000% in factors VII, VIII, IX, and X as well as vWF.²⁸ Levels of prothrombin and factor V remain relatively unchanged, and levels of factor XI decline modestly. The net effect is an increase in thrombin-generating potential. Pregnancy is also associated with 60% to 70% declines in free PS levels, which nadir at delivery due to hormonally induced increases in levels of its carrier protein, the complement 4B-binding protein.²⁹ As a consequence, pregnancy is associated with an increased resistance to aPC. These effects are exacerbated by cesarean delivery and infection, which drive further reduction in the concentration of free PS. Levels of PAI-1 increase threefold to fourfold during pregnancy, and plasma PAI-2 values, which are negligible before pregnancy, reach high concentrations at term.³⁰ Thus, pregnancy is associated with increased clotting potential, decreased anticoagulant activity, and decreased fibrinolysis.³⁰

Pregnancy is also associated with venous stasis in the lower extremities resulting from compression of the inferior vena cava and pelvic veins by the enlarging uterus as well as a hormone-mediated increase in deep vein capacitance secondary to increased circulating levels of

estrogen and local production of prostacyclin and nitric oxide. Pregnancy is also frequently associated with obesity, insulin resistance, and hyperlipidemia, all of which further increase levels of PAI-1.³¹

Disorders Promoting Thrombosis in Pregnancy

Acquired Thrombophilias: Antiphospholipid Antibodies

The combination of VTE, obstetric complications, and antiphospholipid antibodies (APA) defines the antiphospholipid antibody syndrome (APS).³² These antibodies are directed against proteins bound to negatively charged surfaces, usually anionic phospholipids. Therefore, APAs can be detected (1) by screening for antibodies that directly bind protein epitopes such as β_2 -glycoprotein-1, prothrombin, annexin V, aPC, PS, protein Z, ZPI, tPA, factor VII(a), and XII, the complement cascade constituents C4 and CH50, and oxidized low-density lipoproteins, or (2) by indirectly assessing antibodies that react to proteins present in an anionic phospholipid matrix (e.g., cardiolipin, phosphatidylserine), or (3) by assessing the downstream effects of these antibodies on prothrombin activation in a phospholipid milieu (i.e., lupus anticoagulants).³³

The diagnosis of APS has been a controversial topic. A recent consensus conference proposed the criteria outlined in Table 40-1.³⁴ In brief, APS requires the presence of at least one clinical criterion (confirmed thrombosis or pregnancy morbidity) and one laboratory criterion (lupus anticoagulant [LA], anticardiolipin (ACA), or anti- β_2 -glycoprotein-1 antibody). However, the presence of thrombosis must take into account confounding variables that lessen the certainty of the diagnosis (see Table 40-1). Uteroplacental insufficiency may be recognized by the sequelae of nonreassuring fetal surveillance tests suggestive of fetal hypoxemia, abnormal Doppler flow velocimetry waveform analysis suggestive of fetal hypoxemia, oligohydramnios (amniotic fluid index ≤ 5 cm), or birth weight less than the 10th percentile. Classification of APS should not be made if less than 12 wk or more than 5 years separates the positive APA test and the clinical manifestation.

Venous thrombotic events associated with APA include deep venous thrombosis (DVT) with or without acute pulmonary emboli; cerebral vascular accidents and transient ischemic attacks are the most common arterial events. At least half of patients with APA have systemic lupus erythematosus (SLE). A meta-analysis of 18 studies examining the thrombotic risk among SLE patients with LA, found odds ratios (OR) of 6.32 (95% confidence interval [CI], 3.71 to 10.78) for a VTE episode and 11.6 (CI, 3.65 to 36.91) for recurrent VTE.³⁵ By contrast, ACAs were associated with lower ORs of 2.50 (CI, 1.51 to 4.14) for an acute VTE and 3.91 (CI, 1.14 to 13.38) for recurrent VTE. A meta-analysis of studies involving more than 7000 patients in the general population identified a range of ORs for arterial and venous thromboses in patients with LA: 8.6 to 10.8 and 4.1 to 16.2, respectively.³³ The comparable numbers for ACA were 1 to 18 and 1 to 2.5. Therefore, there appears to be a consistently greater risk of VTE associated with LA compared with isolated ACA. Recurrence risks of up to 30% have been reported in affected patients, so long-term prophylaxis is required.³⁶ The risk of VTE in pregnancy and the puerperium accruing to affected patients is poorly studied but may be as high as 5% despite treatment.³⁷

As noted, APA are associated with obstetric complications including fetal loss, abruption, severe preeclampsia, and intrauterine growth

TABLE 40-1 REVISED CLASSIFICATION CRITERIA FOR DIAGNOSIS OF THE ANTIPHOSPHOLIPID ANTIBODY SYNDROME (APS)***Clinical Criteria**

1. Vascular thrombosis[†]: One or more clinical episodes of arterial, venous, or small-vessel thrombosis, in any tissue or organ confirmed by objective, validated criteria (i.e., unequivocal findings of appropriate imaging studies or histopathology).
2. Pregnancy morbidity:
 - a. One or more unexplained deaths of a morphologically normal fetus at or beyond 10 weeks of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, or
 - b. One or more premature births of a morphologically normal neonate before the 34th week of gestation because of (i) eclampsia or severe preeclampsia or (ii) recognized uteroplacental insufficiency, or
 - c. Three or more unexplained consecutive euploid spontaneous abortions before 10 weeks of gestation, with maternal anatomic or hormonal abnormalities and paternal and parental chromosomal causes excluded.

Laboratory Criteria[‡]

1. Lupus anticoagulant (LA) present in plasma, on two or more occasions at least 12 wk apart, detected according to the guidelines of the ISTH Scientific Subcommittee on Lupus Anticoagulants/Phospholipid-Dependent Antibodies.
2. Anticardiolipin antibody (aCL) of IgG and/or IgM isotype in serum or plasma, present in medium or high titer (i.e., >40 GPL or MPL, or >99th percentile), on two or more occasions, at least 12 wk apart, measured by a standardized ELISA.
3. Anti- β_2 -glycoprotein-1 antibody of IgG and/or IgM isotype in serum or plasma (in titer >99th percentile), present on two or more occasions, at least 12 wk apart, measured by a standardized ELISA, according to recommended procedures.

*APS is present if at least one clinical criterion and one laboratory criterion are met.

[†]Coexisting inherited or acquired factors for thrombosis are not reasons for excluding patients from APS trials. However, two subgroups of APS patients should be recognized, according to (1) the presence or (2) the absence of additional risk factors for thrombosis. Indicative (but not exhaustive) of such factors are age (>55 yr in men, >65 yr in women); presence of any of the established risk factors for cardiovascular disease (hypertension, diabetes mellitus, elevated LDL or low HDL cholesterol, cigarette smoking, family history of premature cardiovascular disease, BMI ≥ 30 kg/m², microalbuminuria, estimated GFR <60 mL/min), inherited thrombophilias, oral contraceptive use, nephrotic syndrome, malignancy, immobilization, and surgery. Patients who fulfill criteria should be stratified according to contributing causes of thrombosis.

[‡]Investigators are strongly advised to classify APS patients in studies into one of the following categories: I, more than one laboratory criteria present (any combination); IIa, LA present alone; IIb, aCL antibody present alone; IIc, Anti- β_2 glycoprotein-1 antibody present alone.

APA, antiphospholipid antibody; BMI, body mass index; ELISA, enzyme-linked immunosorbent assay; GFR, glomerular filtration rate; GPL, IgG phospholipid units; HDL, high-density lipoprotein; IgG, immunoglobulin G; IgM, immunoglobulin M; ISTH, International Society on Thrombosis and Hemostasis; LDL, low-density lipoprotein; MPL, IgM phospholipid units.

Modified from Miyakis S, Lockshin MD, Atsumi D, et al: International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS). *J Thromb Haemost* 4:295-306, 2006.

restriction (IUGR). LA are associated with fetal loss after the first trimester, with ORs ranging from 3.0 to 4.8, and ACA display a wider range of ORs, 0.86 to 20.0.³³ It is controversial whether APA are associated with recurrent (more than three) early (<10 weeks) spontaneous abortions in the absence of stillbirth. At least 50% of pregnancy losses in patients with APA occur after the 10th week of gestation.³⁸ Moreover, compared with patients who have unexplained first-trimester spontaneous abortions without APA, those with antibodies more often have demonstrable embryonic cardiac activity (86% versus 43%; $P < .01$).³⁹

The association between APA and infertility also is uncertain. Increased levels of APA have been reported in women with infertility.^{40,41} However, a meta-analysis of seven studies of affected patients undergoing in vitro fertilization found no significant association between APA and either clinical pregnancy (OR, 0.99; CI, 0.64 to 1.53) or live birth rate (OR, 1.07; CI, 0.66 to 1.75).⁴² Finally, there is also no evidence that treating patients who have APA with anticoagulant medications improves outcomes of in vitro fertilization.⁴³

Women with APS who have pregnancies reaching viability are at increased risk for obstetric outcomes associated with abnormal placentation such as preeclampsia and IUGR. Up to 50% of pregnancies in women with APS develop preeclampsia, and one third have IUGR.³⁷ Abnormal fetal heart rate tracings prompting cesarean delivery are also common. Conversely, most cases of preeclampsia and IUGR occur in women without APA. Although increased positive tests for APA have been reported in women with preeclampsia, especially in severe disease with onset before 34 weeks' gestation⁴⁴ and IUGR, most large retro-

spective and prospective studies have not found an association between these conditions and APA.⁴⁵ This is not surprising, given the common occurrence of preeclampsia and IUGR and the relative infrequency of APS.

A myriad of mechanisms have been proposed for APA-mediated arterial and venous thrombosis. Direct inhibition of the anticoagulant effects of anionic phospholipid-binding proteins such as β_2 -glycoprotein-1 and annexin V has been shown.^{46,47} In addition, APA appear to inhibit thrombomodulin, aPC, and AT activity; to induce TF, PAI-1, and vWF expression in endothelial cells; and to augment platelet activation. Recently, APA induction of complement activation has been suggested to play a role in fetal loss, with heparin preventing such aberrant activation.⁴⁸

Contemporary management of affected patients during pregnancy requires treatment with either unfractionated heparin or low-molecular-weight heparin (LMWH) plus low-dose aspirin (LDA) at 50 to 80 mg/day. Rai and colleagues conducted a randomized, controlled trial among 90 APA-positive women with a history of recurrent fetal loss who received either LDA alone or LDA plus 5000 U of unfractionated heparin SQ every 12 hours until either recurrent loss or 34 weeks of gestation.³⁹ The live birth rate was significantly higher with combined heparin and LDA than with LDA alone: 71% (32/45) versus 42% (19/45) (OR, 3.37; CI, 1.40 to 8.10). Interestingly, 90% of the losses occurred in the first trimester, and there was no difference in outcome between the two groups for women whose pregnancies advanced beyond 13 weeks' gestation. Similar results were found in a nonrandomized trial by Kutteh.⁴⁹ On the other hand, Farquharson and

coworkers found no advantage to adding LMWH to LDA.⁵⁰ However, this latter study has been criticized because of the very low levels of APA present in affected patients as well as imperfect randomization. Meta-analysis found that unfractionated heparin plus LDA (two trials; *N* = 140) significantly reduced pregnancy loss compared with LDA alone (relative risk [RR], 0.46; CI, 0.29 to 0.71) and that there was no advantage of high-dose over low-dose unfractionated heparin (one trial; *N* = 50).⁵¹ Another meta-analysis found that enoxaparin treatment resulted in an increased live birth rate, compared with LDA (RR, 10.0; CI, 1.56 to 64.20).⁵² Three studies of LDA alone versus placebo included in the meta-analysis showed no significant reduction in pregnancy loss (RR, 1.05; CI, 0.66 to 1.68).⁵¹

Adverse pregnancy outcomes can still occur despite treatment. Backos and associates conducted a prospective observational study of 150 women treated with LDA and either unfractionated heparin (5000 U given SQ every 12 hours) or enoxaparin (20 mg daily) from the time of positive embryonic cardiac activity to either pregnancy loss or 34 weeks of gestation.⁵³ The live birth rate was 71%. However, 27% of the patients miscarried (mostly in the first trimester), and gestational hypertension occurred in 17%, abruption in 7%, and IUGR in 15%.

Intravenous immune globulin (IVIG) has been reported to improve outcome in women with APS for whom treatment with heparin and LDA has failed.⁵⁴ The efficacy of the combination of LDA and LMWH in affected patients was compared with that of IVIG for the prevention of recurrent fetal loss in a study including 40 women,⁵⁵ who were randomized to receive either LMWH (5700 IU/day SQ) and LDA or IVIG (400 mg/kg IV for 2 days, followed by 400 mg/kg every month). Although the clinical characteristics of the two groups were similar at the time of randomization, women receiving LMWH and LDA had a higher live birth rate (84%) than those receiving IVIG alone (57%). Moreover, IVIG plus heparin and LDA was also not superior to heparin and LDA alone in another small, randomized trial.⁵⁶ Therefore, IVIG is not recommended as first-line therapy for APS.

Given these small study sizes and heterogeneous therapies employed, recommendations for treatment are difficult to make. It is unlikely that a patient with no history of VTE who has repetitive early losses and borderline positive APA levels reflects the same degree of risk or need for intense therapy as a patient with high levels of APA, prior VTE, and recurrent growth-retarded stillbirths. It is unclear whether the former

patient requires any therapy, but the latter patient needs therapeutic unfractionated heparin or LMWH with LDA.⁵⁷ Tincani and associates reported on a survey of members of the International Advisory Board of the 10th International Congress on Antiphospholipid Antibodies. The consensus of the group was that treatment for APA-positive pregnant patients should be LMWH and LDA.⁵⁷ The dosage and frequency of LMWH depends on the situation, including the patient's body weight and past history. Patients with previous thromboses should receive two injections per day. The use of IVIG should be restricted to patients with pregnancy losses despite conventional treatment (see later discussion for details of heparin dosing).

Inherited Thrombophilias

Inherited thrombophilias have been linked to VTE. However, the occurrence of VTE in patients with an inherited thrombophilia is highly dependent on the presence of other predisposing factors, especially a personal or family history of VTE. Even more controversial is the association between inherited thrombophilias and adverse pregnancy outcomes.

Factor V Leiden Mutation

Present in about 5% of the European population and 3% of African-Americans, factor V Leiden (FVL) is the most common of the serious heritable thrombophilias.⁵⁸ The mutation is virtually absent in African blacks, Chinese, Japanese, and other Asians. The mutation causes a substitution of glutamine for arginine at position 506, the site of proteolysis and inactivation by aPC/PS, and FVL is the leading cause of aPC resistance. The heterozygous state is symptomatic, with a fivefold increased risk of VTE, but homozygous patients have a 25-fold increased risk (Table 40-2). FVL is associated with about 40% of VTE events in pregnant patients.⁵⁹ However, given the low prevalence of VTE in pregnancy (1/1400) and the high incidence of the mutation in the European-derived population, the risk of VTE among FVL heterozygotes without a personal history of VTE or an affected first-degree relative is less than 0.3%.⁵⁹ Nevertheless, the risk is at least 10% among pregnant women who have either a personal history of VTE or an affected first-degree relative.⁶⁰ Pregnant homozygous patients without a personal history of VTE or an affected first-degree relative have a 1.5% risk for VTE in pregnancy; if there is a personal or family history

TABLE 40-2 INHERITED THROMBOPHILIAS AND THEIR ASSOCIATION WITH VENOUS THROMBOEMBOLISM (VTE) IN PREGNANCY

Thrombophilia	Relative Risk of VTE (95% CI)	Probability of VTE (%) without or with a Personal History of VTE or a First-Degree Relative with VTE		Ref. No.
		Without	With	
FVL (homozygous)	25.4 (8.8-66)	1.5	17	46
FVL (heterozygous)	5.3 (3.7-7.6)	0.20-0.26	10	45, 46
PGM (homozygous)	NA	2.8	>17	46
PGM (heterozygous)	6.1 (3.4-11.2)	0.37	>10	45, 46

Antithrombin deficiency (<60% activity)	119	3.0-7.2	>40%	46, 47
Protein S deficiency (<55% activity)	NA	<1	6.6	46, 47
Protein C deficiency (<50% activity)	13.0 (1.4-123)	0.8-1.7	2-8	46, 47

CI, confidence interval; FVL, factor V Leiden mutation; NA, not available; PGM, prothrombin gene mutation.

of VTE, the risk is 17% (see Table 40-2). Screening can be done by assessing aPC resistance using a second-generation coagulation assay followed by genotyping for the FVL mutation if aPC resistance is found in a pregnant or nonpregnant woman. Alternatively, patients can simply be genotyped for FVL.

The College of American Pathologists Consensus Conference on Thrombophilia compared 16 case-control studies reporting a link between FVL and unexplained recurrent fetal loss and 6 studies failing to establish such an association and concluded that the latter studies were smaller and tended to include patients with early first-trimester losses.^{61,62} In a meta-analysis of 31 studies, FVL was associated with early (<13 weeks) pregnancy loss, with an OR of 2.01 (CI, 1.13 to 3.58), but it was more strongly associated with late (>19 weeks), nonrecurrent fetal loss, with an OR of 3.26 (CI, 1.82 to 5.83).⁶³ A case-control study noted an even stronger link between FVL and recurrent fetal losses after 22 weeks' gestation (OR, 7.83; CI, 2.83 to 21.67).⁶⁴ Dudding and Attia conducted a meta-analysis and found no significant association between FVL and first-trimester loss but an OR of 2.4 (CI, 1.1 to 5.2) for isolated (nonrecurrent) third-trimester fetal loss, which increased to 10.7 (CI, 4.0 to 28.5) for two or more second- or third-trimester fetal losses.⁶⁵ Similarly, Lissalde-Lavigne and associates reported the results of a case-control study nested in the 32,700 Nimes Obstetricians and Haematologists (NOHA) First study cohort.⁶⁶ Multivariate analysis revealed an association between FVL and pregnancy loss after 10 weeks (OR, 3.46; CI, 2.53 to 4.72) but not for losses occurring between 3 and 9 weeks. These studies strongly suggest that FVL is associated with fetal (>9 weeks) and not embryonic (<9 weeks) losses.

The association between FVL and late, compared with early, pregnancy losses was also demonstrated by a large European retrospective cohort study involving 571 women with thrombophilia having 1524 pregnancies, compared with 395 controls having 1019 pregnancies.⁶⁷ There was a statistically significant association between any inherited thrombophilia and stillbirth (OR, 3.6; CI, 1.4 to 9.4) but not spontaneous abortion (OR, 1.27; CI, 0.94 to 1.71). The same trend was noted for FVL, with an OR for stillbirth of 2.0 (CI, 0.5 to 7.7) compared with 0.9 for spontaneous abortion (CI, 0.5 to 1.5). These same investigators then monitored a subset of 39 thrombophilic and 51 control patients who had no previous history of fetal loss and did not receive anticoagulation during the prospective follow-up aspect of the study.⁶⁸ They reported a modestly increased overall risk of fetal loss in a subsequent pregnancy among women with thrombophilia (7/39 versus 7/51; RR, 1.4; CI, 0.4 to 4.7) and also among those with FVL (RR, 1.4; CI, 0.3 to 5.5). However, this study lacked power to exclude the usually reported twofold to threefold higher rates of loss associated with FVL, because there were only 21 patients. Nevertheless, given the trends, the authors concluded that "Women with thrombophilia appear to have an increased risk of fetal loss, although the likelihood of a positive outcome is high in both women with thrombophilia and in controls."⁶⁸

In a retrospective cohort study, Roque and colleagues evaluated 491 patients with a history of various adverse pregnancy outcomes for a variety of thrombophilias and reported that the presence of FVL was paradoxically protective against losses before 10 weeks of gestation (OR, 0.23; CI, 0.07 to 0.77) but was significantly associated with losses after 14 weeks (OR, 3.71; CI, 1.68 to 8.23).⁶⁹ Moreover, women who experienced only euploid losses were not more likely to have an identified thrombophilia than women who experienced only aneuploid early losses (OR, 1.03; CI, 0.38 to 2.75). Consistent with this protective effect of FVL on early pregnancy is the observation that implantation rates after in vitro fertilization were substantially higher among FVL carriers than among noncarriers (90% versus 49%; $P = .02$).⁷⁰

Early pregnancy is associated with a low-oxygen environment, with intervillous oxygen pressures of 17.9 ± 6.9 mm Hg at 8 to 10 weeks, rising to 60.7 ± 8.5 mm Hg at 12 to 13 weeks.⁷¹ Trophoblast plugging of the spiral arteries has been demonstrated in placental histologic studies before 10 weeks of gestation, and low Doppler flow is noted in the uteroplacental circulation before 10 weeks.⁷² Indeed, the undetectable levels of superoxide dismutase in trophoblast before 10 weeks of gestation are consistent with a hypoxic state.⁷³ Therefore, if FVL or other thrombophilias are associated with early pregnancy loss, it is most likely through mechanisms other than placental thrombosis. Also, because a majority of early pregnancy losses are associated with aneuploidy, thrombophilias are likely to play a far lesser role in such cases. In contrast, uteroplacental thrombosis after 9 weeks would be expected to reduce oxygen and nutrient delivery to a progressively larger embryo, accounting for the apparent link between FVL and the other maternal thrombophilias and later adverse pregnancy outcomes.

The correlation between FVL and other later adverse pregnancy events is more controversial. Kupferminc and associates studied 110 women and reported a link between FVL and severe preeclampsia (OR, 5.3; CI, 1.8 to 15.6).⁷⁴ However, multiple case-control studies have failed to demonstrate a link between FVL and moderate or severe preeclampsia.⁷⁵⁻⁷⁷ Dudding and Attia's meta-analysis estimated a 2.9-fold (CI, 2.0 to 4.3) increased risk of severe preeclampsia among FVL carriers.⁶⁵ Similarly, Lin and August conducted a meta-analysis of 31 studies involving 7522 patients and reported pooled ORs of 1.81 (CI, 1.14 to 2.87) for FVL and all preeclampsia and 2.24 (CI, 1.28 to 3.94) for FVL and severe preeclampsia.⁷⁸ However, Kosmas and coauthors evaluated 19 studies involving 2742 hypertensive women and 2403 controls and reported that, whereas the studies published before 2000 found a modest association between FVL and preeclampsia (OR, 3.16; CI, 2.04 to 4.92), those published after 2000 did not (OR, 0.97; CI, 0.61 to 1.54).⁷⁹ This suggests a reporting bias. Therefore, there is not sufficient evidence to conclude that FVL is associated with an increased occurrence of preeclampsia, although there is inadequate power to rule out an association between this thrombophilia and severe, early-onset preeclampsia.

Kupferminc and colleagues also reported a modest association between FVL and abruptio (OR, 4.9; CI, 1.4 to 17.4).⁷⁴ A second case-control study found that 17 of 27 patients with abruptio had aPC resistance, compared with 5 of 29 control subjects (OR, 8.16; CI, 3.6 to 12.75), and 8 cases were found to have the FVL mutation, compared with one control.⁸⁰ Prochazka and associates conducted a retrospective case-control study among 180 women with placental abruptio and 196 controls and found a significantly increased incidence of FVL carriage among cases compared with controls (14.1% versus 5.1%; OR, 3.0; CI, 1.4 to 6.7).⁸¹ Alfrevic and coworkers conducted a meta-analysis that revealed a strong association between placental abruptio and both homozygosity and heterozygosity for the FVL mutation (OR, 16.9; CI, 2.0 to 141.9, and OR, 6.7; CI, 2.0 to 21.6, respectively).⁸² Therefore, there appears to be evidence of an association between FVL carriage and placental abruptio, although large case-control and retrospective cohort studies are needed to confirm this link.

There is less consistent evidence for an association between FVL and IUGR. Martinelli and coauthors reported a strong association between FVL and IUGR (OR, 6.9; CI, 1.4 to 33.5).⁸³ However, multiple, large case-control and cohort studies have reported no statistically significant association between FVL and IUGR of less than the 10th or less than the 5th percentile.^{74,77,84} Howley and colleagues conducted a systematic review of studies describing the association between FVL and IUGR; among 10 case-control studies meeting selection criteria, there was a significant association between FVL and IUGR (OR, 2.7;

CI, 1.3 to 5.5).⁸⁵ However, no association was found among five cohort studies, of which three were prospective and two retrospective (RR, 0.99; CI, 0.5 to 1.9). The authors suggested that the putative association between IUGR and FVL was most likely driven by small, poor-quality studies that demonstrated extreme associations.

In summary, there appears to be a modest association between FVL and fetal loss after 10 weeks, and particularly with isolated losses after 22 weeks. There is a possible association between FVL and abruption. However, no clear association exists between FVL and either preeclampsia or IUGR, although studies have been underpowered to definitely exclude a link with severe early-onset preeclampsia or severe IUGR. It also is noteworthy that two prospective cohort studies found no association between FVL and any adverse obstetric outcome, including pregnancy loss, preeclampsia, and IUGR,^{86,87} but these studies were underpowered to draw firm conclusions. It is important to note that, although thrombophilia may be sufficient to cause pregnancy loss and perhaps abruption, most affected individuals without such prior obstetric complications are at low risk for subsequent adverse pregnancy outcomes.

Other Factor V Mutations

Other mutations in the factor V gene have been variably linked to maternal VTE and adverse pregnancy outcomes. The factor V HR2 haplotype causes decreased factor V cofactor activity in the aPC-mediated degradation of factor VIIIa; however, a meta-analysis demonstrated no statistically significant association between the HR2 haplotype and risk of VTE (OR, 1.15; CI, 0.98 to 1.36).⁸⁸ There are conflicting reports about the linkage of the factor V HR2 haplotype and recurrent pregnancy loss. Zammiti and associates reported no association with losses before 8 weeks, but homozygosity for the factor V HR2 haplotype was associated with significant and independent risks of pregnancy loss during weeks 8 and 9, which increased during weeks 10 to 12 and culminated after 12 weeks.⁸⁹ In contrast, Dilley and colleagues found no association between carriage of the factor V HR2 haplotype and pregnancy loss.⁹⁰ The sample sizes of these studies were too small to draw firm conclusions from, nor can conclusions be reached about the link between factor V HR2 haplotype and other adverse pregnancy outcomes.

Two other mutations in the factor V gene that occur at the second aPC cleavage site, factor V R306G Hong Kong and factor V R306T Cambridge, have also been described but do not appear to be strongly associated with VTE.⁹¹ There are inadequate data to assess any linkage between these mutations and adverse pregnancy outcomes.⁸⁹

Prothrombin Gene Mutation

The prothrombin G20210A polymorphism is a point mutation causing a guanine→adenine switch at nucleotide position 20210 in the 3'-untranslated region of the gene.⁵⁸ This nucleotide switch results in increased translation, possibly due to enhanced stability of messenger RNA (mRNA). As a consequence, there are increased circulating levels of prothrombin. Although the mutation is present in only 2% to 3% of the European population, it is associated with 17% of VTEs in pregnancy.⁵⁹ However, as was the case with FVL, the risk of VTE in pregnant patients who are heterozygous for the prothrombin G20210A gene mutation (PGM) but who are without a personal or strong family history of VTE is less than 0.5%.⁵⁹ Pregnant PGM-heterozygous patients with such a history have at least a 10% risk of VTE.⁶⁰ PGM-homozygous patients without a personal or strong family history have a 2.8% risk for VTE in pregnancy, whereas such a history probably confers a risk of at least 20% (see Table 40-2). Because the combination of FVL and PGM has synergistic hypercoagulable effects, compound heterozygotes are at

greater thrombotic risk than either FVL or PGM homozygotes. Pregnant patients who are compound heterozygotes without a personal or strong family history have a 4.7% risk of VTE.^{59,60}

The PGM has been associated with an increased risk of pregnancy loss in multiple case-control studies. One such study reported the presence of the PGM in 7 of 80 patients with recurrent miscarriage, compared with 2 of 100 control patients (9% versus 2%; $P = .04$; OR, 4.7; CI, 0.9 to 23).⁹² Finan and associates also found an association between PGM and recurrent abortion, with an OR of 5.05 (CI, 1.14 to 23.2).⁹³ However, other studies have failed to identify a link.^{94,95} A 2004 meta-analysis of seven studies evaluating the correlation between PGM and recurrent pregnancy loss, defined as two or more losses in the first or second trimester, found a combined OR of 2.0 (CI, 1.0 to 4.0).⁹⁶ Analogous to FVL, the association between PGM and pregnancy loss increases with increasing gestational age. In the meta-analysis by Rey and colleagues, an association was reported between PGM and recurrent loss before 13 weeks' gestation (OR, 2.3; CI, 1.2 to 4.79), but, as with FVL, a stronger association was observed between PGM and recurrent fetal loss before 25 weeks (OR, 2.56; CI, 1.04 to 6.29).⁶³ Therefore, PGM appears to fit the pattern displayed by FVL carriers of progressively greater risk of fetal loss with advancing gestation; however, these risks remain quite modest.

There are more limited data on the association between PGM and abruption. The case-control study of Kupferminc and associates found an association between the PGM and abruptio placentae (OR, 8.9; CI, 1.8 to 43.6),⁷⁴ whereas Prochazka and colleagues found no such link.⁸¹ Meta-analyses suggested a strong link between PGM heterozygosity and placental abruption (OR, 28.9; CI, 3.5 to 236.7).⁸² It can be concluded that there is probably a link between the PGM and abruptio placentae.

The link between the PGM and other adverse pregnancy events is far less certain. Kupferminc and colleagues found an association between the PGM and IUGR of less than the 5th percentile (OR, 4.6; CI, 1 to 20) but no link between the PGM and severe preeclampsia.⁷⁴ Martinelli and coworkers noted a strong association between PGM and IUGR in their case-control study (OR, 5.9; CI, 1.2 to 29.4).⁸³ In contrast, the large case-control study of Infante-Rivard and colleagues reported no link in heterozygotes between PGM and IUGR, with an OR of 0.92 (CI, 0.36 to 2.35).⁸⁴ Similar results have been observed by other workers.^{74,80} A number of other case-control studies and meta-analyses have failed to establish a link between PGM and either preeclampsia or severe preeclampsia.^{77,78,97,98}

Therefore, although most individual studies are limited by small sample size, case-control design, and the potential for selection biases (as was the case with FVL), there may be a weak association between the PGM and fetal loss as well as abruptio placentae. However, there does not appear to be a significant link between PGM and IUGR or preeclampsia.

Hyperhomocysteinemia

Hyperhomocysteinemia can result from a number of mutations in the methionine metabolic pathway. Homozygosity for mutations in the methylene tetrahydrofolate reductase (MTHFR) gene is by far the most common cause. Homozygosity for the MTHFR C677T polymorphism is present in 10% to 16% of all Europeans, and that for the A1298C mutation occurs in 4% to 6%.⁹⁹ Importantly, about 40% of whites are heterozygous for this polymorphism, and most heterozygotes have normal levels of homocysteine. Moreover, because homocysteine levels decrease in pregnancy and U.S. diets are replete with folic acid supplementation, hyperhomocysteinemia is extremely rare even among homozygotes. In addition, although hyperhomocysteinemia is a risk factor for VTE (OR, 2.5; CI, 1.8 to 3.5),¹⁰⁰ MTHFR mutations per se

do not appear to convey an increased risk for VTE in either nonpregnant¹⁰¹ or pregnant women.¹⁰²

As with thrombotic risk, meta-analyses suggest that elevated fasting homocysteine levels are more strongly associated with recurrent pregnancy loss (<16 weeks) than are MTHFR mutations, with an OR of 2.7 (CI, 1.4 to 5.2) versus 1.4 (CI, 1.0 to 2.0), respectively.¹⁰³ The Hordaland Homocysteine Study assessed the relationship between plasma homocysteine values in 5883 women and their prior 14,492 pregnancy outcomes.¹⁰⁴ When the authors compared the upper with the lower quartile of plasma homocysteine levels, elevated levels trended toward an association with preeclampsia (OR, 1.32; CI, 0.98 to 1.77), very low birth weight (OR, 2.01; CI, 1.23 to 3.27), and stillbirth (OR, 2.03; CI, 0.98 to 4.21), although none of these associations reached statistical significance.¹⁰⁵ In contrast, a clear association was demonstrated between placental abruption and homocysteine levels greater than 15 $\mu\text{mol/L}$ (OR, 3.13; CI, 1.63 to 6.03), and a weaker but significant association was observed between homozygosity for the C677T MTHFR mutation and abruption (OR, 1.6; CI, 1.4 to 4.8). Indeed, a meta-analysis of these two risk factors found that hyperhomocysteinemia had a larger pooled OR for abruption (5.3; CI, 1.8 to 15.9) than did homozygosity for the MTHFR mutation (2.3; CI, 1.1 to 4.9).¹⁰⁶

These studies strongly suggest that hyperhomocysteinemia, but not simply the presence of the MTHFR mutations, is linked to VTE and adverse pregnancy outcomes. Moreover, whereas homozygosity for MTHFR mutations is very common (10% to 20% in European populations), hyperhomocysteinemia is quite rare. Therefore, screening for this disorder should be limited, requiring a fasting homocysteine level greater than 12 $\mu\text{mol/L}$ to be considered positive in pregnant patients.¹⁴⁶

Antithrombin Deficiency

Deficiency of AT is both the rarest and the most thrombogenic of the heritable thrombophilias. More than 250 mutations have been identified in the AT gene, producing a highly variable phenotype. In general, disorders can be classified into three types: type 1, those associated with reductions in both antigen and activity; type 2, those associated with normal levels of antigen but decreased activity; and type 3, the very rare homozygous deficiency associated with little or no activity.^{58,108} Complicating matters further, patients can develop acquired AT deficiency due to liver impairment, increased consumption of AT associated with sepsis or DIC, or increased renal excretion in severe nephrotic syndrome. However, both inherited and acquired AT deficiencies are associated with VTE.

Because screening for AT deficiency is done by assessing activity, its prevalence varies with the activity cutoff level employed, ranging from 0.02% to 1.1%. The recommended cutoff for "abnormality" is 50% activity, which is associated with a prevalence of 0.04% (1/2500 people).¹⁰⁸ Although it increases the risk of VTE up to 25-fold in the nonpregnant state,¹⁰⁸ because of its rarity AT deficiency is associated with only 1% to 8% of VTE episodes.⁵⁸ Pregnancy may increase its thrombogenic potential substantially (see Table 40-2). Moreover, use of a less stringent threshold yields a higher prevalence of AT deficiency in patients with VTE. For example, in one study, 19.3% of pregnant women with VTE had less than 80% AT activity,⁵⁹ but many of these cases may have been acquired due to clot-associated AT consumption. Conversely, the overall risk of VTE in pregnancy associated with AT deficiency has been variably reported as 3% to 48%.^{30,60,109,110} The risk of VTE in pregnancy among AT-deficient patients most likely varies also with a personal or family history (from 3% to 7% without such a history to as much as 40% with such a history).⁶⁰

In the largest retrospective cohort study, AT deficiency was associated with a significantly increased risk of stillbirth after 28 weeks' gesta-

tion (OR, 5.2; CI, 1.5 to 18.1) but had a more modest association with miscarriage before 28 weeks (OR, 1.7; CI, 1.0 to 2.8).⁶⁷ Given its rarity, there is a paucity of evidence concerning the link between AT deficiency and other adverse pregnancy outcomes. Roque and associates found it to be associated with increased risks of IUGR (OR, 12.93; CI, 2.72 to 61.45), abruption (OR, 60.01; CI, 12.02 to 300.46), and preterm delivery (OR, 4.72; CI, 1.22 to 18.26).⁶⁹

Protein C Deficiency

Deficiency of PC results from more than 160 distinct mutations, producing a highly variable phenotype. As was the case with AT deficiency, PC deficiency can be associated with either reductions in both antigen and activity (type 1) or normal levels of antigen but decreased activity (type 2).⁵⁸ The very rare homozygous PC deficiency results in neonatal purpura fulminans and a requirement for lifelong anticoagulation.¹¹¹ Activity levels can be ascertained by either a functional (clotting) or chromogenic assay.

Estimates of prevalence and thrombotic risk reflect the cutoff values employed. Most laboratories use activity cutoff values of 50% to 60%, which are associated with prevalence estimates of 0.2% to 0.3% and RRs for VTE of 6.5 to 12.5.^{58,68,108} The risk of VTE in pregnancy among PC-deficient patients has been reported to range from 2% to 8%.^{30,112,113} Because of its rarity, there are few reports linking PC deficiency to adverse pregnancy outcomes, and those that exist involve too few patients to draw any firm conclusions. In their case-control study, Roque and colleagues reported a strong link between PC deficiency and abruption (OR, 13.9; CI, 2.21 to 86.9) and between PC deficiency and preeclampsia (OR, 6.85; CI, 1.09 to 43.2).⁶⁹ A meta-analysis also reported a strong association of this deficiency and preeclampsia/eclampsia (OR, 21.5; CI, 1.1 to 414.4) but not stillbirth.⁸² It is biologically plausible that PC deficiency should pose risks of fetal loss and abruption analogous to those associated with FVL. However, given the very small sample sizes, no firm conclusions can be drawn regarding the link between PC deficiency and either preeclampsia or IUGR.

Protein S Deficiency

More than 130 mutations have been linked to deficiency of PS.⁵⁸ The great majority of affected patients can be characterized as having low levels of both total and free PS antigen (type 1) or as having only a low free PS level due to enhanced binding to the complement 4B-binding protein (type 2a). The latter condition is frequently caused by a serine 460 to proline mutation (protein S Heerlen), which has been associated with either FVL or PC mutation in about half of affected patients.¹¹⁴ As with PC deficiency, homozygous PS deficiency results in neonatal purpura fulminans.¹¹¹

Screening for PS deficiency can be done with an activity assay, but this approach is associated with substantial interassay and intra-assay variability, in part because of frequently changing physiologic levels of complement 4B-binding protein.¹¹⁵ Detection of free PS antigen levels lower than 55% in a nonpregnant woman is consistent with the diagnosis.¹¹⁵ However, Paidas and colleagues found far lower levels in normal pregnancy, with suggested cutoff levels for free PS of 29% for the first and second trimesters and 23% for the third trimester.²⁹ With such criteria, the prevalence of true PS deficiency is low (0.03% to 0.13%) in the nonpregnant state and rises up to 3% in the pregnant state, but its degree of thrombogenicity is modest (OR, 2.4; CI, 0.8 to 7.9).^{29,58,115} Among those patients with PS deficiency and a strong family history of VTE, the risk of VTE in pregnancy is 6.6% (see Table 40-2).¹¹²

The meta-analysis by Rey and colleagues reported an association between PS deficiency and recurrent late (>22 weeks or <25 weeks)

fetal loss (OR, 14.7; CI, 1.0 to 2181) as well as nonrecurrent fetal losses at greater than 22 weeks (OR, 7.4; CI, 1.3 to 43).⁶³ A second meta-analysis suggested an even stronger link between PS deficiency and stillbirth (OR, 16.2; CI, 5.0 to 52.3), IUGR (OR, 10.2; CI, 1.1 to 91.0), and preeclampsia/eclampsia (OR, 12.7; CI, 4 to 39.7), but not abruptio.⁸² Again, the small sample sizes limit the ability to draw firm conclusions.

Protein Z-Dependent Protease Inhibitor and Protein Z Deficiency

Two nonsense mutations in the coding region of the ZPI gene have been identified to occur more often in patients with VTE (4.4%) than in controls (0.8%) (OR, 5.7; CI, 1.25 to 26.0).¹¹⁶ Deficiency of PZ (activity <5th percentile) has been associated with strokes but not with VTE.¹¹⁷ PZ deficiency was linked to late fetal loss (10 to 16 weeks' gestation) in one study (OR, 6.7; CI, 3.1 to 14.8)¹¹⁸ but not in another.¹¹⁹ Paidas and associates prospectively compared PZ levels in 103 patients with subsequent normal pregnancy outcome and 106 women with various adverse pregnancy outcomes including fetal loss, IUGR, preeclampsia, and abruptio; they noted lower first-trimester PZ levels among the patients with subsequent adverse outcomes (1.81 ± 0.7 versus 2.21 ± 0.8 $\mu\text{g/mL}$; $P < .001$).²⁹ There were also lower PZ levels in affected patients in the second trimester (1.5 ± 0.4 versus 2.0 ± 0.5 $\mu\text{g/mL}$; $P < .0001$) and in the third trimester (1.6 ± 0.5 versus 1.9 ± 0.5 $\mu\text{g/mL}$; $P < .0002$). However, it is unclear whether low PZ levels were causative or whether PZ was reduced as a result of other thrombophilias or the ongoing uteroplacental pathologic processes. Although PZ deficiency may have its own pathogenic potential, its presence with other thrombophilic mutations in patients with prior fetal loss may also confer resistance to heparin therapy.¹¹⁹

Mutations in Fibrinolytic Pathway Genes

Two polymorphisms, 675 4G/5G and A844G, in the promoter region of the PAI-1 gene have been described.¹²⁰ Homozygosity for the 4G/4G allele in the PAI-1 gene results in the presence of four instead of five consecutive guanine nucleotides in the promoter region, producing a site that is too small to permit repressor binding. Conversely, the A844G polymorphism affects a consensus sequence binding site for the regulatory protein Ets, enhancing PAI-1 gene transcription. The prevalence of the 4G/4G genotype in the general population is high, ranging from 23.5% to 32.3%.^{121,122} Moreover, most studies have not found any independent relationship between the 4G/4G polymorphism and the development of VTE in unselected patients.¹²³⁻¹²⁵ However, the 4G/4G genotype has been linked to a further increased risk for VTE when it is present in patients with PS deficiency or FVL, suggesting that it plays an additive but not independent role in the genesis of VTE.^{126,127} No relationship has been demonstrated between the A844G polymorphism and VTE.¹²³

There are limited data on the association between the 4G/4G allele and adverse pregnancy outcomes. No statistically significant association was found between isolated homozygosity for the 4G/4G mutation and recurrent spontaneous abortion in several small studies.^{128,129} However, endothelial expression of PAI-1 is induced by angiotensin II, and generation of the latter molecule is increased by a deletion (D)/insertion (I) polymorphism in the angiotensin I-converting enzyme (ACE) gene. Buchholz and associates observed a significant increase in the combination of the PAI-1 4G/4G and ACE D/D genotypes among patients with recurrent spontaneous abortion compared with controls (13.6% versus 4.7%; OR, 3.2; $P = .01$).¹²¹

Moreover, a possible association exists between the 4G/4G allele and later adverse pregnancy outcomes. Yamada and coworkers

described a modest association between 4G/4G homozygosity and the occurrence of severe preeclampsia (OR, 1.62; CI, 1.02 to 2.57).¹³⁰ Glueck and colleagues conducted a case-control study and observed that compared to patients with either the 5G/5G or the 4G/5G allele, those who were homozygous for the 4G/4G allele had greater rates of prematurity (14% versus 3%; $P = .001$), second- and third-trimester deaths (9% versus 2%; $P = .004$), and IUGR (4% versus 0.4%; $P = .012$).¹³¹ However, caution must be exercised in the interpretation of these data, because the occurrence of adverse outcomes was lower in the control group than would be expected in the general population, and 30% of patients who were homozygous for the 4G/4G mutation had coexisting thrombophilias.¹³¹ As was the case for the association between 4G/4G homozygosity and VTE, this mutation may be more likely to be linked with adverse pregnancy outcomes when it occurs simultaneously with other thrombophilic disorders or with triggers of increased PAI-1 expression such as the ACE D/D genotype and disorders linked to insulin resistance (e.g., obesity, type 2 diabetes, hyperlipidemia, polycystic ovary syndrome).

Polymorphisms have been described in the TAFI and tPA genes, but no clear link has been established for either with increased VTE risk or adverse pregnancy outcomes.

Other Thrombophilic Mutations

The -455GtoA polymorphism in the fibrinogen β gene leads to increased plasma fibrinogen levels but an unclear thrombotic risk.¹³² Both the apolipoprotein B R3500Q and E2/E3/E4 polymorphisms and the platelet receptor gene polymorphisms GpIIIa L33P and GpIa 807CtoT also offer an uncertain VTE risk, although they may contribute to coronary and cerebral artery thrombosis, particularly in the presence of other risk factors such as smoking, hypertension, obesity, and diabetes. The common hereditary hemochromatosis gene (HFE gene C282Y mutation) does not appear to be a risk factor for VTE, even when it is present in patients with FVL.¹³³ An analysis of links between fetal loss and β -fibrinogen -455GtoA, between apolipoprotein B R3500Q and E2/E3/E4, and between GpIIIa L33P and HFE C282Y found no significant associations.¹³⁴

Polymorphisms have also been described in the thrombomodulin, TFPI, and endothelial PC receptor genes, but they are of no or unknown thrombogenic potential.⁵⁸ The Val34Leu polymorphism in the factor XIII gene is associated with increased activation by thrombin and a potentially thrombotic phenotype¹³⁵ but confers uncertain risks for VTE and adverse pregnancy outcome.

Summary

A great number of potentially thrombophilic polymorphisms are being uncovered, at an ever-increasing pace. Although most of these mutations do not appear to be highly thrombogenic when present in isolation, they may exert an additive or even a synergistic effect on the thrombogenicity of other disorders. This might account for the finding of a very modest association between a given thrombophilic state (e.g., FVL, PS deficiency) and the isolated occurrence of VTE or adverse pregnancy outcomes in low-risk populations together with a far higher concordance rate within certain families.

Screening for Thrombophilias

Screening and Prevention of Venous Thromboembolism

The presence of a known thrombophilia increases the recurrence risk of VTE among pregnant women. Brill-Edwards and associates pro-

spectively evaluated 125 pregnant women with a prior VTE, 95 of whom were tested for acquired and inherited thrombophilias (including APAs, FVL, and PGM) and for PC, PS and AT deficiencies.¹³⁶ Antenatal heparin was withheld in all patients, but postpartum anticoagulation was provided. The overall antepartum recurrence rate for VTE was 2.4% (CI, 0.2% to 6.9%), but no recurrences were observed in the 44 women who had no evidence of thrombophilia and whose previous episode of thrombosis was associated with temporary risk factors that included pregnancy itself. Among the 51 women who had a thrombophilia or whose previous VTE was considered idiopathic, the antepartum recurrence rate was 5.9% (CI, 1.2% to 16.2%), and among the 25 thrombophilic patients the recurrence risk was 16% (4 patients) (OR, 6.5; CI, 0.8 to 56.3). Therefore, there appears to be evidence-based justification to test pregnant patients with a prior history of VTE associated with temporary and reversible risk factors (e.g., fractures, prolonged immobilization, cancer), because the presence of a thrombophilic state would be an indication for antepartum as well as postpartum thromboprophylaxis. Conversely, women with a prior VTE associated with a nonrecurrent risk factor who are without thrombophilia or other current major risk or susceptibility factors (e.g., need for prolonged bed rest, obesity, current superficial thrombophlebitis) may not need antepartum prophylactic heparin therapy during pregnancy.¹³⁶ However, because thrombotic events during pregnancy in such women have been reported on rare occasions,¹¹⁰ the risks and benefits of antepartum thromboprophylaxis should be discussed with the patient. Also, such patients should receive postpartum prophylaxis, because most pregnancy-associated fatal pulmonary embolisms occur in the postpartum period. In this setting, knowledge of the thrombophilic state affects management.

The 7th American College of Chest Physicians Guidelines for the Antenatal and Peripartum Management of Thrombophilia suggest that the occurrence of VTE in nonpregnant patients who are receiving estrogen-containing contraceptives is comparable with such events occurring in pregnancy. In either case they would recommend antepartum and postpartum prophylaxis in a subsequent pregnancy, regardless of thrombophilia status in women who had a VTE during a prior pregnancy or while taking estrogen-containing contraceptives.¹³⁷ Similarly, consideration should also be given to screening of pregnant women who have a strong family history (i.e., affected first-degree relative) of VTE. Given the greater than 10% risk of VTE in pregnancy among patients with such a history and a thrombophilia (see Table 40-2), thromboprophylaxis, although of unproven efficacy, is a reasonable option. Cost-effective screens should be initially limited to the most common and most thrombogenic disorders, including FVL and PGM. Negative results should lead to evaluation of fasting homocysteine levels and PC, PS, and AT deficiencies.

The dosing regimen to be employed varies with the severity of the thrombophilia, the patient's family history, and the nature of the prior VTE episodes. In general, for patients with a personal or strong family history of VTE and a lesser thrombogenic thrombophilia (e.g., FVL, PGM, hyperhomocysteinemia refractory to folate therapy, PC or PS deficiency), antepartum prophylaxis with either mini-dose unfractionated heparin or low-dose LMWH is effective in preventing DVT in pregnant patients at risk. The standard regimen of unfractionated heparin used in pregnancy consists of 5000 units administered SQ every 12 hours, increased by 2500 units in the second and third trimesters. However, Barbour and associates observed that this standard unfractionated heparin regimen was inadequate to achieve the desired anti-factor Xa therapeutic range in 5 of 9 second-trimester pregnancies and in 6 of 13 third-trimester pregnancies.¹³⁸ Therefore, assessment of anti-factor Xa levels may be important.

Alternatively, prophylaxis can employ LMWH. Regimens can include dalteparin 5000 U SQ, given every 12 hours or once a day, or enoxaparin 30 mg SQ, every 12 hours or 40 mg SQ once a day. Whereas monitoring of anti-factor Xa levels is not necessary in nonpregnant patients, given the absence of data in pregnancy, the greater variability in heparin binding, and the increased volume of distribution and/or metabolism and excretion in pregnancy, we recommend serial measurements of anti-factor Xa levels, with a goal of 0.1 to 0.2 U/mL at 4 hours after each injection.

For patients with highly thrombogenic thrombophilias (e.g., homozygotes or compound heterozygotes for FVL and PGM, patients with AT deficiency or APS with prior VTE) who have a personal or strong family history of VTE, and for patients with recurrent VTE, therapeutic (high-dose) unfractionated heparin or LMWH should be used. The goal of unfractionated heparin therapy is to obtain and maintain an activated partial thromboplastin time (aPTT) of 1.5 to 2.5 times control values or a plasma heparin concentration of 0.2 to 0.4 U/mL, or an anti-factor Xa concentration of 0.4 to 0.7 U/mL. The aPTT should not be used to guide unfractionated heparin therapy in patients with prolonged aPTT due to LAs. Therapeutic LMWH therapy consists of enoxaparin 1 mg/kg SQ twice daily or a comparable dose of dalteparin (e.g., 10,000 U SQ every 12 hours). Barbour and colleagues evaluated whether the standard therapeutic doses of dalteparin maintained peak therapeutic levels of anticoagulation during pregnancy and reported that 85% (11/13) of patients required an upward dosage adjustment.¹³⁹ Therefore, we recommend titrating either agent to maintain factor Xa levels at 0.6 to 1.0 U/mL 4 hours after injection. For patients with highly thrombogenic thrombophilias in the absence of a personal or strong family history of VTE, we recommend using an intermediate or "high prophylactic" dose of LMWH, titrating the dose to maintain factor Xa levels at 0.4 to 0.6 U/mL.

Regardless of whether the patient is receiving prophylactic, therapeutic, or high prophylactic doses of LMWH, we recommend switching to the comparable dose of unfractionated heparin at 36 weeks, to permit application of neuraxial anesthesia if desired or indicated during labor or delivery. Both heparin and LMWH are associated with an increased risk for osteopenia. Although of unproven benefit, it seems prudent to advise axial skeleton weight-bearing exercise and calcium supplementation. These medications also increase the risk for heparin-induced thrombocytopenia, which paradoxically is associated with thrombosis. With therapeutic doses of LMWH and with any dose of unfractionated heparin, platelet counts should be obtained after 3 to 4 days of therapy and intermittently for the first 3 weeks of treatment.¹⁴⁰

Postpartum thromboprophylaxis is also required. Warfarin is considered safe to take while breast feeding. Warfarin is started within 24 hours of commencing heparin therapy. Doses are determined by monitoring the international normalized ratio (INR). To avoid paradoxical thrombosis and skin necrosis from warfarin's early, predominantly anti-PC effect, it is critical to maintain these women on therapeutic doses of unfractionated heparin or LMWH for a minimum of 5 days and until the INR is in the therapeutic range (2.0 to 3.0) for 2 consecutive days.

Screening and Prevention of Adverse Pregnancy Outcomes

As can be discerned from the preceding review, there appears to be a modest and consistent association between the major inherited thrombophilias (including FVL, PGM, elevated fasting homocysteine levels and PC, PS, and AT deficiency) and fetal loss after 10 weeks, and particularly isolated losses after 22 weeks. There is also a possible associa-

tion between these thrombophilic states and abruption. However, no clear association exists between FVL or the other major thrombophilias and either preeclampsia or IUGR, although studies have been underpowered to definitely exclude a link with severe early-onset preeclampsia and/or severe (<5th percentile) IUGR.

There are few studies examining the effectiveness of anticoagulation therapy in patients harboring inherited thrombophilias who have experienced recurrent fetal loss or other adverse pregnancy outcomes. Kupferminc and associates treated pregnant thrombophilic women who had a prior history of severe preeclampsia, abruption, IUGR, or stillbirth with enoxaparin 40 mg/day and LDA, plus folate supplementation for those patients found to be homozygous for the MTHFR mutation.¹⁴¹ They reported that, compared to their prior pregnancies, patients receiving LMWH plus LDA had an increased mean gestational age at delivery (32.1 [±5.0] versus 37.6 [±2.3] weeks) and also increased birth weight of their infants (1175 [±590] versus 2719 [±526] g) ($P < .0001$ for both comparisons).

In a prospective cohort study, Folkeringa and colleagues assessed the effects of anticoagulant drugs on fetal loss in women with AT, PC, or PS deficiency.¹⁴² Of 37 women with a deficiency, 26 (70%) received thromboprophylaxis during pregnancy, with no fetal losses, compared to 45% fetal loss in deficient women not receiving thromboprophylaxis ($P = .001$). The adjusted RR of fetal loss with versus without thromboprophylaxis was 0.07 (CI, 0.001 to 0.7).

Gris and colleagues conducted a randomized trial of anticoagulation in 160 women who had had one unexplained fetal loss after 10 weeks of gestation and who were heterozygous for FVL, PGM, or PS deficiency.¹¹⁹ All patients were given 5 mg folic acid daily before conception; once pregnant, they were randomized to receive either LDA (100 mg daily) or enoxaparin (40 mg daily) beginning in the 8th week. Uncomplicated live births were noted in 28.8% of the LDA group and in 86.2% of the enoxaparin group ($P < .0001$; OR, 15.5; CI, 7 to 34). Enoxaparin proved superior to LDA among FVL patients. PZ deficiency and/or positive anti-PZ antibodies was associated with poorer outcomes. Although these results are impressive, this study has been criticized because of its lack of blinding and the high loss rate in the LDA-only group.

In summary, observational, prospective cohort, and randomized, controlled trials all suggest that LMWH with or without LDA reduces the recurrence risk of fetal loss in thrombophilic patients. Based on these findings, the following recommendations can be made:

1. Women with hyperhomocysteinemia should receive folic acid supplementation regardless of their antecedent VTE or obstetric history, given its low toxicity. For those with a history of VTE or recurrent fetal loss in whom folate does not correct the metabolic disorder, prophylactic unfractionated heparin or LMWH should be considered.
2. As noted earlier, patients in the highly thrombogenic thrombophilia group (AT deficiency, homozygous or compound heterozygous FVL or PGM), regardless of their obstetric history, should be offered “high prophylactic” doses of LMWH, with the dose titrated to maintain factor Xa levels at 0.4 to 0.6 U/mL (if there is no personal or strong family history of VTE) or to maintain therapeutic doses of LMWH (if there is such a history).
3. Pregnant women with less thrombogenic thrombophilias (e.g., heterozygous FVL or PGM, PC or PD deficiency, hyperhomocysteinemia unresponsive to folate therapy) who have no personal or strong family history of VTE but unexplained fetal loss after 9 weeks can be offered antepartum prophylaxis after full informed consent is obtained regarding the unproven efficacy of this treatment. They should receive postpartum thromboprophylaxis if they require a cesarean delivery, because most fatal acute pulmonary emboli occur during this period.
4. It is unclear whether patients with recurrent abruption in the absence of other known risk factors (e.g., smoking, renal disease, hypertension, uterine anomalies) should be offered antepartum prophylaxis.
5. At this time, there appears to be no justification for offering antepartum thromboprophylaxis to asymptomatic, otherwise low-risk women with lesser thrombophilias who have recurrent preeclampsia or IUGR. However, given the possible association between inherited thrombophilias and later adverse pregnancy outcomes, it is reasonable to consider close maternal/fetal surveillance appropriate in this population. Fetal growth may be monitored with serial ultrasound examinations (every 4 to 6 weeks) beginning at 20 weeks’ gestation. Doppler flow studies of the umbilical artery may be used as a fetal assessment tool in the setting of IUGR. Nonstress testing and biophysical profiles may be appropriate at 36 weeks or earlier, as clinically indicated. Early delivery may be indicated for deteriorating maternal or fetal condition. Surveillance can be decreased if there is no evidence of placental insufficiency.

Acquired Platelet Disorders

Idiopathic Thrombocytopenic Purpura

Also known as primary immune or autoimmune thrombocytopenic purpura, idiopathic thrombocytopenic purpura (ITP) is a syndrome of immunologically mediated thrombocytopenia that is characterized by increased platelet destruction. Immunoglobulin G (IgG) antibody binds to platelets, rendering them more susceptible to sequestration and premature destruction in the reticuloendothelial system, especially the spleen. The rate of destruction exceeds the compensatory ability of the bone marrow to produce new platelets, leading to thrombocytopenia.

In adults, ITP is usually chronic. It may coexist with pregnancy, because the disease usually manifests in the second to third decade of life and has a female preponderance of 2:1.¹⁴³ In fact, ITP is the most common autoimmune bleeding disorder encountered during pregnancy. The overall course of ITP is not consistently influenced by pregnancy (although, rarely, women experience repeated flares with each pregnancy); however, pregnancy may be adversely affected by ITP, and the primary risk is hemorrhage in the peripartum period. Because the placenta selectively transports maternal IgG antiplatelet antibodies into the fetal circulation, fetal thrombocytopenia also may occur.

DIAGNOSIS

Most women with ITP have a history of petechiae, ecchymoses, easy bruising, menorrhagia, or other bleeding manifestations. The diagnosis is primarily one of exclusion and is based on the history, physical examination, complete blood count (CBC), and examination of the peripheral blood smear.¹⁴⁴ The CBC is normal except for thrombocytopenia (platelet count <100,000/ μ L), and the smear may show an increased proportion of slightly enlarged platelets. The history and physical examination usually exclude other causes of thrombocytopenia. Rarely, a bone marrow biopsy is required to clarify the diagnosis. Typical bone marrow findings include increased numbers of immature megakaryocytes. Although the issue is controversial, many authorities

do not routinely perform this procedure in typical cases of ITP, especially in women younger than 40 years of age.¹⁴³

It can be difficult to distinguish ITP from other causes of maternal thrombocytopenia. The condition most commonly confused with ITP is incidental thrombocytopenia of pregnancy, also known as “essential” or “gestational” thrombocytopenia. Incidental thrombocytopenia of pregnancy is mild (platelets >70,000 cells/ μ L), asymptomatic, and often first noted by the clinician after a CBC obtained as part of a routine automated prenatal screening test.^{145,146} In contrast to ITP, incidental thrombocytopenia of pregnancy is common. It occurs in up to 5% of pregnant women and accounts for more than 70% of maternal thrombocytopenia.^{146,147} Individuals with incidental thrombocytopenia have no prior history of thrombocytopenia and are not at risk for bleeding complications or fetal thrombocytopenia. No special care is required for these women. Other causes of maternal thrombocytopenia that should be considered are preeclampsia, pseudothrombocytopenia due to laboratory artifact, SLE, APS, human immunodeficiency virus (HIV) or hepatitis C virus infection, drug-induced thrombocytopenia, thrombotic thrombocytopenia, immunodeficiency states, hereditary thrombocytopenias, and DIC.

Numerous direct and indirect assays of antiplatelet antibodies have been developed to confirm the diagnosis of ITP. Most patients with ITP have platelet-associated immunoglobulin, and many also have circulating unbound antiplatelet antibodies. Levels of direct (platelet-associated) IgG have a strong inverse correlation with the maternal platelet count and intravascular platelet life span.¹⁴⁸ Nonetheless, a negative result does not exclude a diagnosis of ITP.¹⁴⁹ Concentrations of indirect (circulating) antiplatelet antibodies less reliably predict maternal platelet counts. Although assays for direct and indirect antiplatelet antibodies are widely available, they are not recommended for the routine evaluation of maternal thrombocytopenia or ITP.¹⁴⁴ Assays for antiplatelet antibodies are hampered by a variety of problems, including the use of several different assays, a large degree of interlaboratory variation, and a high background rate of platelet-associated IgG. Furthermore, women with ITP cannot be distinguished from those with incidental thrombocytopenia of pregnancy on the basis of antiplatelet antibody testing.¹⁵⁰

MATERNAL CONSIDERATIONS

The goal of maternal therapy during pregnancy is to minimize the risk of hemorrhage and to restore a normal platelet count. Asymptomatic pregnant women with ITP and platelet counts greater than 50,000/ μ L do not require treatment. In nonpregnant patients, most authorities recommend treatment if the platelet count is lower than 10,000/ μ L or in the presence of bleeding, but it is controversial whether a particular platelet count (e.g., <50,000/ μ L or <30,000/ μ L) is sufficient indication for therapy during pregnancy in asymptomatic women. A reasonable approach is to aim for a platelet count greater than 30,000/ μ L throughout pregnancy and greater than 50,000/ μ L near term.

The American Society of Hematology ITP Practice Guideline Panel¹⁵¹ recommends treating pregnant women with platelet counts between 10,000 and 30,000/ μ L during the second or third trimester. More aggressive treatment is often pursued close to the estimated due date, in anticipation of potential bleeding, surgery, or need for regional anesthesia. Some anesthesiologists may require a platelet count greater than 80,000/ μ L before deeming the woman’s condition safe for placement of an epidural catheter.¹⁵²

Glucocorticoid Drugs. Glucocorticoid drugs have been the cornerstone of ITP therapy in pregnancy. Prednisone, 1 to 1.5 mg/kg/day, or the therapeutic equivalent, is the initial treatment of choice.

Improvement usually occurs within 3 to 7 days and reaches a maximum within 2 to 3 weeks. Some increase in the platelet count occurs in 50% to more than 70% of patients, depending on the duration and intensity of therapy.¹⁴⁴ Complete remission has been reported in 5% to 30% of cases.¹⁴⁴ If platelet counts become normal, the steroid dose can be tapered by 10% to 20% per week until the lowest dosage required to maintain the platelet count higher than 50,000/ μ L is reached.

It is uncertain how steroids improve platelet counts and decrease bleeding in patients with ITP. Proposed mechanisms of action¹⁵³ include increased platelet production, decreased production of antiplatelet antibodies and platelet-associated IgG, decreased clearance of antibody-coated platelets by the reticuloendothelial system, and decreased capillary fragility. Adverse effects of steroid use in pregnancy are well known and include glucose intolerance, osteoporosis, hypertension, psychosis, and moon facies. Accordingly, the dose and duration of therapy should be minimized.

Intravenous Immune Globulin. IVIG is used in cases of ITP refractory to corticosteroids as well as in urgent circumstances, such as preoperatively, in the peripartum period, or when the platelet count is less than 10,000/ μ L (or <30,000/ μ L in a bleeding patient). IVIG is a pooled concentrate of immunoglobulins collected from many donors. High doses of IVIG (1000 mg/kg/day for 2 to 5 days) usually induce a peak platelet count within 7 to 9 days. More than 80% of patients treated with this regimen will have a peak platelet count greater than 50,000/ μ L, and in 30% of patients the duration of the response lasts for more than 30 days.^{154,155} Although the mechanism of action is unclear, it seems to involve depression of antiplatelet antibody production, interference with antibody attachment to platelets, inhibition of macrophage receptor-mediated immune complex clearance, and blockage of Fc receptors in the reticuloendothelial system.¹⁵⁵⁻¹⁵⁷ In responders, only 2 or 3 days of IVIG therapy may be needed, and higher doses of 800 or 1000 mg/kg may suffice as a single or double infusion.¹⁵⁸

Although IVIG had previously been associated with occasional hepatitis C transmission, the current purification process eliminates the risk of blood-borne infections. HIV transmission has never been associated with IVIG use. Untoward effects of IVIG include headache, chills, nausea, liver dysfunction, alopecia, transient neutropenia, flushing, autoimmune hemolytic anemia, and anaphylactic reactions in patients with IgA deficiencies.¹⁵⁹ There are no known adverse fetal effects. IVIG is extremely expensive, and for that reason its use is best reserved for urgent cases and for ITP refractory to corticosteroids. Examples include a platelet count less than 5000/ μ L despite treatment with steroids for several days, active bleeding, and extensive and progressive purpura.¹⁴³

Platelet Transfusions. Platelet transfusions should be considered only as a temporary measure to control life-threatening hemorrhage or to prepare a patient for cesarean delivery or other surgery. Survival of transfused platelets is decreased in patients with ITP, because antiplatelet antibodies also bind to platelets. Therefore, the usual elevation in platelets of approximately 10,000/ μ L per unit of platelet concentrate is not achieved in patients with ITP. A transfusion of 8 to 10 packs is sufficient in most cases.

Splenectomy. Complete remission is obtained in 80% of patients with ITP who undergo splenectomy. This operation, which removes the major sites of platelet destruction and antiplatelet antibody production, is usually avoided during pregnancy because of risks to the fetus and technical difficulties with the procedure. Nonetheless, splenectomy can be safely accomplished during pregnancy if necessary, ideally in the second trimester. It also has been combined with cesarean delivery at term without reported morbidity. Splenectomy (during

pregnancy) is appropriate for women with platelet counts lower than 10,000/ μL who are bleeding and have not responded to IVIG and steroids.¹⁴⁴

Rhesus Immune Globulin. Anti-Rh(D) immune globulin has been successfully used to treat ITP in RhD-positive individuals. Indeed, immune globulin against Rh(D) (75 μg per kilogram of maternal weight) works as well as corticosteroids at initial presentation.¹⁶⁰ It is more costly than steroids but has fewer side effects. Anti-Rh(D) is not typically used during pregnancy because of a theoretic risk of fetal erythrocyte destruction, although it would most likely bind maternal red blood cells before reaching the fetal circulation. Cases of successful and safe use of anti-Rh(D) during pregnancy (in RhD-positive women) have been reported.¹⁶¹

Other drugs used to treat ITP, such as vinca alkaloids, colchicine, cyclophosphamide, and danazol, are best avoided in pregnancy because of the potential for adverse effects on the fetus. Azathioprine may be considered in refractory cases.

FETAL CONSIDERATIONS

Because the placenta is permeable to circulating maternal antiplatelet IgG, fetal thrombocytopenia may occur with maternal ITP. Occasionally, this results in minor clinical bleeding, such as purpura, ecchymoses, hematuria, or melena. In rare cases, fetal thrombocytopenia can lead to intracranial hemorrhage (ICH), resulting in severe neurologic impairment or death. Indeed, concern for ICH and its avoidance has become the central issue in the obstetric management of ITP.

Clinicians have tried a variety of strategies intended to minimize fetal bleeding problems in women with ITP. It is now clear that maternal medical therapies such as IVIG¹⁶² and steroids¹⁶²⁻¹⁶⁴ do not reliably prevent fetal thrombocytopenia. On the basis of reports of ICH associated with vaginal birth,¹⁶⁵ some clinicians recommended cesarean delivery for women with ITP.¹⁶⁶ Others have proposed that cesarean delivery be reserved for fetuses with platelet counts lower than 50,000/ μL .¹⁶⁷ This tactic was prompted by observations that hemorrhagic complications are extremely rare in infants with platelet counts greater than 50,000/ μL , and the risk of fetal bleeding is inversely proportional to the platelet count.^{163,168} With this plan, however, a method is needed to determine which fetuses are thrombocytopenic—ideally, one that is noninvasive, reproducible, and sensitive in identifying at-risk fetuses. No such test is available.

Maternal characteristics and serologic findings, including thrombocytopenia, previous splenectomy, and platelet-associated antibodies, do not correlate strongly with neonatal thrombocytopenia.^{146,169} Fetal thrombocytopenia is uncommon in the absence of circulating antiplatelet antibodies,¹⁷⁰ but exceptional cases have been reported.¹⁷¹ In addition, positive results have a low positive predictive value,¹⁷⁰ and assays for indirect antiplatelet antibodies can be difficult to perform.

Good correlation has been reported between neonatal platelet counts and the platelet count of infants born previously to a woman with ITP.¹⁶⁴ However, older siblings are not always available for comparison, and concordance among sibling platelet counts is imperfect.¹⁶⁴ Furthermore, discordant platelet counts have been detected in twin gestations complicated by ITP.^{169,172} Therefore, no historical factor or maternal blood test can accurately predict the fetal platelet count in all cases.

Some investigators have advocated the use of fetal scalp sampling during labor to directly measure the fetal platelet count.^{167,173} Vaginal delivery is permitted if the platelet count is greater than 50,000/ μL ; otherwise, the birth is by cesarean delivery. This method is attractive

because it involves negligible risk to mother and fetus and uses an assay (platelet count) that is widely available and inexpensive. Indeed, fetal scalp sampling has allowed 80% of fetuses with platelet counts greater than 50,000/ μL to safely deliver vaginally.¹⁶⁹ The major drawback is the occasional occurrence of falsely low platelet counts, resulting in unnecessary cesarean deliveries.¹⁷⁴⁻¹⁷⁶ Further, fetal scalp sampling cannot always easily be accomplished if there is limited cervical dilation or a high presenting part.

These problems can be circumvented with the use of cordocentesis to determine the fetal platelet count. This method results in accurate platelet counts and can be performed before labor.^{162,177,178} The procedure is usually deferred until fetal maturity is present. As with scalp sampling, the delivery route is based on the fetal platelet count. However, cordocentesis cannot always be accomplished in the late third trimester,^{177,178} the skills required are not available in all centers, and the procedure is expensive. Cordocentesis also may result in serious complications.¹⁷⁶ Hemorrhage at the puncture site, cord hematoma, and cord spasm with fetal bradycardia contribute to an overall associated mortality rate of 2.7%.¹⁷⁹ Procedure-related complications have been reported in about 4% to 5% of cordocenteses in patients with presumed ITP.¹⁸⁰ In several instances, fetuses with normal platelet counts were delivered by cesarean section or incurred serious morbidity. Bleeding is more likely in the presence of severe thrombocytopenia.^{181,182} The true incidence of complications may be even higher: procedure-related complications often go unreported, and reporting centers tend to have the most expertise with the procedure and are likely to have lower complication rates than other facilities.¹⁷⁹

Problems with fetal scalp sampling and cordocentesis have prompted reevaluation of the efficacy of these procedures in the management of pregnancies complicated by ITP.^{163,183,184} In addition, several reports have suggested that hemorrhagic complications in thrombocytopenic neonates are unrelated to the route of delivery.^{163,168,176,185} In a review of 474 neonates born to mothers with ITP, 29% of thrombocytopenic infants delivered vaginally suffered clinically apparent bleeding, compared with 30% of those delivered by cesarean section.¹⁶³ A careful analysis of the literature also suggests that no case of ICH has been directly attributable to intrapartum events.^{176,184}

Another important consideration is the relative infrequency of ICH in infants born to mothers with ITP. For example, in a comprehensive population-based study of almost 16,000 pregnancies complicated by ITP, there were no cases of ICH.¹⁴⁷ The only three infants with ICH had alloimmune, not autoimmune, thrombocytopenia. These observations were confirmed in retrospective analyses of ITP in pregnancy. The proportion of infants with platelet counts lower than 50,000/ μL is about 15%, and this may be an overestimate of the risk because of publication bias. Serious bleeding complications occurred in 22 of 688 neonates,¹⁸⁰ and only 6 (0.87%) had ICH. None of the cases of ICH were clearly demonstrated to be caused by intrapartum events. In one review of 288 ITP pregnancies wherein fetal platelet counts were determined at the time of delivery, there were no cases of ICH or perinatal death.¹⁶⁸

In summary, obstetric management of ITP remains controversial, but most investigators now believe that fetal scalp sampling, cordocentesis, and cesarean delivery contribute to cost and morbidity without preventing neonatal bleeding complications. Therefore, it is recommended that ITP be managed without determination of the fetal platelet count and that cesarean delivery be reserved for the usual obstetric indications.^{163,168,176,184} In contrast, others have found that the potential 1% risk of ICH warrants cesarean delivery in selected cases.^{144,186} Those clinicians who favor interventional management use fetal scalp sampling to determine the fetal platelet count in pregnancies most at risk

for thrombocytopenia (e.g., when there is a sibling with severe thrombocytopenia). The use of cordocentesis in the obstetric management of ITP is difficult to justify.

Delivery should be accomplished in a setting in which platelets, fresh-frozen plasma, and IVIG are available. A neonatologist or pediatrician familiar with the disorder should be present to promptly treat any hemorrhagic complications in the neonate. The platelet count of the affected newborn usually falls after delivery, and the lowest platelet count is not reached for several days.¹⁸⁷ Most infants are asymptomatic, and the thrombocytopenia is self-limited. Nonetheless, daily platelet counts should be obtained for several days. Although breastfeeding early in the puerperium may theoretically cause neonatal thrombocytopenia, many women with ITP have done so without clinical sequelae.

Neonatal Alloimmune Thrombocytopenia

In contrast to the minimal fetal risks in maternal ITP, fetal/neonatal alloimmune thrombocytopenia (NAIT) is a serious and potentially life-threatening condition that affects 0.2 to 1.0 of every 1000 live births in white people.¹⁸⁸⁻¹⁹⁰ Rates vary by ethnicity, and African Americans appear to be affected less frequently.¹⁹¹ The disorder occurs as the result of maternal alloimmunization against fetal platelet antigens that are lacking on the mother's own platelets; it is analogous to the hemolytic anemia caused by maternal alloimmunization against fetal erythrocyte antigens.

Several polymorphic, diallelic platelet antigen systems are responsible for NAIT. Many of these antigen systems were simultaneously identified in different parts of the world and given several names. To minimize confusion, uniform nomenclature has been adopted to describe these antigen systems as human platelet antigens (e.g., HPA-1), with alleles designated as "a" or "b."¹⁹² The most frequent cause of NAIT in whites is sensitization against HPA-1a, also known as PLAT or Zwa. The antigens HPA-1a (PLA1) and HPA-1b (PLA2) are the product of polymorphic alleles that differ by a single base-pair change in the gene encoding the platelet glycoprotein GpIIIa (integrin β_3).¹⁹³ In turn, this causes a substitution of proline for leucine in the protein, resulting in antigenically distinct conformations. Of all white people, 97% are HPA-1a positive; 69% are homozygous HPA-1a, and 28% are heterozygous.¹⁹⁴ Several other antigens, including HPA-1b, HPA-5b (Br), HPA-3b (Bak), and HPA-4b (Yuk), also may cause NAIT (Table 40-3). In Asians, sensitization against HPA-4 is the most common cause of NAIT.

Although approximately 1 in 42 pregnancies is incompatible for HPA-1a, NAIT develops in only 1 of every 20 to 40 of these cases. In some instances,¹⁹⁵ the disorder remains subclinical because the antiplatelet antibodies are not potent enough to induce thrombocytopenia in the infant.¹⁹⁶ In addition to antigen exposure, there appears to be a need for an immunologic susceptibility to HPA-1a sensitization. The human leukocyte antigen (HLA) class II determinant, Dw52a, appears to be a requirement for the development of antibodies against HPA-1a.¹⁹⁷ Associations between sensitization to other platelet antigens and HLA phenotypes are less well characterized, although DR6 has been linked to anti-HPA-5.¹⁹⁸ In contrast to rhesus isoimmunization, NAIT can occur during a first pregnancy without prior exposure to the offending antigen. The diagnosis is usually made after birth in an infant with unexplained severe thrombocytopenia, often associated with ecchymoses or petechiae.^{188,199} The most serious bleeding complication is ICH, which occurs in 10% to 20% of infants with NAIT.^{199,200} Fetal ICH due to NAIT can occur in utero,²⁰¹ and 25% to 50% of cases of ICH are detected by sonography before delivery.²⁰¹ Characteristic sonographic findings include evidence of intracranial hematoma or

hemorrhage and porencephalic cysts. Obstructive hydrocephalus also may be present. As with red cell alloimmunization, the condition tends to worsen throughout pregnancy, as well as in subsequent pregnancies.^{200,202,203} NAIT should be suspected in cases of otherwise unexplained fetal or neonatal thrombocytopenia, in utero or ex utero ICH, or porencephaly. Serologic evaluation should be performed in an experienced laboratory with special interest and expertise in NAIT.

In most cases, the diagnosis of NAIT can be determined by testing the parents; testing of fetal or neonatal blood is confirmatory and occasionally helpful. Appropriate assays include serologic confirmation of maternal antiplatelet antibodies that are specific for paternal or fetal/neonatal platelets. In addition, individuals should undergo platelet typing with zygosity testing. This can be determined serologically or with DNA-based tests, because the genes and polymorphisms for HPAs recognized to cause NAIT are well characterized. This is particularly useful for obstetric management, because fetal HPA typing can be accomplished with amniocytes.²⁰⁴ Chorionic villus sampling should be avoided, because it may exacerbate the alloimmune reaction.

Occasionally, results are ambiguous, and in some cases, an antigen incompatibility cannot be identified. The management of such difficult cases is best individualized and underscores the need for consultation with physicians and laboratories familiar with the disorder.

The natural history of NAIT is difficult to ascertain, because it is usually unrecognized during first affected pregnancies, and subsequent pregnancies are influenced by therapeutic interventions. Nonetheless, several observations can be made from a large cohort of 107 fetuses with NAIT (97 with HPA-la incompatibility) who were followed with serial cordocenteses to determine the fetal platelet count:²⁰⁵

1. The recurrence risk of NAIT is extremely high and is 100% if the fetus has the HPA-la antigen in sensitized HPA-la-negative mothers.
2. Fetal thrombocytopenia caused by HPA-la sensitization is often severe and can occur early in gestation. Of the patients studied, 50% had initial platelet counts of less than 20,000/ μ L. This included 21 (46%) of 46 fetuses tested before 24 weeks' gestation.
3. A history of a sibling with antepartum ICH is a risk factor for the development of severe thrombocytopenia. However, neither a sibling platelet count nor a sibling with ICH recognized after delivery reliably predicts the initial fetal platelet count.
4. Thrombocytopenia uniformly worsens in untreated fetuses. Seven fetuses in this cohort had initial platelet counts higher than 80,000/ μ L and were not treated. All demonstrated rapid and substantial decreases in their platelet counts.

NAIT associated with antigens other than HPA-la is less well studied. In the large series reported by Bussel and colleagues, thrombocytopenia associated with anti-HPA-la was more severe than NAIT caused by other antigen incompatibilities.²⁰⁵ Therefore, data regarding HPA-la incompatibility cannot be generalized to other causes of NAIT.

The explicit goal of the obstetric management of pregnancies at risk for NAIT is to prevent ICH and its associated complications. As with ITP, antepartum management is controversial and few randomized data are available to guide therapy. In contrast to ITP, however, the dramatically higher frequency of ICH associated with NAIT justifies more aggressive interventions. Also, therapy must be initiated antenatally because of the risk of in utero ICH. If the diagnosis is uncertain, the risk of NAIT should be confirmed by documentation of platelet incompatibility or maternal antiplatelet antibodies specific for paternal or fetal platelets. It is unnecessary to repeat testing in a family with a case of previously confirmed NAIT. Antibody titers are poorly predictive of risk to the current pregnancy and need not be obtained once the diagnosis is secure. If the father is heterozygous for the offending antigen, fetal genotyping should be accomplished with amniocytes. This strategy can prevent additional expensive and risky interventions in approximately 50% of cases.

If the fetus is considered to be at risk, most investigators recommend cordocentesis to determine the fetal platelet count. This strategy avoids treatment of fetuses with normal platelet counts and provides feedback about treatment response in cases of thrombocytopenia. The drawback is the modest but clinically important risk of fetal hemorrhage after cordocentesis in the setting of severe NAIT.^{182,191} Because of this risk, a case could be made to initiate therapy without knowledge of the fetal platelet count. It is controversial whether the benefits of fetal blood sampling outweigh the risks in most cases. Many clinicians now transfuse between 5 and 15 mL of packed, washed, and irradiated maternal platelets (obtained by plateletpheresis) at the time of cordo-

centesis.¹⁸² Although the efficacy of this approach is unproved, it may decrease the risk of bleeding complications at the time of the procedure. It is important to distinguish this use of platelets from platelet transfusions intended as primary therapy (see later discussion).

The optimal timing of the initial cordocentesis is controversial. ICH can occur early in gestation,²⁰⁶ prompting some authorities to recommend fetal blood sampling as soon as the procedure is technically feasible (18 to 20 weeks). Such cases are rare, however, and the consequences of bleeding complications from cordocentesis are potentially more grave at preivable gestational ages. Fetal blood sampling can probably be safely delayed until 24 to 26 weeks in most cases. Further studies should resolve some of these issues. Meanwhile, it seems prudent to individualize the management of each case, depending on the pertinent antigen and the severity of NAIT during previously affected pregnancies.

Proposed therapies to increase the fetal platelet count and prevent ICH include maternal treatment with steroids and IVIG,^{189,207-210} fetal treatment with IVIG,²¹¹⁻²¹³ and fetal platelet transfusions.²⁰³ However, no therapy is effective in all cases.

The administration of IVIG directly to the fetus has not consistently raised fetal platelet counts²¹⁶; however, because only a small number of patients have been treated, lack of efficacy has not been proved. Platelet transfusions are effective,²¹⁷ but the short half-life of transfused platelets necessitates weekly procedures. The potential risks involved with multiple transfusions and the potential for increased sensitization^{191,217,218} limit the attractiveness of this treatment. Platelet transfusions are perhaps best reserved for severe cases refractory to other therapies.

Administration of IVIG to the mother appears to be the most consistently effective antenatal therapy for NAIT. Bussel and colleagues demonstrated that weekly infusions of 1 g/kg maternal weight of IVIG often stabilize or increase the fetal platelet count.^{189,207,209} In a study of 55 women with NAIT and thrombocytopenic fetuses, between 62% and 85% of fetuses responded to IVIG therapy, depending on how "response" was defined.²⁰⁷ No fetus suffered ICH. In fact, ICH is extremely rare in pregnancies treated with IVIG, occurring in only 1 of more than 100 cases managed by Bussel and his collaborators.²⁰² The mechanism of action is uncertain but may be related to placental Fc receptor blockade preventing active transport of antiplatelet antibodies across the placenta.²¹⁹

Bussel and coworkers²⁰⁷ also showed that low-dose dexamethasone therapy does not improve fetal platelet counts beyond the effect achieved with IVIG. Fetal platelet counts increased to a similar degree in NAIT patients randomized to treatment with either IVIG alone or IVIG plus 1.5 mg/day of dexamethasone.²⁰⁷ In contrast, 5 of 10 patients with no response to IVIG had increased fetal platelet counts after the addition of 60 mg/day of prednisone.²⁰⁷ They also noted that fewer than half of fetuses with platelet counts lower than 20,000/ μ L responded to the initial dose of IVIG.

This led to a subsequent parallel set of randomized trials, in which patients were stratified by level of risk for severe thrombocytopenia and ICH. The first trial, conducted in 40 women with either a prior infant with ex utero ICH or a current fetus with a platelet count of less than 20,000/ μ L, randomized treatment IVIG 1 g/kg/wk plus prednisone 1 mg/kg/day versus IVIG 1 mg/kg/wk alone, after a cordocentesis at 20 weeks.²²⁰ IVIG and steroids increased the mean platelet count over 3 to 8 weeks by 67,100/ μ L, compared with 17,300/ μ L for IVIG alone ($P < .001$). Moreover, the difference in treatment was more profound in the subgroup of cases with initial fetal platelet counts lower than 10,000/ μ L. In these cases, IVIG and prednisone increased the platelet count in 82% of cases, compared with 18% for IVIG alone.²⁰⁰

Thirty-nine women at lower risk for fetal ICH (i.e., no prior infant with ICH and current fetal platelet count $>20,000/\mu\text{L}$) were randomized to treatment with IVIG (1 g/kg/wk) or lower-dose prednisone (0.5 mg/kg/day). There was no significant difference in fetal response to these two regimens.²⁰⁰ The same group also treated 15 women who had prior infants with in utero ICH with IVIG, 1 or 2 g/kg/wk, beginning at 12 weeks' gestation. Therapy was intensified (increased IVIG and/or adding steroids) if there was severe thrombocytopenia at 20 weeks. All fetuses responded adequately to intensified therapy, except one that had in utero ICH at 19 weeks' gestation.¹⁸⁹

Berkowitz, Bussel, and colleagues reported further results of a recent randomized clinical trial comparing outcome in "standard risk (no prior infant with ICH)" pregnancies for NAIT treated with IVIG 2 g/kg/wk versus IVIG 1 g/kg/wk plus 0.5 mg/kg/day of prednisone.²⁰⁰ Outcomes were similar and excellent in both groups, with no cases of ICH. Empiric therapy was started at 20 weeks' gestation, and cordocentesis was done once at 32 weeks. Salvage therapy (either adding steroids or increasing the dose of IVIG) was done if the platelet count was lower than $50,000/\mu\text{L}$.²⁰⁰

Most authorities recommend cesarean delivery for fetuses with platelet counts of less than $50,000/\mu\text{L}$.¹⁹¹ As discussed in the section on ITP, vaginal delivery has never been shown to cause ICH, and cesarean delivery has never prevented it. Furthermore, the use of $50,000/\mu\text{L}$ as a cutoff is entirely arbitrary. Nonetheless, the substantial rate of ICH probably justifies cesarean delivery in pregnancies with severe NAIT.

In summary, according to the available current data, it seems appropriate to stratify treatment based on the level of risk for NAIT. In families with prior in utero ICH, empiric treatment early in pregnancy is advised. In women who previously delivered infants with ex utero ICH, or who currently have a fetus with a platelet count lower than $20,000/\mu\text{L}$, appropriate treatment is IVIG and glucocorticoids. However, lower doses of IVIG (or glucocorticoids) may be used in lower-risk cases. It is controversial whether the information obtained from assessment of fetal platelet count by cordocentesis justifies the risk of that procedure.^{191,220,221} There appears to be value in adjusting the initial treatment based on fetal platelet count—increasing the dose of IVIG or adding glucocorticoids, or both—in cases of treatment failure.^{191,207,220} Therefore, we consider assessment of the fetal platelet count between 24 and 32 weeks' gestation in fetuses at risk based on genotyping or paternal testing. The procedure can usually be safely delayed until the fetus reaches viability. Cordocentesis may be especially helpful in cases that are not caused by HPA-1a, because the recurrence risk is less and the clinical course less predictable. The fetal platelet count may be again determined at term to guide the route of delivery, as outlined, if vaginal birth is desired. Alternatively, a platelet count of greater than $100,000/\mu\text{L}$ at 32 weeks can be used as a threshold to allow vaginal delivery at term.²⁰⁰ This strategy usually limits the number of cordocenteses to no more than two or three per pregnancy. Empiric treatment without cordocentesis also is a reasonable option, and care should be individualized after appropriate counseling regarding pros and cons of cordocentesis.

There are no data to support population-wide screening for potential HPA incompatibility.¹⁹¹ Studies are ongoing to address the efficacy and cost-effectiveness of such programs. Another clinical dilemma is the patient whose sister has had a pregnancy with NAIT. It may be worthwhile to assess platelet antigen incompatibility, HLA phenotype, and (in cases at risk based on these tests) fetal platelet count in such patients. However, we have not found such testing to be useful. Instead, we reassure such women that their prospective risk of NAIT is low and that we are unsure about the clinical relevance of such testing.

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

Thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) are thrombotic microangiopathies that are characterized by thrombocytopenia, hemolytic anemia, and multisystem organ failure. They are rare entities, but they may occur during pregnancy, are life-threatening, and can be difficult to distinguish from the HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*). The incidence is estimated to be 1:25,000 births.²²² Early diagnosis and treatment are critical, because mortality may be reduced by 90%.²²³

TTP is characterized by central nervous system (CNS) abnormalities, severe thrombocytopenia, and intravascular hemolytic anemia. The most common CNS abnormalities are headache, altered consciousness, seizures, and sensory-motor deficits. Renal dysfunction and fever also may occur. Individuals with HUS have renal involvement as the major finding, as well as thrombocytopenia and hemolytic anemia. The conditions are difficult to distinguish from each other, because up to 50% of patients with HUS have CNS abnormalities, and renal dysfunction may occur in up to 80% of those with TTP. For this reason, the two disorders are often considered as a single entity.^{224,225}

The pathophysiology of both conditions is abnormal and profound intravascular platelet aggregation leading to multiorgan ischemia. In HUS, this occurs predominantly in the kidney. The inciting event in TTP is uncertain. One possibility is an abnormal immune response, because the condition is associated with several autoimmune disorders. It is more common in women, consistent with many other autoimmune conditions. Other possibilities are medications such as chemotherapy agents, viral infection, and perhaps pregnancy itself, although many individuals have no risk factors. Larger than average vWF multimers appear to contribute to the pathophysiology, promoting abnormal platelet aggregation.²²⁶ A plasma enzyme termed ADAMTS13 cleaves these vWF multimers, thereby preventing the formation of platelet clumps. ADAMTS13 activity may be absent in patients with TTP, making it a risk factor for the condition.²²⁷ Deficiency in ADAMTS13 may be congenital,²²⁸ or it may be acquired through the development of autoantibodies.²²⁹ HUS is most often seen in children after a diarrheal illness caused by *Escherichia coli*. Hemolysis from Shiga toxin–negative *E. coli* O26 attaches to receptors in renal epithelium, leading to endothelial injury, platelet activation/aggregation, and ischemia.²³⁰ In adults, HUS is often precipitated by pregnancy, chemotherapy, or bone marrow transplantation. The recurrence risk is higher in adults and in patients who do not have infectious diarrhea as an inciting event.

The diagnosis of these conditions is clinical, because there is no laboratory "gold standard." CBC and peripheral blood smear confirms thrombocytopenia and microangiopathic hemolytic anemia (schistocytes, helmet cells, and burr cells). Lactate dehydrogenase and bilirubin are elevated, indicating hemolysis. Serum creatinine and blood urea nitrogen may be elevated, especially in HUS. Clotting studies are typically normal early in the disease process. However, secondary DIC may occur after tissue necrosis. Large multimers of vWF may be present in cases of TTP, and renal biopsy may show microvascular occlusions and intraglomerular platelet aggregates in HUS. ADAMTS13 activity may be decreased in both TTP and HUS.²²⁷ However, in many centers, results may not be available in a timely fashion.²³¹ Both disorders are hard to distinguish from preeclampsia.^{231,232} Potential clinical signs and laboratory tests to differentiate these conditions are shown in Table 40-4.²³³ The distinction between preeclampsia and TTP or HUS is

ADAMTS13, von Willebrand factor–cleaving protease; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; Cr, creatinine; HELLP, hemolysis, elevated liver enzymes, and low platelets; HUS, hemolytic uremic syndrome; LDH, lactate dehydrogenase; PT, prothrombin time; PTT, partial thromboplastin time; TTP, thrombotic thrombocytopenic purpura; vWF, von Willebrand factor.

Modified from Esplin MS, Branch DW: Diagnosis and management of thrombotic microangiopathies during pregnancy. *Clin Obstet Gynecol* 42:360, 1999.

critical, because the former will improve with delivery, but TTP and HUS require additional therapy.

Plasmapheresis has been reported to substantially increase the survival rate with TTP to about 80%.^{234,235} Efficacy is less certain for HUS, but good outcomes have been reported.^{233,235} The mechanism of action is unclear but may involve removal of platelet-aggregating agents, such as large vWF multimers, or autoantibodies against ADAMTS13. Additional treatment includes infusion of platelet-poor or cryoprecipitate-poor fresh-frozen plasma (30 mL/kg/day), which may replace ADAMTS13, thus reducing vWF multimer size and reducing platelet aggregation. Platelet transfusions should be avoided, because it may precipitate the disease.²²³ However, red blood cell transfusion is often necessary. Glucocorticoids or other immunosuppressive therapy may be useful (potentially to reduce antibodies to ADAMTS13) and is recommended for patients who do not respond immediately to plasma exchange.²²⁷ Efficacy is uncertain. Treatment should continue for several days after recovery. Refractory cases may benefit from cytotoxic immunosuppressive agents. These therapies are generally accepted for TTP. Therapy is similar for HUS, although efficacy is less certain. Individuals with HUS often require dialysis as well.

About 10% to 25% of TTP cases occur during pregnancy or the postpartum period. Indeed, pregnancy is considered to be a risk factor for TTP and HUS, perhaps because of physiologic reduction in ADAMTS13 levels, general hypercoagulability, and synergistic features with preeclampsia.^{236,237} HUS is more likely to occur in the peripartum

or postpartum period. If TTP or HUS manifests during pregnancy, there is a risk of up to 33% for fetal mortality.^{238,239} Fetal death is caused by previsible delivery, severe maternal illness, and placental insufficiency. If TTP or HUS occurs early in gestation, aggressive treatment with plasma infusions, plasmapheresis, and steroids should be initiated. Delivery of the fetus should be considered in refractory cases, because improvement has been reported in sporadic cases.²³³ At later gestational ages, delivery becomes a more attractive option. It is important to consider TTP and HUS in cases of apparent preeclampsia or HELLP syndrome that do not improve without 48 to 72 hours after delivery.

It also is important to counsel women about the recurrence risk for these conditions. In a small series of women with TTP or HUS in pregnancy, half had a least one recurrence.²²² Long-term morbidity and mortality were substantial. However, good outcomes have been reported in subsequent pregnancies in women with prior TTP or HUS associated with pregnancy.^{240,241} Serial and prophylactic plasma exchange may be useful in women with prior TTP or HUS and persistently severely reduced ADAMTS13 activity.²⁴¹

Drug-Induced Thrombocytopenia and Functional Platelet Defects

Some drugs, such as heparin and quinidine, can cause thrombocytopenia. Functional platelet defects occur when there are normal numbers of platelets that do not function properly. Drugs are a common cause of this condition. Examples include aspirin, NSAIDs, antimicrobial agents such as carbenicillin, and glyceryl guaiacolate, which is present in some cold remedies.

Congenital Platelet Disorders

Von Willebrand Disease

vWD occurs in 1.3% of individuals, making it the most common inherited bleeding disorder.^{242,243} The condition is caused by abnormal platelet adhesion resulting from deficiencies or abnormalities in vWF. There are three types. Type I, the most common variety, accounts for 80% of cases; it is usually inherited in an autosomal dominant fashion and is characterized by deficiencies in structurally normal factor VIII and vWF. In type I vWD, platelets fail to aggregate in the presence of ristocetin. Type II vWD is less common and may be transmitted in an autosomal recessive fashion. There are several subtypes of type II vWD, which is notable for vWF that does not function normally. Type IIA involves a deficiency of normal high-molecular-weight multimers of vWF, with consequent decreased affinity for platelets. Type IIB is characterized by vWF with an increased affinity for platelets due to an increased affinity for GpIb. The clinical disorder is similar to that caused by pseudo-vWD, which results from defective GpIb and also leads to hyperactive platelet binding to vWF. Type IIM is notable for morphologically and qualitatively abnormal vWF with reduced interaction with GpIb. Type IIN is caused by vWF with impaired binding to factor VIII. Type III also is an autosomal recessive trait and is the least common of the three types. Individuals with type III vWD have severe deficiencies of vWF/factor VIII. vWD and its subtypes may be diagnosed with a variety of laboratory studies, as summarized in Table 40-5.^{244,245}

A primary treatment for many women with vWD is desmopressin (DDAVP), which increases plasma factor VIII and vWF levels (Table 40-6).^{246,247} Response to DDAVP is highly variable among women with vWD, although most of those with type I disease have a favorable

TABLE 40-5 CONGENITAL BLEEDING AND PLATELET DISORDERS

Disorders	Definition	Diagnostic Assays
Hemophilia A		
Severe	Factor VIII <2%	Prolonged aPTT, low factor VIII
Mild	Factor VIII 2-25%	Prolonged aPTT, low factor VIII
Carrier	Factor VIII ≈50%	aPTT usually normal, low factor VIII
Hemophilia B		
Severe	Factor IX <2%	Prolonged aPTT, low factor IX
Mild	Factor IX 2-25%	Prolonged aPTT, low factor IX
Carrier	Factor IX ≈50%	aPTT usually normal, low factor IX
Factor VII deficiency	Low factor VII	Prolonged INR, low factor VII
Factor X deficiency	Low factor X	Prolonged aPTT, prolonged INR, low factor X
Factor XI deficiency	Low factor XI	Prolonged aPTT, low factor XII
Factor XII deficiency	Low factor XII	Prolonged aPTT, low factor XII
Factor XIII deficiency	Low factor XIII	Normal aPTT and INR, low factor XIII
Hypofibrinogenemia	Low fibrinogen	Low fibrinogen
vWD Types I and III	Deficient (type I) or absent (type III) vWF	Absent vWF:RCoF and RIPA; platelets aggregate with bovine plasma
Type IIA	Qualitatively abnormal vWF: lack of HMW multimers	Multimeric analysis
Type IIB	Qualitatively abnormal vWF; spontaneously binds platelets; lack of HMW multimers	Platelets aggregate to 0.5 mg/mL of ristocetin; multimeric analysis ↓ platelets
Pseudo-vWD	Platelets spontaneously bind GpIb-IX-V complex	Absent vWF:RCoF activity; differentiated from vWD by no clumping to bovine plasma
Bernard-Soulier syndrome	Platelet GpIb is defective	Absent vWF:RCoF activity; differentiated from vWD by no clumping to bovine plasma
Secretion defects	Arachidonic acid and prostaglandin pathway abnormalities	Aspirin/NSAIDs are common causes; abnormal response to collagen, arachidonic acid; normal primary wave only
Storage pool deficiencies	Abnormal function or component deficiency of platelet granules (α, δ, or both)	Primary wave only; decreased collagen assay; variable arachidonic acid assay; mepacrine labeling
Glanzmann thrombasthenia	GpIIb-IIIa is absent, present in minimal amounts, or qualitatively abnormal	Platelets not activated by ADP, collagen, or arachidonic acid

ADP, adenosine diphosphate; aPTT, activated partial thromboplastin time; Gp glycoprotein; HMW, high molecular weight; INR, international normalized ratio; NSAIDs, nonsteroidal anti-inflammatory drugs; RCoF, ristocetin cofactor; RIPA, ristocetin-induced platelet agglutination; vWD, von Willebrand disease; vWF, von Willebrand factor.

response. Some women with type IIA vWD also respond well to DDAVP. However, the drug should be avoided in women with type IIB disease, because it may cause thrombocytopenia.²⁴⁸ Patients with type III disease rarely respond. Ideally, an individual's response to DDAVP should be tested under nonurgent circumstances. A typical dose is 0.3 µg/kg to a maximum of 20 µg SQ or diluted in 50 to 100 mL of normal saline and given intravenously over 30 minutes. If the patient is not pregnant, the drug may be administered on day 1 of menses. A subjective decrease in flow is considered a positive response. If the patient is pregnant or not bleeding, the response is gauged by assessing a change in platelet count and vWF:ristocetin cofactor (RCoF) peak activity at 90 minutes after the administration of DDAVP. Adverse effects of DDAVP include headache, flushing, changes in blood pressure, fluid retention, and hyponatremia. The drug is pregnancy category B.

Replacement of clotting factors is the other standard treatment for vWD. In cases with factor VIII:c or vWF levels less than 50 IU/dL, prophylactic treatment should be given to cover invasive procedures and delivery.²⁴⁷ Patients with low vWF levels and either known positive responses to DDAVP or type I disease should be given prophylactic treatment with a single dose of DDAVP, either 60 minutes before anticipated delivery or at the time of cord clamping.²⁴⁷ Additional doses are of uncertain benefit and may be harmful. Special attention must be given to the possibility of fluid retention and hyponatremia

when using DDAVP near the time of childbirth.²⁴³ Women who do not respond to DDAVP may be treated with factor VIII/vWF plasma concentrate in the form of plasma, cryoprecipitate, Humate-P, and Koate. These products are typically labeled with vWF:Ac concentrations indicating functional activity: 1 IU/kg of vWF:Ac increases the plasma level by 2.0 U/dL. Ideally, vWF:Ac levels should be 50% of normal (50 IU/dL) in prophylactic settings; 100% of normal is the goal in cases of bleeding or surgery. This level should be maintained for at least 3 days after vaginal delivery or 5 days after cesarean delivery.²⁴⁷ Tranexamic acid also may be useful in controlling or preventing postpartum hemorrhage.²⁴⁷

Pregnancy is not contraindicated in women with vWD, but they should be informed of the potential for bleeding.^{243,244} A recent large epidemiologic study estimated the OR of postpartum hemorrhage for women with vWD to be 1.5 (CI, 1.1 to 2.0).²⁴⁹ The OR for needing a blood transfusion was 4.7 (CI, 3.2 to 7.0), and 5 of 4067 women died (a rate 10-fold higher than in the general population).²⁴⁹ The antepartum period is an ideal time to characterize the type of vWD and the response to DDAVP. If possible, a multidisciplinary team including a hematologist, obstetrician, and anesthesiologist should coordinate care and a management plan.²⁴⁷ Prenatal diagnosis is possible in many cases, and genetic counseling should be offered to affected families (Table 40-7). This is especially pertinent for patients who are at risk of having a fetus with severe type III disease. At times, genetic testing of amnio-

TABLE 40-6 TREATMENT OF CONGENITAL BLEEDING AND PLATELET DISORDERS

Disorder	Threshold for Treatment	Treatment
Hemophilia A	Bleeding; before delivery/procedures if factor VIII level <50 IU/dL	Factor VIII concentrate, cryoprecipitate, DDAVP
Hemophilia B	Bleeding; before delivery/procedures if factor IX level <50 IU/dL	Factor IX concentrate, cryoprecipitate
Factor VII deficiency	Bleeding; before delivery/procedures if factor VII level <50 IU/dL	rFVIIa, factor VII concentrate
Factor X deficiency	Bleeding; possibly before delivery/procedures	Factor IX concentrate, FFP
Factor XI deficiency	Bleeding; before delivery/procedures if factor XI level <15 IU/dL	Factor XI concentrate, FFP (do not exceed peak factor XI levels of 70 IU/dL)
Factor XII deficiency	?	?
Factor XIII deficiency	Bleeding; pregnancy	Factor XIII concentrate, FFP, cryoprecipitate (keep XIIIa antigen or activity >10% of normal)
Hypofibrinogenemia	Bleeding; fibrinogen <150 mg/dL; pregnancy	FFP, cryoprecipitate (keep fibrinogen >100 mg/dL)
vWD		
Type I	Bleeding	DDAVP (if favorable response), tranexamic acid, FFP, cryoprecipitate, Humate-P, Koate (goals are >50 IU/dL of vWF:Ac)
Type IIA	Bleeding; operative delivery; procedures	DDAVP (if favorable response), tranexamic acid, FFP, cryoprecipitate, Humate-P, Koate (goal is >50 IU/dL of vWF:Ac)
Type IIB	Bleeding; operative delivery; procedures	FFP, cryoprecipitate, Humate-P, Koate (goal is >50 IU/dL of vWF:Ac); DDAVP is contraindicated
Type IIN	Bleeding; operative delivery; procedures	FFP, cryoprecipitate, Humate-P, Koate (goal is >50 IU/dL of vWF:Ac)
Type IIM	Bleeding; operative delivery; procedures	FFP, cryoprecipitate, Humate-P, Koate (goal is >50 IU/dL of vWF:Ac)
Type III	Bleeding; all deliveries; procedures	FFP, cryoprecipitate, Humate-P, Koate (goal is >50 IU/dL of vWF:Ac); DDAVP is not effective
Bernard-Soulier syndrome	Bleeding (prophylaxis for delivery is controversial)	Platelet transfusion (possibly DDAVP, tranexamic acid, immune suppression, rFVIIa)
Storage pool deficiencies	Bleeding (prophylaxis for delivery is controversial)	Platelet transfusion; ? DDAVP
Glanzmann thrombasthenia	Bleeding; delivery; procedures	Platelet transfusion, rFVIIa

DDAVP, desmopressin; FFP, fresh-frozen plasma; rFVIIa, recombinant activated factor VII; vWD, von Willebrand disease; vWF, von Willebrand factor.

cytes or chorionic villi is possible in cases of known mutations or restriction fragment length polymorphisms.^{250,251} Also, cordocentesis to perform functional assays on fetal blood may be diagnostic, although results can be unreliable due to variable penetrance, and the risk of bleeding at cordocentesis is increased in affected cases.^{252,253} It may be helpful to assess levels of vWF antigen (vWF:Ag), vWF:Ac, and factor VIII:c on a serial basis (e.g., on the initial visit, at 28 and 34 weeks' gestation, and before invasive procedures and delivery).²⁴⁷ VIII/vWF concentrates, DDAVP, skilled anesthesia personnel, and hematology consultation should be available at delivery.

Neuraxial anesthesia is considered to be contraindicated in most women with vWD, but safe use of regional anesthesia has been reported in a few women with mild type I disease.^{254,255} Regional anesthesia is thought to be safe if factor VIII and vWF:RCof levels are greater than 50 IU/dL, although this is unproven.^{243,247} Cesarean delivery has been advised by some authorities in an attempt to avoid fetal bleeding.²⁵⁶ However, the procedure is of unproven efficacy and bleeding has been reported in affected infants born by cesarean.²⁵⁶ Given the unproven efficacy and the risk of maternal hemorrhage, elective cesarean delivery is not routinely advised in cases of vWD.^{244,247} However, traumatic delivery, such as vacuum or rotational forceps, should be avoided. Neonates born to mothers with vWD should be tested to determine their vWF status. There is an increased risk of hemorrhage after delivery, even several weeks later. Frequent patient contact, monitoring of

vFW levels, and prolonged prophylaxis may reduce this risk, but this also is unproven.²⁴³

Bernard-Soulier Syndrome

Bernard-Soulier syndrome is usually transmitted in an autosomal recessive fashion; therefore, a family history is rare, although a variant appears to be autosomal dominant. Affected individuals have mucocutaneous bleeding due to a defect or deficiency in the platelet glycoproteins (GpIb-IX-V) that form a transmembrane complex that binds vWF.²⁵⁷ The result is platelets that cannot bind to subendothelial surface. Laboratory diagnosis includes a decreased number of relatively large platelets, absent ristocetin response, a failure of platelets to aggregate in response to bovine plasma, and decreased platelet GpIb-IX-V complex density as measured by flow cytometry.²⁵⁸ Successful treatment requires platelet transfusion.

Prenatal diagnosis is possible in many cases and should be offered to families with a prior affected child. Because of previous platelet transfusions, affected mothers often are at risk for NAIT. Cesarean delivery is controversial and should be reserved for obstetric indications.^{244,259} Regional anesthesia is considered to be contraindicated. Prophylactic platelet transfusion before delivery in this setting is also controversial because of the risk of alloimmune thrombocytopenia. This risk must be weighed against frequent hemorrhagic complications related to delivery, especially postpartum complications.²⁵⁹ The use of

TABLE 40-7 PRENATAL DIAGNOSIS OF CONGENITAL BLEEDING AND PLATELET DISORDERS*

Disorder	Tissue Required	Tests	Comment
Hemophilia A	Amniocytes, fetal blood	Fetal gender; factor VIII mutation analysis, linkage analysis (if family mutation is known); cord blood factor VIII levels	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
Hemophilia B	Amniocytes, fetal blood	Fetal gender; factor IX mutation analysis, linkage analysis (if family mutation is known); cord blood factor IX levels	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
Factor VII deficiency	Amniocytes, fetal blood	Factor VII mutation analysis, linkage analysis (if family mutation is known); cord blood factor VII levels	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
Factor X deficiency	Amniocytes, fetal blood	Factor X mutation analysis, linkage analysis (if family mutation is known); cord blood factor X levels	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
vWD (types I and III)	Amniocytes or fetal blood	Mutation analysis, linkage analysis if family mutation known; vWF:RCoF	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
vWD (type II)	Amniocytes or fetal blood	Mutation analysis, linkage analysis if family mutation known; vWF:RCoF	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
Bernard-Soulier syndrome	Amniocytes or fetal blood	Mutation analysis, linkage analysis if family mutation known; vWF:RCoF; bovine plasma	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic. Cordocentesis is extremely hazardous if fetus is positive for the mutation.
Glanzmann thrombasthenia	Amniocytes or fetal blood	Mutation analysis, linkage analysis if family mutation known; functional assays; anti-GpIIb-IIIa antibody binding	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic. Cordocentesis is extremely hazardous if fetus is positive for the mutation.
Gray platelet syndrome	Fetal blood	Microscopic analysis	Normal fetal platelets have α -granules.
Wiscott-Aldrich syndrome	Amniocytes or fetal blood	Mutation analysis, linkage analysis if family mutation known; platelet size/volume	Because of the risk of bleeding, cordocentesis is reserved for cases in which genetic testing is nondiagnostic.
Chediak-Higashi syndrome	Fetal blood	Peroxidase stain of neutrophils	Proven successful in feline model.
Hermansky-Pudlak syndrome	Amniocytes	Mutation analysis, linkage analysis if family mutation known	—

*Genes and some mutations have been identified for deficiencies of factors X, XI, XII, XIII, and fibrinogen. Therefore, prenatal diagnosis using amniocytes may be possible. Cordocentesis also may be informative through the direct measurement of factor levels. Gp, glycoprotein; RCoF, ristocetin cofactor; vWD, von Willebrand disease; vWF, von Willebrand factor.

HLA and platelet antigen–matched platelets may reduce this risk. Several other strategies may reduce the risk of bleeding, or may be used to treat bleeding after delivery, in women with Bernard-Soulier syndrome. These include DDAVP, antifibrinolytic therapy with tranexamic acid, immune suppression to prolong platelet survival, and recombinant activated factor VII (rFVIIa).²⁵⁹⁻²⁶² The optimal dose of rFVIIa is uncertain, but a dose of 90 to 120 $\mu\text{g}/\text{kg}$ body weight, repeated every 2 hours (if there is a good response), has been recommended.²⁵⁹

Disorders of Platelet Secretion

Disorders of platelet secretion include several rare conditions characterized by platelet storage pool deficiencies. These disorders involve deficient or abnormal platelet granules or their contents.

GRAY PLATELET SYNDROME

Gray platelet syndrome is caused by a deficiency of α -granules in platelets and megakaryocytes. Platelet α -granules contain vWF, platelet factor 4, and platelet-derived growth factor. Characteristic gray-appearing platelets are noted on peripheral smear or marrow aspirate after

staining with Romanowsky solution. Treatment includes platelet transfusion. Good pregnancy outcome was reported in a patient with gray platelet syndrome after platelet transfusion.²⁶³

DELTA STORAGE POOL DISEASE

Delta (δ) storage pool disease involves a deficiency in dense granules (δ granules) in platelets containing ADP. Diagnosis is made by electron microscopy or by an adenosine triphosphate (ATP)-to-ADP ratio greater than 3:1 in inactive platelets. Other syndromes associated with δ storage pool disease include the Chediak-Higashi, Wiscott-Aldrich, thrombocytopenia with absent radii (TAR), and Hermansky-Pudlak syndromes. Most patients with δ -storage pool diseases respond to platelet transfusion, although some may respond to DDAVP. Rarely, individuals have congenital or acquired abnormalities of δ and α granules, termed $\alpha\delta$ storage pool disease. A case of an uncomplicated pregnancy without treatment was reported in a patient with Chediak-Higashi syndrome.²⁶⁴ Wiscott-Aldrich syndrome is an X-linked immunodeficiency syndrome that is associated with early mortality. Prenatal diagnosis is possible and should be offered to affected families.²⁶⁵

Thrombocytopenia associated with TAR typically resolves at 1 year of life. Prenatal diagnosis of the syndrome has been reported.²⁶⁶ Several pregnancies have been reported in women with Hermansky-Pudlak syndrome.^{267,268} This autosomal recessive condition is characterized by oculocutaneous albinism, platelet storage pool deficiency, and the accumulation of ceroid (a yellow, granular substance) in reticuloendothelial cells. It is common in some areas of Puerto Rico.^{267,268}

GLANZMANN THROMBASTHENIA

Glanzmann thrombasthenia is an abnormality in the quantity or quality (or both) of the platelet membrane glycoprotein, GpIIb-IIIa.²⁶⁹ The disease is transmitted in an autosomal dominant fashion and has been reported to occur most often in Iraqi-Jewish and Arab populations in Israel, in Southern India, and among European Gypsies.^{270,271} Patients with type 1 Glanzmann thrombasthenia lack detectable GpIIb-IIIa, whereas those with type 2 disease have only 10% to 20% of normal platelet surface GpIIb-IIIa.

These patients are at lifelong risk for bleeding, often requiring frequent platelet transfusions. Accordingly, many develop alloimmune antibodies against platelet antigens, causing their pregnancies to be at risk for NAIT (see earlier discussion).²⁷² Women with a history of multiple platelet transfusions should undergo evaluation for parental platelet antigen incompatibility and the presence of specific anti-platelet antibodies for fetal antigens. Cordocentesis has been particularly risky in affected pregnancies and is best avoided if possible. This makes prenatal diagnosis more difficult. In cases of known mutations, fetal genotype may be obtained from amniocytes or chorionic villi (avoid chorionic villus sampling if the patient has antibodies).

The primary intrapartum treatment for Glanzmann thrombasthenia is platelet transfusion.^{273,274} If possible, type-specific platelets should be used to avoid platelet alloimmunization. If pooled platelets must be used in sensitized women, immunosuppressive therapy may prolong the lifespan and effectiveness of the platelets. Cesarean delivery should be reserved for the usual obstetric indications, including alloimmune thrombocytopenia. Postpartum hemorrhage is common. Hormonal treatment and prolonged use of uterotonic agents may reduce the risk of this complication, although this approach is of unproven efficacy. The use of rFVIIa appears to be safe and relatively effective in patients with Glanzmann thrombasthenia,²⁷⁴⁻²⁷⁶ and it may prove to be an important tool for the treatment of this disease during pregnancy.

Bleeding Disorders

Acquired Bleeding Disorders

Factor VIII Inhibitors

The development of antibodies against factor VIII is a rare but serious acquired bleeding disorder. The inciting event is unknown, but the condition often manifests in the postpartum period.²⁷⁷ Clinical features are similar to those seen in hemophilia. Diagnosis is made by prolonged clotting times that do not normalize in response to mixing studies with normal plasma. Demonstration of a specific factor VIII inhibitor and documentation of low levels of factor VIII in the plasma confirm the diagnosis. Hemorrhage may be severe and may respond to activated prothrombin complex concentrate or rFVIIa.^{276,277} Mild cases often respond to DDAVP and factor VIII concentrates.²⁷⁷ Plasmapheresis may be helpful in refractory cases. The disease typically regresses spontaneously over time. Although IgG antibodies to factor VIII may develop, infants are rarely affected. The condition usually

remits spontaneously, with or without the use of immunosuppressive therapy.²⁷⁷

Congenital Bleeding Disorders

Hemophilia A (Factor VIII Deficiency) and Hemophilia B (Factor IX Deficiency)

Hemophilia A and B are caused by congenital deficiencies of factor VIII and IX, respectively. They are inherited in an X-linked recessive fashion. Therefore, affected females are uncommon. Heterozygous carriers are usually asymptomatic. Rarely, a heterozygous female has clinical symptoms of bleeding, perhaps because of skewed X inactivation of the X chromosome containing the normal gene. Symptoms tend to be mild, and serious hemorrhage during labor and delivery is rare. Treatment may be accomplished with factor VIII concentrate or cryoprecipitate for hemophilia A and factor IX concentrate or fresh-frozen plasma for hemophilia B.²⁴⁷

Pregnancy issues often focus on the fetus/neonate, because 50% of male offspring born to female carriers will be affected. Carrier detection of hemophilia A may be accomplished using assays for factor VIII and is reliable during pregnancy. Prenatal diagnosis is feasible through factor VIII and IX gene mutation analysis or linkage analysis (or both).²⁵¹ Rarely, cordocentesis may be used to detect an affected fetus by testing levels of factors VIII and IX (which are normally lower in a fetus than in an adult). However, this approach is reserved for cases in which genetic testing is not diagnostic, because the procedure is risky.²⁴⁷

Levels of factor VIII or IX, or both, should be assessed at the initial pregnancy visit, at 28 and 34 weeks of gestation, and again at delivery.²⁴⁷ Recombinant factor VIII and IX should be used as the treatment of choice in pregnant carriers of hemophilia A and B, respectively. Treatment should be initiated in the setting of bleeding or factor VIII or IX levels lower than 50 IU/dL.²⁴⁷ DDAVP may be helpful in women with hemophilia A, but not in those with hemophilia B. Regional anesthesia should be safe in women with normal coagulation studies and factor levels greater than 50 IU/dL. Vaginal delivery has not been shown to increase bleeding in affected male infants. However, fetal scalp electrodes, operative vaginal delivery, and circumcision should be avoided in male infants born to carriers of hemophilia A. Postnatal diagnosis may be established in newborns through assays of maternal and cord blood. Carriers of hemophilia B are detected by factor IX assay. Levels of factor IX in carriers are usually decreased, although they may be normal. Delivery issues with hemophilia B are similar to those for hemophilia A.

Other Factor Deficiencies

Deficiencies of factors VII, X, XI, and XIII are uncommon hereditary bleeding disorders. Factor VII, X, and XIII deficiencies are probably autosomal recessive traits, whereas factor XI deficiency appears to be an incompletely autosomal-recessive trait. Replacement with rFVIIa is the treatment of choice for women with factor VII deficiency.²⁷⁸ Factor X-deficient women may be treated with fresh-frozen plasma or factor IX concentrates to treat active bleeding.^{279,280} Prophylactic transfusion may be useful before vaginal or cesarean delivery.^{279,281} Individuals who are homozygous for factor XI deficiency have levels less than 20% of normal, whereas heterozygotes have levels that are 30% to 65% of normal.²⁸² Bleeding does not always correlate with factor XI concentrations, and heterozygotes may have minor bleeding problems. Most women do not experience hemorrhage during delivery,^{283,284} and it may be possible to stratify patients with the condition into bleeding and

nonbleeding phenotypes.²⁸⁴ Prophylactic treatment is not required for all deliveries, and treatment may be reserved for excessive bleeding.^{283,284} This may be accomplished with fresh-frozen plasma given as a 10 mL/kg load followed by 5 mL/kg per day, or through direct replacement with factor XI concentrate.

Factor XIII deficiency is rare but can lead to severe bleeding such as ICH after minor trauma and abnormal wound healing. Life-threatening umbilical cord stump hemorrhage has occurred in affected newborns. An increased risk of recurrent pregnancy loss also has been reported in women with factor XIII deficiency.²⁸⁵ This is thought to be the result of decidual bleeding, and successful pregnancy rarely occurs without treatment. Diagnosis is made by assessment of factor XIII (A and S subunits) or by dissolution of clot in 5-molar urea. Treatment includes transfusion with factor XIII concentrate, fresh-frozen plasma, cryoprecipitate, and/or whole blood. Small amounts of plasma may provide adequate factor XIII for hemostasis. Although of uncertain efficacy, maintenance of XIIIa-antigen (Ag) or XIII-activity (act) at 10% is advised.²⁸⁵ This may require the administration of 1 vial of XIIIa concentrate (250 IU) every 7 days in early pregnancy, followed by 2 vials every 7 days after 23 weeks gestation.^{285,286} Extra replacement (e.g., 4 vials) may be helpful at the time of delivery.²⁸⁵

Hypofibrinogenemia/Afibrinogenemia

Congenital hypofibrinogenemia is a rare, autosomal-dominant condition characterized by bleeding as well as obstetric problems such as abruptio, postpartum hemorrhage, and recurrent pregnancy loss.^{287,288}

The condition is defined as the presence of structurally normal fibrinogen in concentrations of less than 150 mg/dL.²⁸⁷ Miscarriage at mid-gestation appears to be caused by perigestational hemorrhage.²⁸⁸ This is supported by data from transgenic mice lacking fibrinogen, who suffer uniform pregnancy loss at day 10.²⁸⁹ Pregnancy loss in these mice is corrected by the addition of fibrinogen. Dysfibrinogenemia has been weakly associated with hypercoagulability, rather than hypocoagulability. Successful pregnancies in women with hypofibrinogenemia have been reported with the use of fresh-frozen plasma or cryoprecipitate to maintain fibrinogen levels greater than 100 to 150 mg/dL.^{287,288} Each unit of cryoprecipitate contains about 300 mg of fibrinogen, which raises the plasma concentration by approximately 6 mg/dL.

Factor XII deficiency

Factor XII is involved in both coagulation and fibrinolysis, and deficient individuals have been reported to be at increased risk for both bleeding and thrombosis. However, it is not clear that this condition increases the risk for either bleeding or thrombosis.²⁹⁰ The condition is of interest because it is associated with recurrent pregnancy loss.^{291,292}

Plasminogen Activator Inhibitor 1 Deficiency

Individuals with elevated levels of PAI-1 are at increased risk for thrombosis and possibly for pregnancy loss. In contrast, deficiency of PAI-1 has been reported to be associated with an increased risk of bleeding.²⁹³ The condition often manifests as menorrhagia and may be responsive to aminocaproic acid.²⁹³ Indeed, low PAI-1 activity has been reported in 23% of patients referred for evaluation of bleeding diathesis, compared with 10% of controls (OR, 2.75; CI, 1.39 to 5.42).²⁹⁴ It may prove to be an important cause of abnormal bleeding. There are few data regarding pregnancy in women with PAI-1 deficiency.

Chapter 41

Thromboembolic Disease in Pregnancy

Charles J. Lockwood, MD

Venous thromboembolism (VTE) is the leading cause of maternal mortality in the United States, accounting for almost 20% of pregnancy-related deaths in the past decade.¹ A retrospective cohort study of 268,525 patients over a 19-year period reported a prevalence of VTE of 1 per 1627 births; of these cases, 77% were deep venous thromboses (DVTs), and 23% were acute pulmonary emboli (PE).² No antecedent history of VTE was present in 86% of these patients. Moreover, among nonpregnant adults who have a fatal PE, 65% (95% confidence intervals [CI], 40.8% to 84.6%) die within 1 hour after onset.³ These findings underscore the need for a high index of suspicion, a sensitive and rapid diagnostic algorithm, and expeditious initiation of treatment in pregnant women with suspected VTE.

Among pregnant women, 98.4% of DVTs are localized to the lower extremities, with the left leg affected in 82% of cases.² The occurrence of DVT is more common in the antepartum than in the postpartum period (74% versus 26%; $P < .001$), with a mean gestational age at diagnosis of 16.8 ± 2.4 weeks. Nearly 50% of antepartum DVTs are detected by 15 weeks, 38% between 16 and 30 weeks, and only 12% after 30 weeks. In contrast, most PEs are diagnosed in the postpartum period (60.5%) and are strongly associated with cesarean delivery (relative risk [RR], 30.3; $P < .001$).²

Risk Factors

Pregnancy Is a Prothrombotic State

Normally, VTE is a disease of aging, occurring in fewer than 1 of every 10,000 healthy women before 40 years of age.⁴ However, the risk of VTE is increased sixfold in pregnancy. Pregnancy induces this prothrombotic state in a number of ways. Compared to nonpregnant women of reproductive age, pregnancy is associated with increases of 20% to 1000% in plasma concentrations of fibrinogen; factors VII, VIII, IX, X, and XII; and von Willebrand factor.⁵ In addition, activity of the anticoagulant factor, protein S, declines, on average, to 39% of normal in the second trimester and 31% of normal in the third trimester.⁶ As a consequence, pregnancy is associated with an increase in resistance to activated protein C. The net effect of these changes is an increase in thrombin generation, as measured by increased levels of fibrinopeptide A and the thrombin-antithrombin complex.⁷ Protein S levels drop even further after cesarean delivery or infection, helping to account for the high prevalence of PE after cesarean deliveries. Levels of plasminogen activator inhibitor 1 (PAI-1), which inhibits clot lysis, increase threefold to fourfold during pregnancy, whereas plasma PAI-2 values, which are negligible before pregnancy, reach high con-

centrations at term.⁵ Thus, pregnancy is associated with increased thrombin-generating potential, decreased endogenous anticoagulant effects, and impaired fibrinolysis.

The occurrence of VTE in pregnancy is also promoted by venous stasis in the lower extremities resulting from compression of the inferior vena cava and pelvic veins by the enlarging uterus, compression of the left common iliac vein by the right iliac artery,⁸ and increases in deep vein capacitance caused by increased circulating levels of progesterone and local endothelial production of prostacyclin and nitric oxide.^{9,10}

Risk Factors Not Specific to Pregnancy

Additional risk factors for VTE that may be more common in pregnancy include trauma, infection, obesity, severe proteinuria, and prolonged bed rest. Maternal age greater than 35 years doubles the risk of VTE in pregnancy.¹¹ One study found that, among patients undergoing cesarean delivery who developed a PE, 36% were older than 35 years of age, and 55% were obese (body mass index >29).¹²

Antiphospholipid antibody (APA) syndrome is associated with a 1% to 5% risk of VTE in pregnancy and the puerperium despite thromboprophylaxis.^{13,14} In a case-control study of 30 pregnant women with VTE versus matched controls who were subsequently analyzed for APA, the prevalence of these antibodies was substantially increased in cases compared with controls (27% versus 3%; $P = .026$).¹⁵

The presence of an inherited thrombophilic disorder also increases the risk of VTE during pregnancy, particularly in the setting of a personal or strong family history. For example, the factor V Leiden (FVL) mutation is present in 40% of pregnant patients with VTE.^{16,17} However, because the prevalence of VTE in pregnancy is low (1/1600) and the incidence of heterozygosity for FVL in European populations is high (5%), the actual risk of VTE among gravidas who are without a personal history of VTE or an affected first-degree relative is less than 0.2% to 0.3%.^{16,17} With such a history, the risk of VTE in the antepartum or postpartum period is greater than 10%. Similar observations have been made for the other common inherited thrombophilias (see Chapter 40 and Table 41-1).

The presence of a thrombophilia can also affect the recurrence risk for VTE among pregnant women. Brill-Edwards and colleagues prospectively followed 125 pregnant women with a prior VTE, 95 of whom were tested for thrombophilias, including FVL; the prothrombin G20210A gene mutation (PGM); protein C, protein S, and antithrombin deficiencies; and the APAs, anticardiolipin antibodies, and lupus anticoagulant.²³ The authors withheld antepartum thrombopro-

TABLE 41-1 INHERITED THROMBOPHILIAS AND THEIR ASSOCIATION WITH VENOUS THROMBOEMBOLISM IN PREGNANCY

Thrombophilia	% VTE in Pregnancy	% Thrombophilia in European Populations	Relative Risk or Odds Ratio (95% CI)	Probability of VTE in Patients without Personal or Family History of VTE (%)	Probability of VTE with a Personal or Strong Family History of VTE (%)	References
FVL (homozygous)	<1	0.06 ⁺	25.4 [8.8-66]	1.5	17	16-19
FVL (heterozygous)	40-44	5	6.9 [3.3-15.2]	0.26	10	16,17
PGM (homozygous)	<1	0.02 ⁺	NA	2.8	>17	18
PGM (heterozygous)	17	3	9.5 [2.1-66.7]	0.37	>10	16,17
FVL/PGM (compound heterozygous)	<1	0.15	84 [19-369]	4.7	NA	16,17
Antithrombin deficiency	1-8	0.04	119	3.0-7.2	>40	16-21
Protein S deficiency	12.4	0.03-0.13	2.4 [0.8-7.9]	<1	6.6	16-18, 21
Protein C deficiency	<10	0.2-0.3	6.5-12.5	0.8-1.7	NA	16,18, 22

⁺, calculated based on a Hardy-Weinberg equilibrium; CI, confidence interval; FVL, factor V Leiden; NA, not applicable; PGM, prothrombin G20210A gene mutation; VTE, venous thromboembolism.

phylaxis but employed it in the postpartum period. They noted an overall antepartum recurrence rate of 2.4% (CI, 0.2% to 6.9%) but no recurrences in the 44 women without a detectable thrombophilia whose previous VTE was associated with a temporary risk factor (among which the authors included pregnancy itself). In contrast, the recurrence risk for VTE among the 25 thrombophilic patients was 16% (4 patients) (odds ratio [OR], 6.5; CI, 0.8 to 56.3). Therefore, it would appear prudent to test pregnant patients who have a history of a VTE associated with a transient risk factor (e.g., fracture) for thrombophilias. Similarly, consideration should be given to screening pregnant women who have a strong family history (i.e., affected first-degree relative) of VTE, particularly if they are likely to be exposed to other risk factors such as prolonged mobilization or cesarean delivery.

Diagnosis and Evaluation of Venous Thromboembolism in Pregnancy

The clinical signs and symptoms of VTE are neither sensitive nor specific. Indeed, three quarters of patients in whom the diagnosis of either DVT or PE is suspected are unaffected.²⁴ Conversely, many of those ultimately diagnosed with VTE do not have classic features. To make an early diagnosis, clinicians must exercise a high index of suspicion and approach the diagnosis in a systematic fashion.

Deep Venous Thrombosis

Clinical Presentation

Only a third of patients with unilateral lower extremity edema, erythema, warmth, pain, tenderness, and a positive Homan sign—the traditional hallmarks of DVT—prove to have the diagnosis when objective diagnostic tests are performed.²⁵ Differential diagnoses include a ruptured or strained muscle or tendon, cellulitis, knee joint injury, Baker cyst, cutaneous vasculitis, superficial thrombophlebitis, and lymphedema. The positive predictive value of these signs and symptoms increases substantially in patients at increased risk. However, there is no risk assessment model that has been validated in pregnancy.

TABLE 41-2 DVT CLINICAL CHARACTERISTIC SCORE

Item No.	Description	Score
1	Immobilization due to cast or paresis	+1
2	Bed rest for >3 days or major surgery within 12 wk requiring general or regional anesthesia	+1
3	Localized tenderness along deep venous system	+1
4	Entire leg swollen	+1
5	Asymmetric calf swelling >3 cm measured 10 cm below tibial tuberosity	+1
6	Pitting edema only in symptomatic leg	+1
7	Collateral nonvaricose superficial veins	+1
8	Active cancer	+1
9	Prior documented DVT	+1
10	Alternative diagnosis at least as likely as DVT	-2

*Patients with a score <2 are considered unlikely, and those with a score ≥2 are considered likely, to have deep venous thrombosis (DVT). Adapted from Wells PS, Anderson DR, Rodger M, et al: Evaluation of D-dimer in the diagnosis of suspected deep-vein thrombosis. *N Engl J Med* 349:1227-1235, 2003.

Wells and associates introduced and validated a simple model in nonpregnant patients (Table 41-2).²⁶ In the Wells model, 46% of nonpregnant patients were categorized as likely to have a DVT (score = 2), and, of these patients, 28% (CI, 24% to 32%) were found to have either proximal DVT or PE. In contrast, of the 54% who were categorized as unlikely to have a DVT, only 6% (CI, 4% to 8%) proved to have a proximal DVT or PE. Therefore, the first step in diagnosing DVT is risk ascertainment.

Venous Ultrasonography

Venous ultrasonography (VUS) with or without color Doppler imaging has become the primary diagnostic modality for evaluating pregnant patients who are at risk for DVT. The test is performed by placing the ultrasound transducer over the common femoral vein, beginning at the inguinal ligament, and then moving down the leg to sequentially

image the greater saphenous vein, the superficial femoral vein, and then the popliteal vein to its trifurcation with the deep veins of the calf. Calf veins are then insonated. Pressure is applied with the probe to determine whether the vein under examination is compressible. The most accurate ultrasonic criterion for diagnosing DVT is noncompressibility of the venous lumen in a transverse plane under gentle probe pressure using duplex and color flow Doppler.²⁵ The sensitivity and specificity of VUS are reported to be 90% to 100% for proximal vein thromboses.²⁷ Meta-analysis suggests that VUS is also effective at screening for calf vein DVT, with a sensitivity of 92.5% (CI, 81.8% to 97.9%) and a specificity of 98.7% (CI, 95.5% to 99.9%), yielding an overall accuracy of 97.2% (CI, 93.9% to 99.0%).²⁸ Even though there is a paucity of data on the performance of VUS in pregnancy, it has become the gold standard for DVT detection in the nonpregnant state.²⁹

Magnetic Resonance Venography

It appears that magnetic resonance (MR) imaging may be superior to VUS, and perhaps the equivalent of contrast venography, for diagnosing DVT. The sensitivity of MR imaging for the diagnosis of proximal leg vein DVT has been reported to be 100% (CI, 87% to 100%); the specificity, 100% (CI, 92% to 100%); and the overall accuracy, 96% (CI, 89% to 99%).³⁰ Moreover, MR venography is significantly more sensitive and more accurate than sonography for the detection of pelvic and calf DVT. The published literature suggests that the range of sensitivity for MR imaging in the diagnosis of DVT is 80% to 100%, and its specificity is 90% to 100%, with median published rates of 100% for both.³¹

Contrast Venography

Before improvements in sonographic imaging technology and the introduction of MR venography, contrast venography was the gold standard for the diagnosis of DVT. The procedure involved injecting a contrast agent into a superficial vein on the dorsum of the foot and allowing it to circulate into the deep venous system while radiographic images were obtained of the lower leg, thigh, and pelvis. The diagnosis required intraluminal filling defects observed on two or more views or an abrupt cutoff of contrast material. It was the most sensitive test for calf vein DVTs. Although accurate, it was expensive, invasive, and painful and risked radiation exposure. In addition, the contrast medium could potentially induce renal compromise and chemical phlebitis.

D-dimer Assays

Laboratory evaluation of D-dimer concentrations has been advocated as an exclusionary test for DVT in low-risk nonpregnant women. A D-dimer study is very likely to be positive in a patient with DVT, but it is also commonly positive in patients with uncomplicated pregnancies. Conversely, if a D-dimer assay is negative in a pregnant patient with suspected DVT, the diagnosis is even less likely than with a comparable negative finding in the nonpregnant state. Recently developed D-dimer assays include two rapid enzyme-linked immunosorbent assays (ELISAs) (Instant-IA D-Dimer, Stago, Asnières, France, and VIDAS DD, bioMérieux, Marcy-l'Étoile, France) and a rapid whole blood assay (SimpliRED D-Dimer, Agen Biomedical, Brisbane, Australia). In nonpregnant patients, the sensitivity of the rapid ELISAs is greater than 95% and that of the SimpliRED D-dimer assay is reportedly 85%.³² In nonpregnant patients, there appears to be utility in combining a sensitive D-dimer assay with a noninvasive imaging test. Wells and associates reported that, when the whole blood assay for D-dimer (SimpliRED) was used in combination with impedance plethys-

mography (IPG), two clinically useful patterns emerged in 70% of at-risk patients.³³ The first pattern was a normal IPG and a negative D-dimer assay, which had a negative predictive value for DVT of 97% overall and 99% for proximal vein DVT. The second pattern was the combination of a positive D-dimer and an abnormal IPG, which had a positive predictive value of 93% for any DVT and 90% for proximal DVT. However, if the D-dimer and IPG results were discordant, it was not possible to reliably exclude or diagnose DVT, and such discordant results occurred in 28% of patients. Extrapolation of these findings to pregnancy is difficult, not only because of the high “false-positive” rate of D-dimer testing (>50%)³⁴ but because IPG is rarely performed anymore.

A number of investigators have argued that, given the high rate of false-positive results on D-dimer testing in pregnancy, it can be used as a screening test in low-risk patients, because a negative D-dimer result in a pregnant woman would have an exceedingly high negative predictive value. Morse measured D-dimer values in 48 women, aged 17 to 36 years, at 16, 26, and 34 weeks of gestation and compared these values to those of 34 healthy, nonpregnant controls.³⁴ Morse found a progressive increase in D-dimer concentrations across gestation (191 ± 25 ng/mL at 16 weeks, 393 ± 72 ng/mL at 26 weeks, and 544 ± 96 ng/mL at 34 weeks), all of which were significantly higher than the values in nonpregnant women (140 ± 58 ng/mL). Because the cutoff value for normal D-dimer levels at the author's hospital was 280 ng/mL, most pregnant patients would be considered positive. The author recommended new threshold ranges for 16 to 26 weeks (<465 ng/mL) and for 27 to 34 weeks (<640 ng/mL) of gestation.

There is preliminary evidence that the combination of VUS and D-dimer values measured by the SimpliRED D-dimer test may be useful in diagnosing DVT in pregnancy.³⁵ Based on the initial VUS and D-dimer results, women were categorized into one of four groups and managed accordingly. Group 1 (VUS normal, D-dimer normal) comprised 31 patients who had routine follow-up until 6 weeks postpartum; none of these patients developed objectively diagnosed VTE (CI, 0% to 9.2%). In group 2 (VUS normal, D-dimer abnormal), 4 (22%) of 18 women were diagnosed with DVT on serial VUS at 3 and 7 days, and, of the 14 (78%) with negative serial VUS, none developed VTE during follow-up (CI, 0% to 19.3%). In patients for whom VUS was equivocal (group 3), venography was performed. If the VUS result was positive (group 4), DVT was diagnosed. The authors concluded that the finding of a normal VUS together with a normal D-dimer result or an abnormal D-dimer result coupled with reassuring serial VUS findings allows the safe exclusion of DVT in pregnant patients, but that larger confirmatory studies were needed.

Testing Algorithms for Deep Venous Thrombosis in Pregnancy

The cornerstone of the evaluation of pregnant patients for possible DVT is a VUS. However, D-dimer assessment can be employed either as an initial screen in low-risk patients or as an adjunct to VUS. Figure 41-1 outlines a diagnostic paradigm which assumes the availability of a sensitive D-dimer assay and clinical risk assessment. In this paradigm, low-risk patients are given a D-dimer test. If the result is negative, they are discharged for routine follow-up. If the D-dimer test is positive, they undergo a VUS. Patients with moderate or high risk on clinical assessment proceed directly to VUS. If the VUS result is positive, DVT is diagnosed and the patient is treated. If it is negative and the patient remains symptomatic, serial VUS testing can be performed in 3 days, 7 days, or both. If the repeat VUS findings are positive, the patient is treated. If both VUS studies are negative, the patient has routine follow-up. In particularly high-risk settings (e.g., known

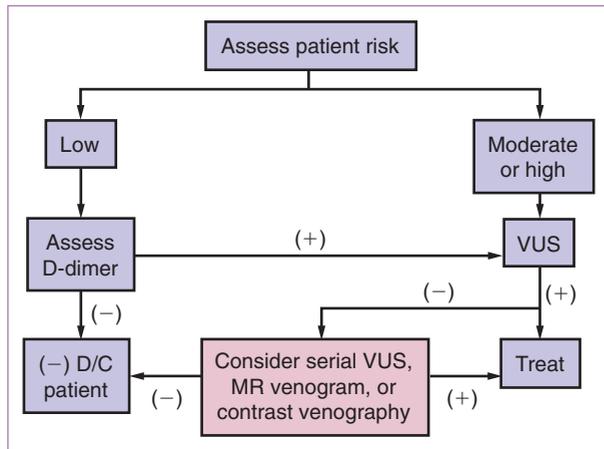

FIGURE 41-1 Testing algorithm for deep venous thrombosis in pregnancy, assuming availability of D-dimer test and clinical assessment. D/C, discharge patient; MR, magnetic resonance; VUS, venous ultrasonography.

thrombophilia, suspected iliac vein thrombus), more definitive diagnostic tests can be performed, such as an MR or contrast venogram if the D-dimer is positive and the initial VUS is negative. The problem with this approach is that, as noted previously, the majority of pregnant women after 16 weeks' gestation will have a positive D-dimer assay if a nonpregnant threshold is used. Moreover, there has been no validation of higher D-dimer thresholds in pregnancy, and there are no validated risk scoring systems. Importantly, the Wells criteria may not be appropriate in pregnancy, which is intrinsically a high-risk state.

Figure 41-2 assumes the use of a VUS as the initial test, with patients subsequently triaged based on the VUS result or clinical risk assessment determining the need for additional evaluations. A positive VUS result prompts treatment. Follow-up of a negative VUS result depends on the patient's risk category. If it is low, the patient is discharged to routine follow-up. If it is moderate or high, she undergoes serial VUS or, if the index of suspicion is high enough, MR or contrast venography.

The diagnostic scheme in Figure 41-3 utilizes VUS and D-dimer testing without formal clinical risk assessment to triage patients. The combination of a negative D-dimer result and a negative VUS study is associated with a very low risk of DVT, and such patients are discharged to routine follow-up. A positive VUS, which is virtually always associated with a positive D-dimer test, prompts treatment. However, a negative VUS result combined with a positive D-dimer test is followed with either serial VUS or MR or contrast venography, depending on the clinician's index of suspicion. It should be noted that D-dimer testing is likely to be completely irrelevant in puerperal and postoperative patients, because these patients have very high false-positive rates.^{36,37} The diagnostic approach outlined in Figure 41-2 should be employed in those settings.

The diagnosis of recurrent DVT in pregnancy presents a diagnostic challenge, because VUS findings remain abnormal after an initial thrombus for up to 1 year in as many as 50% of patients.³² In this setting, an increase of more than 4 mm in the compressed diameter of a previously involved vein has been reported to provide strong evidence of recurrent thrombosis, but this observation requires confirmation.³⁸ In such cases, strong consideration should be given to D-dimer assessment and adjunct imaging with MR or contrast venography. A

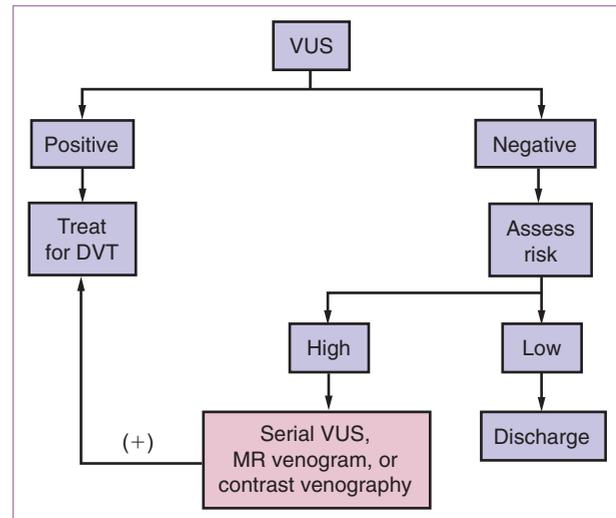

FIGURE 41-2 Testing algorithm for deep venous thrombosis (DVT) in pregnancy with venous ultrasonography (VUS) as the initial test. MR, magnetic resonance.

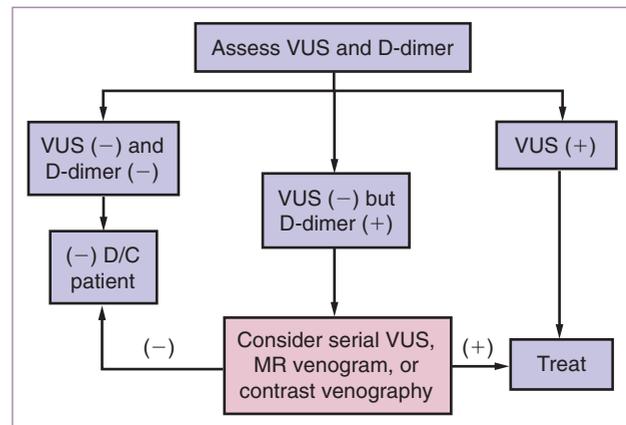

FIGURE 41-3 Testing algorithm for deep venous thrombosis in pregnancy, using venous ultrasonography (VUS) and D-dimer testing without formal clinical risk assessment. D/C, discharge; MR, magnetic resonance.

negative D-dimer finding would be very reassuring, whereas observation of an intraluminal filling defect on MR or contrast venography would be diagnostic of recurrent DVT.³²

Acute Pulmonary Embolus

Clinical Findings

In nonpregnant women, the classic presentation of PE includes tachypnea (>20 breaths/min) and tachycardia (>100 beats/min), either of which is present in 90% of cases.³⁹ Additional common symptoms include dyspnea and pleuritic chest pain. In contrast, lightheadedness and syncope are rare and are indicative of massive emboli.⁴⁰ In the nonpregnant state, the nonspecific nature of these signs and symptoms is a result of the common comorbidities found in older patients, including viral and bacterial pneumonia, postoperative atelectasis, pneumothorax, exacerbation of chronic obstructive lung disease, congestive heart failure, lung cancer, musculoskeletal chest wall pain, esophageal

TABLE 41-3 PULMONARY EMBOLISM RISK SCORE*

Scoring Factor	Points
Clinical signs and symptoms of DVT	+3.0
Alternative diagnosis deemed less likely than PE	+3.0
Heart rate >100 beats/min	+1.5
Immobilization or surgery in previous 4 wk	+1.5
Prior VTE	+1.5
Hemoptysis	+1.0
Active cancer	+1.0

*Clinical probability of PE is low with a cumulative score <2.0, intermediate with a score of 2.0-6.0, and high with a score >6.0. DVT, deep venous thrombosis; PE, pulmonary embolism; VTE, venous thromboembolism.

Adapted from Fedullo PF, Tapson VF: Clinical practice: The evaluation of suspected pulmonary embolism. *N Engl J Med* 349:1247-1256, 2003.

spasm, pericarditis, pleuritis, and anxiety. Although these comorbidities are far less common in otherwise young and healthy pregnant women, pregnancy itself can be associated with dyspnea, tachycardia, lightheadedness, orthostatic presyncope, and various chest wall complaints. Therefore, a high index of suspicion is required.

The initial step in the evaluation of any patient is risk assessment. Table 41-3 outlines one scoring system used in nonpregnant patients, in which patients in the low-probability group had a prevalence of PE of 10% or less, those in the intermediate group had a prevalence of about 30%, and those in the high-probability group had a prevalence of PE of 70% or more.⁴⁰ This system has not been validated in pregnant patients. Furthermore, given the thrombogenic nature of pregnancy and the puerperal state, particularly after cesarean delivery, it may be prudent to consider all pregnant patients as being at high risk.

Nonspecific Diagnostic Tests

CHEST RADIOGRAPHY

Chest radiographs can play an important role in the evaluation of pregnant patients with suspected PE. Given concerns about excess breast irradiation during computed tomographic pulmonary angiography (CTPA), and because ventilation-perfusion (V/Q) studies have exceptionally high negative predictive values in otherwise healthy pregnant women, some investigators have advocated obtaining an initial chest radiograph to triage patients to either CTPA or V/Q scan.⁴¹ If the radiograph is normal, a V/Q scan is obtained; if it is abnormal (e.g., infiltrates, which could compromise the V/Q study by causing matched ventilation-perfusion abnormalities), a CTPA is ordered. Abnormal findings on radiography may also be consistent with a PE. Such findings, which include pleural effusion, pulmonary infiltrates, atelectasis, and elevated hemidiaphragm, underscore the need for CTPA, because it can diagnose a broad range of lung pathology. However, chest radiography is rarely directly diagnostic of a PE, because the classic radiographic findings of pulmonary infarction, such as Hampton's hump or decreased vascularity (Westermark sign), are rarely seen.³¹

ELECTROCARDIOGRAPHY

In nonpregnant patients, electrocardiographic (ECG) changes are present in 87% of patients with documented PE who are otherwise without underlying cardiopulmonary disease.⁴² However, truly characteristic ECG changes usually reflect the hemodynamic sequelae of acute cor pulmonale characteristic of a massive PE (i.e., S₁Q₃T₃ pattern,

right bundle branch block, P-wave pulmonale, or right axis deviation) and therefore are rare.⁴² Moreover, such changes are not universal, even among critically ill patients. Constantini and associates reported changes characteristic of right ventricular strain including an S₁Q₃ pattern in 67% of such patients, with a "septal embolic pattern" in 53%, and either anterior lead T-wave inversion or new right bundle branch block in only 16%.⁴³ However, there are no data on ECG changes in pregnant women with PE. Moreover, pregnancy-induced physiologic changes mimic left heart strain (e.g., T inversions in the left precordial leads) and, therefore, may mask PE-induced right heart strain changes. Conversely, some physiologic changes may simulate PE changes (e.g., physiologic Q waves in leads 3 and aVF), leading to false-positive results. For these reasons, the screening value of ECG in the setting of maternal acute PE is probably low. However, assessment of the maternal ECG may have utility in making decisions about how aggressively to pursue secondary diagnostic studies (see Testing Algorithms for Pulmonary Embolism, later).

ARTERIAL BLOOD GASES

In young, nonpregnant patients, assessments of arterial blood gases and oxygen saturation are of limited value in the setting of acute PE, because PO₂ values higher than 80 mm Hg are found in 29% of such patients who are younger than 40 years of age.⁴⁴ Given that PO₂ levels are even higher in pregnant women, the test is likely to produce even more false-negative results in pregnancy. However, as was the case with maternal ECG, assessment of maternal oxygen saturation may have utility in making decisions about how aggressively to pursue secondary diagnostic studies (see Testing Algorithms for Pulmonary Embolism, later).

ECHOCARDIOGRAPHY

More than 80% of nonpregnant patients with acute PE have echocardiographic or Doppler abnormalities, including dilated and hypokinetic right ventricle and tricuspid regurgitation.^{45,46} Because young, pregnant women are unlikely to have cardiorespiratory comorbidities that can mimic these findings (e.g., chronic obstructive pulmonary disease), maternal echocardiography may be useful in pregnant women with suspected PE. Optimal screening requires transesophageal echocardiography with or without contrast enhancement.⁴⁷ Indeed, there is a report in which intraoperative transesophageal echocardiography was used to diagnose a right atrial thrombus during a cesarean delivery.⁴⁸

Specific Diagnostic Tests

VENTILATION-PERFUSION SCANNING

In nonpregnant adults, V/Q scanning has largely been replaced by CTPA. In younger, otherwise healthy, pregnant women, V/Q scans have superior PE diagnostic characteristics compared with their use in older, nongravid patients, who frequently have cardiorespiratory comorbidities.⁴¹ Because of this improved accuracy in pregnancy, and given concerns about the extent of maternal breast irradiation with CTPA, V/Q scans may still have a limited role in ruling out PE in select pregnant and puerperal patients.⁴¹ The perfusion component of a V/Q scan requires injecting human albumin macroaggregates labeled with radioactive isotopes (e.g., technetium 99m) into the bloodstream, where they are deposited in the pulmonary capillary bed and imaged by a photoscanner. The ventilation component requires inhalation of radiolabeled (e.g., xenon 133) aerosols whose distribution in the alveolar space is assessed by a gamma camera. Comparison of the perfusion and ventilation scans produces characteristic patterns that can be used to assign diagnostic probabilities.

The chief limitation of V/Q scanning in nonpregnant patients is that only 30% to 40% of older patients with preexisting lung disease who have large matched V/Q defects are subsequently shown to have a PE, leading to false-positive results.²⁵ Fortunately, pregnant patients are generally free of chronic lung disease. Moreover, as noted earlier, the proportion of nondiagnostic V/Q scans can be further reduced by obtaining an initial chest radiograph and triaging pregnant patients with an abnormal result to CTPA.⁴¹ Furthermore, although fetal radiation exposure is higher with V/Q scanning than with CTPA (0.11 to 0.22 mGy versus 0.003 to 0.08 mGy),⁴⁹ all of these exposures are exceedingly low, and the risk of subsequent leukemogenesis is estimated at 1 case per 16,000 fetuses exposed to 1 mGy of radiation. Moreover, half-dose perfusion scans can be employed in young, healthy, pregnant women. Such half-doses result in breast irradiation levels of 0.25 mGy, which is 140-fold lower than the exposure from CTPA (i.e., 35 mGy per breast).⁴¹

The diagnostic efficacy of V/Q scanning for PE was assessed by the multicenter Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) in 931 nonpregnant adults.⁵⁰ In this study, patients with high-probability scans were found by definitive testing (e.g., pulmonary contrast angiography) to have PE in 87% of cases, but only 41% of patients with PE had high-probability scans (sensitivity, 41%; specificity, 97%). In contrast, 33% of patients with intermediate-probability scans had a PE, and PE was present in only 14% of patients with low-probability scans and 4% of those with negative scans. Investigators also found that PE can be present in a substantial percentage of high-risk patients with nondiagnostic V/Q scans. One study found that, among high-risk women, the prevalence of PE in those with low and intermediate probability on V/Q scanning was 40% and 66%, respectively.³¹ Conversely, 44% of low-risk patients with a high-probability V/Q scan did not have a PE. These findings underscore the value of first determining the patient's clinical risk category if V/Q scanning is to be used as a first-line screening method. This is problematic in pregnancy, because there are no validated risk scoring systems.

The efficacy of V/Q scanning in pregnancy was assessed by Chan and coworkers.⁵¹ They evaluated 120 consecutive pregnant women having 121 V/Q scans for suspected PE. All V/Q results were reinterpreted by two independent experts. Eight of the patients (6.6%) were already receiving treatment for VTE before their V/Q scan. Of the remaining 113 scans, 83 (73.5%) were interpreted as normal, 28 (24.8%) as nondiagnostic, and 2 (1.8%) as high-probability. None of the 104 women who did not receive treatment because of a reassuring scan (i.e., 80 with normal and 24 with nondiagnostic results) had a subsequent VTE over a follow-up period of more than 20 months. This study suggested that the negative predictive value of V/Q scanning is higher in pregnancy than among older, nonpregnant patients.

COMPUTED TOMOGRAPHIC PULMONARY ANGIOGRAPHY

CTPA has become the gold standard for the diagnosis of PE in nonpregnant patients.⁴¹ Cross and colleagues compared CTPA to V/Q scans for the initial investigation of patients with suspected PE and observed that definitive diagnoses of various etiologies were more frequent with CTPA (90% versus 54%; $P < .001$).³² However, although CTPA more often demonstrated nonembolic lesions responsible for the patients' symptoms, there was no difference in the detection rate of PE between the two groups. Meta-analysis of 23 studies demonstrated very low 3-month rates of subsequent VTE (1.4%; CI, 1.1% to 1.8%) and fatal PE (0.51%; CI, 0.33% to 0.76%) after a negative CTPA study.⁵³ These results compare very favorably with both a negative

contrast pulmonary angiogram and a negative (normal or near-normal) V/Q scan.

It had been argued that CTPA is less accurate with small, isolated subsegmental, peripheral vessels and horizontally oriented vessels in the right middle lobe. However, newer technology using spiral computed tomographic scanners with multiple detector rows and 1-mm slices appears to improve the accuracy of CTPA for diagnosing subsegmental infarcts and may reduce false-negative results to 5%.⁵⁴ In addition, traditional contrast pulmonary angiograms have relatively poor interobserver agreement (45% to 66%) for diagnosis of subsegmental PE.^{55,56} Therefore, CTPA appears to be of comparable or superior efficacy to contrast angiography.

MAGNETIC RESONANCE ARTERIOGRAPHY

Meaney and colleagues compared standard conventional intravenous contrast pulmonary angiography with magnetic resonance angiography (MRA) during the pulmonary arterial phase of the cardiac cycle after an intravenous bolus of gadolinium and observed that MRA had an overall sensitivity of 100%, a specificity of 95% (CI, 87% to 100%), and positive and negative predictive values of 87% (CI, 74% to 100%) and 100%, respectively.⁵⁷ Oudkerk and associates conducted a prospective study of MRA in which conventional contrast pulmonary angiography results were available for 118 patients at risk for PE.⁵⁸ The prevalence of PE was 30%, and MRA identified 27 of 35 patients with angiographically confirmed PE (sensitivity, 77%; CI, 61% to 90%). The sensitivity of MRA for isolated subsegmental, segmental, and central or lobar PE was 40%, 84%, and 100%, respectively. In fact, MRA identified PE in two patients with normal angiograms. Given its lack of radiation exposure, and if its efficacy is confirmed by larger studies, MRA may become the primary diagnostic test, where it is available, for ruling out PE in pregnancy.

CONVENTIONAL CONTRAST PULMONARY ARTERIOGRAPHY

Pulmonary arteriography was long considered the gold standard for the diagnosis of PE, with sensitivities and specificities of 100% by definition. However, as noted earlier, interobserver agreement decreases with smaller peripheral lesions. To perform the study, a catheter is usually placed in the right femoral, basilic, or right internal jugular vein. A PE is diagnosed by the finding of an intraluminal filling defect on two views of a pulmonary artery. The procedure has a 0.5% mortality rate and a complication rate of 3%, including sequelae of contrast injections and catheter placement such as respiratory failure (0.4%), renal failure (0.3%), cardiac perforation (1%), and groin hematoma requiring transfusion (0.2%). In light of these risks, pulmonary arteriography has fallen out of favor given the relative safety and efficacy of the other available tests.^{40,59,60} Moreover, contrast pulmonary arteriography is relatively contraindicated in the presence of a significant hemorrhagic risk (e.g., disseminated intravascular coagulation, thrombocytopenia) and in patients with renal insufficiency. Left bundle branch blocks require the use of a temporary pacemaker during the procedure to avoid induction of complete heart block.³¹

Pulmonary arteriography from the brachial vein route generates 0.5 mGy (0.05 rad) of fetal exposure, whereas the femoral vein approach generates 2.2 to 3.3 mGy (0.22 to 0.33 rad) of fetal exposure, making the former the preferable route in pregnancy.⁶¹ Concerns also exist regarding the development of fetal goiter after maternal exposure to iodinated contrast material. Therefore, the fetal heart rate should be assessed biweekly to rule out hypothyroidism, and, if delivery occurs proximate to the test, neonatal thyroid function should be checked during the first week after the procedure.⁶² Given the high sensitivity

and specificity of CTPA and MRA, as well as the relatively high maternal morbidity and concerns with both fetal irradiation and iodinated contrast exposure attendant on contrast pulmonary arteriography, the latter has fallen into disuse as a tool for diagnosing PE in pregnancy.

EVALUATION OF LOWER EXTREMITIES FOR VENOUS THROMBOSIS

Approximately 75% of patients with PE have imaging evidence of DVT, and two thirds of those lesions are present in the proximal vein. However, only a quarter of patients with symptomatic PE have symptomatic DVT.⁶³ Therefore, in stable patients before definitive diagnostic imaging, and in high-risk pregnant patients in whom CTPA, V/Q scanning, or MRA is not diagnostic, detection of leg vein DVT by VUS can establish the need for anticoagulation.⁶⁴

D-DIMER ASSAYS AS A SCREEN FOR PULMONARY EMBOLISM

A negative D-dimer concentration (<500 ng/mL) has been advocated as a “rule-out” test in patients with low probability of PE because of its high (95%) negative predictive value.³¹ Kearon and colleagues observed that, among patients at low clinical risk for PE, none of those with a negative D-dimer result and no additional diagnostic testing had a subsequent VTE, compared with 1 patient with VTE among 182 with negative D-dimer result who had additional testing.⁶⁵ They concluded that, for patients with a low probability of PE whose D-dimer result is negative, additional diagnostic testing can be withheld without increasing the frequency of VTE.

Meta-analysis of studies examining the accuracy of D-dimer determinations in the diagnosis of PE demonstrate a mean sensitivity of 95% (CI, 88.0% to 100%), a specificity of 45% (CI, 38% to 53%), and positive and negative likelihood ratios of 1.74 (CI, 1.55 to 1.91) and 0.11 (CI, 0.03 to 0.39), respectively.⁶⁶ The quantitative rapid ELISA had a sensitivity of 98% (CI, 88.0% to 100%), a specificity of 40% (CI, 29% to 50%), and positive and negative likelihood ratios of 1.62 (CI, 1.38 to 1.91) and 0.05 (CI, 0.00 to 4.15), respectively. The whole blood D-dimer assay kit yielded a sensitivity of 82% (CI, 74 to 91), a specificity of 63% (CI, 54% to 71%), and positive and negative likelihood ratios of 2.21 (CI, 1.81 to 2.70) and 0.28 (CI, 0.18 to 0.43), respectively. The authors concluded that a negative result on quantitative rapid ELISA was as diagnostically useful as a normal V/Q scan for excluding PE. As was discussed for the use of D-dimer assays in the diagnosis of DVT, the specificity and positive predictive value for D-dimer assays in the workup of patients at risk for PE are likely to be far lower in pregnant, puerperal, and postoperative patients, whereas the sensitivity and negative predictive value should be higher in these settings.

Testing Algorithms for Pulmonary Embolism

There is considerable controversy regarding the optimal paradigm for diagnosing PE in pregnancy. Clinical risk assessment tools have not been validated for pregnant patients. D-dimer testing is likely to be associated with a very high false-positive rate. Moreover, as noted earlier, concern has been expressed regarding the relatively high radiation exposure to maternal breasts after CTPA. Conversely, V/Q scans deliver higher radiation doses to the fetus, have limited application in the setting of cardiorespiratory comorbidities, and are frequently no longer available in contemporary radiology practices. MRA may prove to be the ideal alternative, but there are currently too few studies to recommend its widespread use, even where the technology is available.

Two general strategies emerge. The first (Fig. 41-4) seeks to minimize radiation exposure to both the fetus and maternal breasts by performing an initial triage based on clinical probability. Patients who

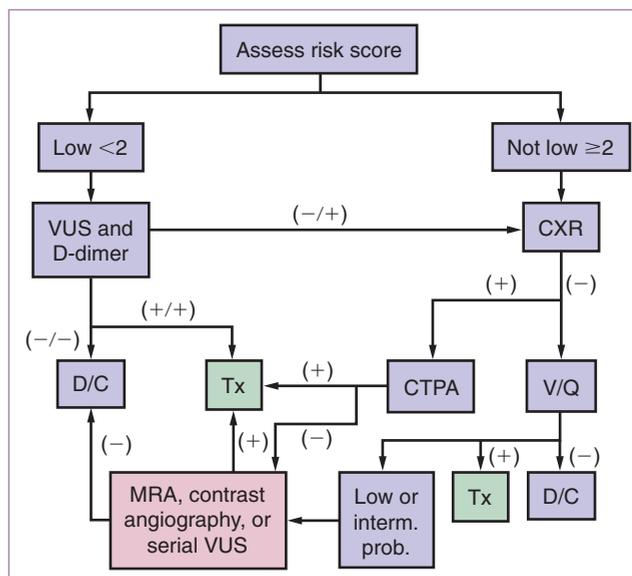

FIGURE 41-4 Testing algorithm for pulmonary emboli with initial triage based on clinical probability. CTPA, computed tomographic pulmonary angiography; CXR, chest radiography; D/C, discharge; interm. prob., intermediate probability; MRA, magnetic resonance angiography; Tx, treatment; V/Q, ventilation-perfusion studies; VUS, venous ultrasonography.

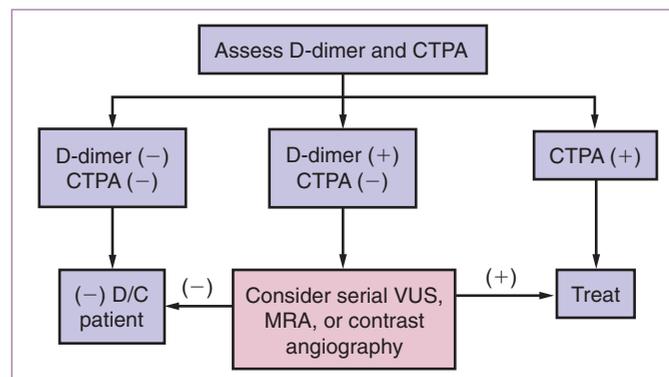

FIGURE 41-5 Testing algorithm for pulmonary emboli with triage based on results from D-dimer testing and computed tomographic pulmonary angiography (CTPA). D/C, discharge; MRA, magnetic resonance angiography; VUS, venous ultrasonography.

are deemed to be at low risk then undergo both VUS and D-dimer testing; those at high risk and those with a positive D-dimer test receive chest radiography followed by either CTPA or V/Q scanning. This approach would be favored in nonacute settings with equivocal signs and symptoms. The second approach (Fig. 41-5) seeks to maximize the speed and sensitivity of the diagnosis and should be used for patients who are more symptomatic or where there is a high index of suspicion. In this paradigm, triage is done with D-dimer testing and CTPA.

In Figure 41-4, patients should be minimally symptomatic and preferably should have reassuring oxygen saturation values (>80%). The workup commences with a risk assessment (see Table 41-3). Patients who are considered to be at low clinical risk (i.e., risk score <2) should have a VUS and D-dimer test. Obviously, if the VUS result

is positive, treatment should be initiated. If both the D-dimer and the VUS studies are negative, the patient can be discharged to routine follow-up. If the VUS is negative but the D-dimer test is positive, the patient is regarded as if she had a clinical risk assessment that was not low (i.e., ≥ 2). In these latter patients, the workup commences with a chest radiograph. If the results are positive, the patient proceeds to a CTPA. If this is positive for PE, treatment is immediately commenced. If the CTPA is negative, consideration can be given to a serial VUS if not already done. If other ancillary tests are not reassuring (e.g., low oxygen saturation, abnormal ECG), then consideration should be given to an MRA or contrast angiogram. Alternatively, if the chest radiograph is negative, a V/Q scan is performed. If this is negative or normal, the patient can be discharged to routine follow-up. If the V/Q scan indicates a high probability of PE, treatment should begin. If the V/Q scan returns an intermediate or low probability of PE, then consideration can be given to a serial VUS if not already done, or, if other ancillary tests are not reassuring, an MRA or contrast angiogram can be done.

The paradigm in Figure 41-5 should be used for women with more pronounced symptoms or unfavorable signs (e.g., oxygen saturation values $< 80\%$, abnormal ECG). The workup begins with D-dimer determination and CTPA. In patients with a high pretest probability of PE or who are very symptomatic, anticoagulation should be commenced as soon as the blood sample is sent to the laboratory for D-dimer determination. If both the D-dimer and CTPA studies are negative, the patient is at very low risk and can be discharged to routine follow-up, though the cause of her symptoms must be identified (e.g., pneumonia, pulmonary edema, cardiomyopathy, esophagitis). If the CTPA is positive, then anticoagulant treatment is begun or continued. If the CTPA is negative and the D-dimer value is positive or the index of suspicion remains high because of low oxygen saturation or an abnormal ECG, consideration should be given to a serial VUS, MRA, or contrast angiography.

Treatment of Venous Thromboembolism in Pregnancy

Patients with new-onset VTE during pregnancy should receive therapeutic anticoagulation for at least 4 months during the pregnancy, followed by prophylactic therapy continuing for at least 6 weeks after delivery. During pregnancy, either unfractionated heparin or low-molecular-weight heparin (LMWH) is the anticoagulant of choice, given its efficacy and safety profile. Neither formulation crosses the placenta, and neither poses teratogenic risks. After delivery, oral anticoagulation with warfarin may be started and is considered safe in breastfeeding mothers. The primary risks of long-term heparin therapy in pregnancy are hemorrhage and osteoporosis.

Heparin Therapy

Therapeutic Unfractionated Heparin

The initial intravenous unfractionated heparin dosage for pregnant patients with acute VTE should be determined with the use of a weight-based nomogram, and subsequent dosage modifications should be predicated on the activated partial thromboplastin time (aPTT) (Table 41-4). This regimen has been shown in nonpregnant patients to reduce recurrence rates.⁶⁷

TABLE 41-4 ADMINISTRATION OF INTRAVENOUS HEPARIN USING A WEIGHT-BASED NOMOGRAM*

aPTT Value	Adjustment
< 35 sec ($< 1.2 \times$ control)	Repeat 80 U/kg bolus, then increase infusion rate by 4 U/kg/hr
35-45 sec (1.2 - $1.5 \times$ control)	Repeat 40 U/kg bolus, then increase infusion rate by 2 U/kg/hr
46-70 sec (1.6 - $2.3 \times$ control)	No change in dosing
71-90 sec (2.4 - $3.0 \times$ control)	Decrease infusion rate by 2 U/kg/hr
> 90 sec ($> 3.0 \times$ control)	Stop infusion for 1 hr, then restart original dose decreased by 3 U/kg/hr

*Give bolus of 80 U/kg of body weight, followed by a maintenance dose of 18 U/kg/hr. Assess aPTT values every 4-6 hr and make adjustments made based on the aPTT values obtained.

aPTT, activated partial thromboplastin time.

Adapted from Raschke RA, Reilly BM, Guidry JR, et al: The weight-based heparin dosing nomogram compared with a "standard care" nomogram: A randomized controlled trial. *Ann Intern Med* 119:874-881, 1993.

The overall goal is to obtain and maintain an aPTT of 1.5 to 2.5 \times control values. The aPTT should not be used to guide unfractionated heparin therapy in patients with prolonged aPTT values due to the presence of lupus anticoagulants. In these patients, plasma heparin activity can be measured by either a protamine sulfate or an anti-factor Xa chromogenic assay. Target plasma heparin concentrations of 0.2 to 0.4 U/mL are equivalent to anti-factor Xa concentrations of 0.4 to 0.7 U/mL. The usual duration of intravenous heparin therapy is 5 days, although patients with large iliofemoral thromboses or massive PEs should receive heparin for 7 to 10 days or until clinical improvement is noted.³¹ After hospital discharge, therapeutic doses of unfractionated heparin are administered subcutaneously every 8 to 12 hours to maintain the aPTT at 1.5 to 2 \times control values 6 hours after the injection. This therapy should be continued for 20 weeks and then followed by prophylactic dosing until delivery.

The standard prophylactic regimen of unfractionated heparin used in pregnancy consists of 5000 units administered subcutaneously every 12 hours, increased by 2500 U in the second and third trimesters. However, Barbour and associates observed that this standard heparin regimen was inadequate to achieve the desired anti-factor Xa therapeutic range in 5 of 9 second-trimester pregnancies and in 6 of 13 third-trimester pregnancies.⁶⁸ Therefore, careful assessment of anti-factor Xa levels 4 to 6 hours after injection is required to properly adjust the dosage.

If vaginal or cesarean delivery occurs more than 4 hours after a prophylactic dose of unfractionated heparin, the patient is not at significant risk for hemorrhagic complications. Patients receiving unfractionated heparin who experience bleeding or require rapid reversal of the anticoagulant to effect delivery can be administered protamine sulfate by slow intravenous infusion of less than 20 mg/min, with no more than 50 mg given over 10 minutes. The amount of protamine needed to neutralize heparin is derived by determining the amount of residual heparin in the circulation, assuming a half-life for intravenously administered heparin of 45 minutes. Full neutralization of heparin activity would require 1 mg protamine sulfate per 100 units of residual circulating heparin. If the heparin was administered subcutaneously, repeated small infusions of protamine are required.

Finally, antithrombin concentrates may be used in antithrombin-deficient patients in the peripartum period.

One of the most serious potential complications of heparin therapy is heparin-induced thrombocytopenia (HIT). This condition arises in 3% of nonpregnant patients given initial heparin therapy. Type 1 HIT (HIT-1) occurs within days after initial heparin exposure, results from benign platelet clumping *in vitro*, is self-limited, is not associated with a significant risk of hemorrhage or thrombosis, and does not require cessation of therapy. In contrast, type 2 HIT is a rare, immunoglobulin-mediated syndrome paradoxically associated with venous and arterial thrombosis that occurs 5 to 14 days after initiation of therapy. Monitoring for HIT should include every-other-day platelet counts for 2 weeks.⁶⁹ Because it can be difficult to distinguish the two entities, a 50% decline in platelet count from its pretreatment high should prompt cessation of therapy. The diagnosis of HIT-2 is confirmed by serotonin release assays, heparin-induced platelet aggregation assays, flow cytometry, or solid phase immunoassays.⁷⁰ If it is confirmed, all forms of heparin, including intravenous flushes, must be avoided.

Low-Molecular-Weight Heparin

In nonpregnant patients, the mainstay of acute treatment of VTE is now LMWH. Meta-analyses of 22 studies including 8867 nonpregnant patients suggest that LMWH has fewer thrombotic complications than unfractionated heparin (3.6% versus 5.4%; OR, 0.68; CI, 0.55 to 0.84; 18 trials), produces a greater reduction in thrombus size (53% versus 45%; OR, 0.69; CI, 0.59 to 0.81; 12 trials), and results in fewer major hemorrhages (1.2% versus 2.0%; OR, 0.57; CI, 0.39 to 0.83; 19 trials) and fewer deaths (4.5% versus 6.0%; OR, 0.76; CI, 0.62 to 0.92; 18 trials).⁷¹ However, comparable data have not been assembled for pregnant patients. Nevertheless, LMWH is now commonly employed to treat acute VTE in pregnancy and also as prophylaxis.

The initial therapeutic dose of LMWH varies with the specific agent. Two agents have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of acute VTE: enoxaparin and tinzaparin. Enoxaparin is given at a dose of 1 mg/kg administered subcutaneously twice daily (i.e., every 12 hours). For tinzaparin, the dose is 175 IU/kg administered subcutaneously once daily. A third LMWH, dalteparin, has also been used off-label at doses of 100 U/kg every 12 hours. Barbour and colleagues evaluated whether the standard therapeutic doses of dalteparin maintained peak therapeutic levels of anticoagulation during pregnancy; in 85% of patients, dosage adjustments were required to maintain peak anti-Xa activity between 0.5 and 1.0 IU/mL.⁷² Given these data and the fact that pregnancy presents a period of rapidly changing volumes of distribution and fluctuating concentrations of heparin-binding proteins, it appears prudent to monitor anti-Xa activity during therapeutic treatment with LMWH in pregnant patients and to adjust the doses to maintain a therapeutic level (i.e., anti-factor Xa levels of 0.6 to 1.2 U/mL) 4 hours after an injection.

As with unfractionated heparin, treatment should continue for 20 weeks, and then prophylactic dosages should be given (e.g., enoxaparin, 40 mg SQ every 12 hr; dalteparin, 5000 U SQ once daily). There is controversy as to whether prophylactic LMWH warrants surveillance with anti-factor Xa levels. If surveillance is undertaken, the goal should be an anti-factor Xa level between 0.1 to 0.2 U/mL 4 hours after an injection.

Patients with antithrombin deficiency, and patients who are homozygotes or compound heterozygotes for the FVL or PGM mutation and have a prior VTE or affected first-degree relative, require therapeutic anticoagulation throughout pregnancy. In our practice, pregnant patients with these highly thrombogenic thrombophilias who are

without a personal or strong family history of VTE should receive subtherapeutic doses of LMWH, with the goal of maintaining anti-factor Xa levels of 0.3 to 0.7 U/mL 4 hours after injection.

Regional anesthesia is contraindicated within 24 hours after therapeutic LMWH administration because of the risk of epidural hematoma; therefore, we recommend switching to unfractionated heparin at 36 weeks, or earlier if preterm delivery is expected. However, vaginal or cesarean delivery occurring more than 12 hours after a prophylactic dose or 24 hours after a therapeutic dose of LMWH should not be associated with treatment-induced hemorrhage. If shorter intervals are encountered, protamine may partially reverse the anticoagulant effects of LMWH. The dosage is 1 mg of protamine for every 100 anti-Xa units of LMWH, but anti-factor Xa activity can be only partially (80%) reversed.⁷³

The risk of HIT-2 appears to be far lower in patients receiving LMWH compared to unfractionated heparin, and it is lower still for obstetric patients receiving prophylactic LMWH therapy.^{74,75} However, platelet counts should still be obtained every 2 or 3 days from day 4 to day 14.⁶⁹

Postpartum Anticoagulation

Unfractionated heparin or LMWH can be restarted 4 to 6 hours after vaginal delivery or 6 to 12 hours after cesarean delivery. Postpartum patients should be started immediately on warfarin. The initial doses of warfarin should be 5 mg daily for 2 days. Subsequent doses are determined by monitoring the international normalized ratio (INR). To avoid paradoxical thrombosis and skin necrosis from warfarin's initial anti-protein C effect, it is critical to maintain these women on therapeutic doses of unfractionated heparin for a minimum of 5 days and until the INR has been at therapeutic levels (2.0 to 3.0) for 2 consecutive days. After an uncomplicated initial VTE during pregnancy, without other high-risk conditions such as APA syndrome or antithrombin deficiency, therapy should be continued in the postpartum period for 3 to 6 months. Because warfarin does not significantly accumulate in breast milk and does not induce an anticoagulant effect in the infant, it is not contraindicated in breastfeeding mothers.

Management of warfarin overdoses or hemorrhagic complications is guided by the severity of the problem. For example, if patients are found to have elevated INRs (>3.0) without bleeding, vitamin K can be given orally. However, if mild bleeding is present, vitamin K can be administered subcutaneously.⁷⁶ Normalization of the INR can occur within 6 hours after a 5-mg oral or subcutaneous dose of vitamin K. Larger doses have a more rapid onset but render patients resistant to re-anticoagulation with warfarin. In the setting of significant hemorrhage, fresh-frozen plasma will replenish clotting factors and can be used with subcutaneous vitamin K to reverse the effects of warfarin.

Complex Presentations

Type 2 Heparin-Induced Thrombocytopenia

In patients with a history or new presentation of HIT-2, heparin and LMWH are contraindicated. Fondaparinux presents an excellent alternative. It is a synthetic heparin pentasaccharide that complexes with the antithrombin binding site for heparin to permit the selective inactivation of factor Xa but not thrombin. Excretion is renal, and the drug has a 15-hour half-life after a once-daily subcutaneous injection. Buller and associates conducted a randomized, double-blind trial of fondaparinux, administered subcutaneously once a day at a dose of 5.0 mg for patients weighing less than 50 kg, 7.5 mg for those weighing 50 to 100 kg, and 10.0 mg for those weighing more than 100 kg, versus

enoxaparin among 2205 patients with acute symptomatic DVT.⁷⁷ No differences in recurrent VTE were observed between the two groups. Fondaparinux is considered a pregnancy class B agent by the FDA. It has been used in a small number of pregnant patients without adverse sequelae, although it has been found to be present in umbilical-cord plasma at concentrations approximately 10% of those in the maternal plasma.⁷⁸ These levels are well below those required for effective anticoagulation. However, fondaparinux use in pregnant women is best limited to those patients with no obvious therapeutic alternatives, such as patients with HIT-2 or severe allergic reaction to heparin.

Thromboprophylaxis in Pregnant Patients with Mechanical Heart Valves

There remains considerable controversy concerning optimal management of VTE in pregnant women with mechanical heart valves. These patients are given warfarin when in the nonpregnant state. However, warfarin is loosely bound to albumin, readily crosses the placenta, and is associated with an increased rate of birth defects (OR, 3.86; CI, 1.86 to 8.00) with exposure between 8 and 12 weeks' gestation.⁷⁹ The classic fetal warfarin syndrome includes nasal hypoplasia, stippled epiphysis, and characteristic central nervous system defects including agenesis of the corpus callosum, Dandy-Walker malformation, midline cerebellar atrophy, and ventral midline dysplasia with optic atrophy. Maternal warfarin therapy after 12 weeks' gestation has been associated with fetal and placental hemorrhage which can occur throughout pregnancy.

For these reasons, the agent is usually avoided during pregnancy. However, it may be appropriate to use warfarin in pregnant patients who have a mechanical heart valve. Meta-analysis suggests that, when warfarin is used throughout pregnancy the cumulative risk of embryopathy in 6.4% (CI, 4.6% to 8.9%), but the risk of valvular thrombosis is quite low (3.9%; CI, 2.9% to 5.9%).⁸⁰ In contrast, a regimen consisting of unfractionated heparin from 6 to 12 weeks, followed by warfarin until 36 weeks and then by unfractionated heparin until delivery, appears to reduce fetal risks but is associated with a substantially increased risk of valve thrombosis (9.2%; CI, 5.9% to 13.9%).

Warfarin is best employed in pregnant patients with mechanical heart valves when the dosage can be kept lower than 5 mg/day, because cohort studies suggest that this dose is associated with a lower rate of fetal complications.⁸¹ If warfarin is used in this setting, the target INR should be 2.5 to 3.5. Low-dose aspirin should be used as an adjunct to warfarin, based on a study of antithrombotic therapy in high-risk patients with mechanical valves.⁸² Warfarin therapy should be stopped by 36 weeks, and unfractionated heparin should then be administered subcutaneously every 8 to 12 hours, with doses adjusted to keep the aPTT value at 2 × control or the anti-Xa heparin level at 0.35 to 0.70 U/mL.

No large clinical studies exist to guide use of LMWH in pregnant patients with mechanical heart valves. However, the manufacturer of enoxaparin (Lovenox, Aventis, Bridgewater, NJ) specifically recommends against its use in this setting, based on a small number of reports to the FDA of valvular thrombosis in pregnant women so treated. The Anticoagulation in Prosthetic Valves and Pregnancy Consensus Report Panel and Scientific Roundtable analyzed these reported cases of valvular thrombosis in pregnant patients receiving LMWH for mechanical heart valve prostheses in 2002 and concluded that virtually all such cases were associated with underdosing or inadequate monitoring.⁸³ Further, the panel recommended enoxaparin therapy in such patients in lieu of warfarin, beginning at a dose of 1 mg/kg SQ every 12 hours. They also recommended weekly monitoring of peak anti-factor Xa levels 4 hours after injection, as well as monitoring trough

levels immediately before the next dose. Dose adjustments should be made to insure that trough levels remain between 0.5 and 1.2 U/mL.⁸³ In addition, the use of low-dose aspirin was recommended for such patients.⁸³ These patients should be extensively counseled about the risks and benefits of these different regimens to both their own health and that of their fetus.

Thrombolytic Therapy

Although the mortality rate for expeditiously diagnosed and treated uncomplicated PE is less than 2% to 7%,⁸⁴ rates higher than 50% have been reported for patients who were hemodynamically unstable at the time of presentation.⁸⁵ This has led to more aggressive use of thrombolytic therapy in patients with massive PE. However, meta-analysis of 9 randomized, controlled trials comparing thrombolytic agents versus intravenous heparin in patients with PE found thrombolytic therapy offered no statistically significant different effect on mortality (RR, 0.63; CI, 0.32 to 1.23) or on recurrence of PE (RR, 0.59; CI, 0.30 to 1.18) compared with heparin, but such therapy was associated with a significantly increased risk of major hemorrhage (RR, 1.76; CI, 1.04 to 2.98).⁸⁶

Pregnancy poses special concerns for thrombolytic therapy given the risk of abruption and puerperal hemorrhage. Turrentine and colleagues reviewed the outcomes of 172 pregnancies treated with thrombolytic therapy and reported a maternal mortality rate of 1.2%, a fetal loss rate of 6%, and maternal hemorrhagic complications in 8%.⁸⁷ Although the data are limited, the risk of hemorrhage in the postpartum period appears to be limited to those treated within 8 hours of delivery.⁸⁸ Therefore, given the lack of clear benefit and potentially unique risks in decompensated pregnant patients refractory to heparin therapy, surgical thrombolectomy may be the preferred option.

Prevention

Nonpharmacologic Prevention

A Cochrane review of randomized, controlled trials indicated that use of graduated compression stockings in hospitalized patients with prolonged medical immobilization, or application of such stockings from before surgery until discharge or restoration of full mobility, reduced the occurrence of DVT from 27% to 13% (OR, 0.34; CI, 0.25 to 0.46).⁸⁹ A cohort study suggested that use of graduated elastic compression stockings also reduced the prevalence of VTE in puerperal patients, from 4.3% to 0.9%.⁹⁰ In addition, graduated elastic compression stockings have been shown to increase femoral vein flow velocity in late pregnancy.⁹¹

Meta-analysis in nonpregnant patients with high or moderate risk suggests that intermittent pneumatic compression devices decrease the relative risk of DVT by 62% compared with placebo, by 47% compared with graduated compression stockings, and by 48% compared with low-dose unfractionated heparin.⁹² Because graduated elastic compression stockings and pneumatic compression stockings have no hemorrhagic risk and have been shown to be an effective means of DVT prophylaxis in surgical patients and possibly in pregnant patients, they should be strongly considered for prophylaxis in high-risk pregnant patients (e.g., obesity, thrombophilia, strong family history) who are admitted for labor and/or delivery or who require prolonged bed rest, and also in all pregnant patients undergoing an elective or repeat cesarean delivery without prior labor. Caution must be exercised in their immediate preoperative use after labor, because DVT may

have already formed and could be theoretically dislodged by either device.

Finally, in pregnancy, left-lateral decubitus positioning during the third trimester may also reduce the risk of VTE.

Pharmacologic Prevention

As noted, among pregnant patients who have had a previous VTE, recurrence risks are highly dependent on the presence of a thrombophilia and the nature of the risk factors associated with the prior thrombus.²⁶ Whereas VTE recurrences were not observed in women without detectable thrombophilias whose previous VTE was associated with a temporary risk factor, 16% of thrombophilic patients who did not receive thromboprophylaxis during pregnancy had a recurrent VTE.²⁶ However, even the former group of patients require postpartum thromboprophylaxis. In addition, it has been argued that thrombophilic patients who are without a personal history of VTE but who have an affected first-degree relative should also receive thromboprophylaxis during pregnancy and the postpartum period. Those with highly thrombogenic thrombophilias (e.g., antithrombin deficiency, homozygosity or compound heterozygosity for the FVL or PGM mutation) should receive both therapeutic or subtherapeutic doses of LMWH throughout pregnancy and postpartum anticoagulation. However, such therapy does not appear to be justified during the antepartum period in patients with less thrombogenic thrombophilias (e.g., heterozygosity for FVL or PGM, protein C deficiency, protein S deficiency) who are without a personal or strong family history of VTE. However, these patients should receive postpartum anticoagulation if they require a cesarean delivery, to reduce the risk of a fatal PE.

A very limited number of studies have assessed the value of perioperative thromboprophylaxis in cesarean delivery.^{93,94} However, perioperative thromboprophylaxis with low-dose unfractionated heparin may be appropriate for patients undergoing cesarean delivery who have a history of VTE and known highly thrombogenic thrombophilia, as well as those with mechanical heart valve prostheses.

Inferior Vena Cava Filters

Inferior vena cava filters are designed for use in patients in whom anticoagulation is absolutely contraindicated, such as those with a hemorrhagic stroke, recent or current hemorrhage, or recent surgery. This intervention appears to be appropriate in patients who have recurrent PE despite adequate anticoagulation and in those in whom a PE would probably be lethal (e.g., patients with pulmonary hypertension). Pregnant patients with a history of HIT-2 were traditional candidates for inferior vena caval filters, but the use of fondaparinux during pregnancy and the direct thrombin inhibitors (e.g., Lepirudin) in the postpartum period has rendered this indication less absolute.⁹⁵ Although the use of filters is generally discouraged in younger patients, retrievable filters have been employed successfully in pregnant women and may prove ideal in this setting.⁹⁶

Summary

Acute PE remains a leading cause of maternal morbidity and mortality. Periods of maximal risk include the immediate puerperal perioperative period. Additional risk factors include prior VTE, positive family history, obesity, thrombophilias, infection, trauma, and immobilization. The prompt diagnosis of VTE requires assessment of clinical risk

followed by initiation of the proper diagnostic algorithm. Treatment requires prompt initiation of unfractionated heparin or LMWH. Prevention includes identification of high-risk patients and both nonpharmacologic and pharmacologic interventions.

Chapter 42

Anemia and Pregnancy

Sarah J. Kilpatrick, MD, PhD

Anemia is defined as a hemoglobin (Hb) value less than the lower limit of normal that is not explained by the state of hydration. This definition has physiologic validity, in that it is the amount of Hb per unit volume of blood that determines the oxygen-carrying capacity of blood. The normal Hb level for the adult female is 14.0 ± 2.0 g/dL.¹ Based on this normal value, 20% to 60% of prenatal patients will be found to be anemic at some time during their pregnancy. In one study, 32% of women presenting at less than 7 weeks' gestation had an Hb value lower than 12 g/dL, suggesting that the prevalence of anemia is high.² Because of the normal hemodilution that occurs during pregnancy, the Centers for Disease Control and Prevention defines anemia in pregnancy as an Hb concentration lower than 11 g/dL in the first and third trimesters, or lower than 10.5 g/dL in the second trimester.³ Some women with mild anemia will be missed using this definition.

Clinical Presentation

Symptoms caused by anemia are those resulting from tissue hypoxia, the cardiovascular system's attempts to compensate for the anemia, or an underlying disease. Tissue hypoxia produces fatigue, lightheadedness, weakness, and exertional dyspnea. Cardiovascular compensation leads to a hyperdynamic circulation, with attendant symptoms of palpitations and tachycardia. Clinical conditions commonly associated with anemia in pregnancy include multiple pregnancy, trophoblastic disease, chronic renal disease, chronic liver disease, and chronic infection. In obstetric patients, however, anemia is most commonly discovered not because of symptoms but because a complete blood count (CBC) is obtained as part of routine laboratory evaluation, either at the initial prenatal visit or at repeat screening at 24 to 28 weeks' gestation.

Evaluation of Anemia

Anemia is not a diagnosis; rather, like fever or edema, it is a sign. The key issue in the evaluation of anemia is to define the underlying mechanism or pathologic process. Although a mild anemia caused by iron deficiency during pregnancy is of little consequence to either the mother or the fetus, a similarly mild anemia caused by carcinoma of the colon has grave implications. One must also keep in mind the genetic implications of many anemias, such as the hemoglobinopathies and hereditary spherocytosis.

Table 42-1 presents a classification of anemia based on the pathophysiologic mechanism involved. Although a mechanistic classifica-

tion of anemia provides an exhaustive catalog of diagnoses, it does not lend itself to a systematic investigation of an individual patient. Rather, when the patient is anemic one wants to know (1) the morphology of the anemia and (2) the reticulocyte count. Determining the answers to these questions allows one to make a first approximation of a specific diagnosis and to answer the following questions:

1. What is the mechanism of the anemia?
2. Is there an underlying disease?
3. What is appropriate treatment?

The CBC and the reticulocyte count provide the answers to the first two questions. These data allow a morphologic classification of the anemia and indicate whether the marrow is hyperproliferative or hypoproliferative. The patient's Hb value is determined by converting the pigment to cyanmethemoglobin and quantitating the amount spectrophotometrically. The remainder of the values are obtained by flow cytometry with an electronic cell counter.

Based on the size of the red blood cells (RBCs), anemia can be classified as microcytic, normocytic, or macrocytic. The appearance of the RBCs may also provide a clue to the mechanism of the anemia. For example, hypochromic microcytic cells associated with a low reticulocyte count suggests iron deficiency, thalassemia trait, sideroblastic anemia, or lead poisoning. Oval macrocytes combined with a low reticulocyte count and hypersegmented polymorphonuclear leukocytes suggest megaloblastic anemia (vitamin B₁₂ or folate deficiency). Oval microcytes and an elevated reticulocyte count are characteristic of hereditary spherocytosis. Various poikilocytes, such as sickle cells, acanthocytes, target cells, and schistocytes, suggest sickle cell disease, acanthocytosis, Hb C disease, and mechanical RBC destruction, respectively. Although the CBC is an excellent first step in the approximate diagnosis of anemia, additional studies are usually necessary to confirm the diagnosis. Table 42-2 lists laboratory studies frequently used in the evaluation of an anemic patient.

Serum Hb and serum haptoglobin levels are useful in defining intravascular hemolysis. If serum haptoglobin is absent or low in conjunction with an elevated serum Hb, the presence of intravascular hemolysis is established. Further studies are necessary to rule in or rule out specific causes of intravascular hemolysis, such as severe autoimmune hemolytic anemia (direct Coombs test), paroxysmal nocturnal hemoglobinuria (PNH) (osmotic fragility), and hemoglobinopathies including sickle cell disease and thalassemia major (Hb electrophoresis).

Total bilirubin is elevated modestly in hemolytic anemia (rarely in excess of 4 mg/dL). The increase results predominantly from an

TABLE 42-1 ANEMIA CLASSIFIED BY PATHOPHYSIOLOGIC MECHANISM

- I. Dilutional (expansion of the plasma volume)
 - A. Pregnancy
 - B. Hyperglobulinemia
 - C. Massive splenomegaly
- II. Decreased RBC production
 - A. Bone marrow failure
 1. Decreased building blocks or stimulation
 - a. Iron, protein
 - b. Chronic infection, chronic renal disease
 2. Decreased erythron
 - a. Hypoplasia (hereditary, drugs, radiation, toxins)
 - b. Marrow replacement (tumor, fibrosis, infection)
 - B. Ineffective production
 1. Megaloblastic (vitamin B₁₂ and folate deficiency, myelodysplasia, erythroleukemia)
 2. Normoblastic (refractory anemia, thalassemia)
- III. Increased RBC loss
 - A. Acute hemorrhage
 - B. Hemolysis
 1. Intrinsic RBC disorders
 - a. Hereditary
 - (1) Hemoglobinopathies
 - (2) RBC enzyme deficiency
 - (3) Membrane defects
 - (4) Porphyrrias
 - b. Acquired
 - (1) Paroxysmal nocturnal hemoglobinuria
 - (2) Lead poisoning
 2. Extrinsic RBC disorders
 - a. Immune
 - b. Mechanical
 - c. Infection
 - d. Chemical agents
 - e. Burns
 - f. Hypersplenism
 - g. Liver disease

RBC, red blood cell.

increase in the indirect fraction. However, significant hemolysis can occur without an elevation in the bilirubin. Therefore, the bilirubin level is helpful only when it is elevated.

The direct Coombs test uses anti-human immunoglobulin to detect immunoglobulins attached to the surface of RBCs. A positive test indicates an immune cause for a hemolytic anemia. In such cases, it is important to search for underlying causes for autoimmunity, such as connective tissue disease, lymphoma, carcinoma, and sarcoidosis. The diagnosis and management of glucose-6-phosphate dehydrogenase (G6PD) deficiency and of the various hemoglobinopathies are discussed later in this chapter.

The free erythrocyte protoporphyrin (FEP),⁴ plasma iron, plasma total iron-binding capacity (TIBC),⁵ and serum ferritin level^{6,7} are useful in establishing a diagnosis of iron deficiency. Protoporphyrin is generated in the penultimate step of heme synthesis, with iron subsequently incorporated into protoporphyrin to create heme. Iron deficiency causes elevated FEP. Serum ferritin correlates closely with body iron stores, and many investigators support the use of serum ferritin as the best single test in patients with anemia to make a diagnosis of iron deficiency anemia.^{6,8} A ferritin level of 12 µg/L or lower is consistent with iron deficiency anemia. Plasma iron and serum ferritin levels are both increased after ingestion of iron.^{9,10} Therefore, iron therapy

TABLE 42-2 LABORATORY STUDIES USEFUL IN EVALUATION OF ANEMIA

Laboratory Study	Reference Range
Red blood cell (RBC) count	4.0-5.2 × 10 ¹² /L
Mean corpuscular volume (MCV)	80-100 µm ³
Mean corpuscular hemoglobin concentration (MCHC)	31-36 g/dL
Reticulocyte count	48-152 × 10 ⁹ /L (0.5-1.5%)
Serum (free) hemoglobin	1.0-5 mg/dL
Serum haptoglobin	30-200 mg/dL
Total bilirubin	0.1-1.2 mg/dL
Direct Coombs test	Negative
Hb electrophoresis	>98% A <3.5% A ₂ <2% F
Serum ferritin	>20 µg/L
Plasma iron	33-102 µg/dL
Plasma total iron-binding capacity	194-372 µg/dL
Transferrin saturation	16-60%
Folate level	
Serum	>20 µg/L
Red blood cells	165 ng/mL
Serum vitamin B ₁₂	190-950 ng/L
Anti-intrinsic factor antibody (AIF)	Negative

must be discontinued for 24 to 48 hours before these studies are carried out. In iron deficiency, the FEP increases approximately fivefold. Iron is transported in the plasma bound to transferrin. In the iron-deficient state, the plasma iron decreases, the TIBC increases, and the percent of iron saturation decreases. In contrast, with chronic infection, both the plasma iron and the TIBC are decreased, but the percent saturation remains normal.

Serum folate, RBC folate, and serum vitamin B₁₂ levels are useful in defining the cause of macrocytic anemia. Because the RBC folate more accurately reflects the body's folate stores, many laboratories no longer offer the serum folate determination. The presence of serum intrinsic factor antibodies is specific for pernicious anemia. However, they are undetectable in approximately 40% of cases, so the absence of these antibodies does not rule out a diagnosis of pernicious anemia.

Although a bone marrow aspiration or biopsy can add much useful information, it is rarely done today in pregnant anemic women. In addition to providing a ratio of myeloid to erythroid production (normal, approximately 3:1), it provides a measure of iron stores, allows a differential count of myeloid and erythroid precursors, provides evidence of infiltration with neoplasm, and allows histologic and bacteriologic confirmation of infection.

Normal Hematologic Events Associated with Pregnancy

Blood Volume Changes

During pregnancy, there is normally a 36% increase in the blood volume, the maximum being reached at 34 weeks' gestation.¹¹ The plasma volume increases by 47%, but the RBC mass increases only by 17%; the latter reaches its maximum at term. As shown in Figure 42-1,

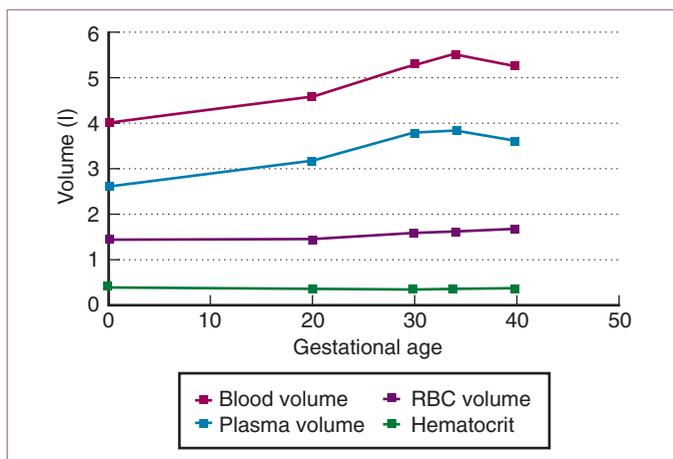

FIGURE 42-1 Hematologic changes during pregnancy. RBC, red blood cell. (Redrawn from Peck TM, Arias F: Hematologic changes associated with pregnancy. Clin Obstet 22:785, 1979.)

this disparity produces a relative hemodilution throughout pregnancy, which reaches its maximum between 28 and 34 weeks. Although this dilutional effect lowers the Hb, hematocrit (Hct), and RBC count, it causes no change in the mean corpuscular volume or in the mean corpuscular Hb concentration. Therefore, serial evaluation of these two indices is useful in differentiating dilutional anemia from progressive iron deficiency anemia during pregnancy: In the former, the indices do not change; in the latter, they decrease progressively.

Iron Kinetics

The classic study by Scott and Pritchard shows that iron stores in healthy women are marginal at best.¹² These authors evaluated iron stores in the bone marrow of healthy, white college students who had never been pregnant and had never donated blood. Approximately two thirds had minimal iron stores. In another study, Pritchard and colleagues demonstrated that almost 50% of healthy primigravidas had minimal iron stores in the marrow during the first trimester.¹³

The major reason for poor iron stores is thought to be menstrual loss. Data from Monsen and associates indicated that the usual menstrual loss is 25 to 30 mL of whole blood.¹⁴ This is equivalent to 12 to 15 mg of elemental iron, because each milliliter of blood contains 0.5 mg of iron. To meet the iron loss for menses alone, a woman must absorb 1.5 to 2.0 mg of elemental iron from her diet each day. Because only 10% of dietary iron is usually absorbed, and the average diet contains only 6 mg/1000 kilocalories, a woman's iron balance is precarious at best.

Pregnancy presents substantial demands on iron balance, exceeding that saved by 9 months of amenorrhea.¹³ Table 42-3 lists the iron requirements for pregnancy. If available iron stores are insufficient to meet the demands of pregnancy, iron-deficient erythropoiesis results. In a prospective study of 35 nonanemic women, ferritin levels were measured before and during pregnancy to determine the relationship of iron stores to developing anemia.¹⁵ Approximately 60% of the women with a ferritin concentration less than 20 µg/L before pregnancy were anemic by 20 weeks' gestation, compared with 25% of women with normal prepregnancy ferritin levels. Fenton and colleagues used serum ferritin levels to evaluate iron stores in pregnant women and found significantly higher ferritin levels in women who

TABLE 42-3 IRON REQUIREMENTS FOR PREGNANCY

Required for	Average (mg)	Range (mg)
External iron loss	170	150-200
Expansion of red blood cell mass	450	200-600
Fetal iron	270	200-370
Iron in placenta and cord	90	30-170
Blood loss at delivery	150	90-310
Total requirement	980	580-1340
Requirement less red blood cell expansion	840	440-1050

were receiving iron supplementation than in those who were not.¹⁶ The usual sequence of events in regard to iron deficiency is an absence of iron in the marrow followed by the development of abnormal plasma iron studies (transferrin, ferritin, or FEP). The RBCs first become microcytic, then hypochromic. Finally, anemia develops.

Most women enter pregnancy with marginal iron stores. Pregnancy places a large demand on iron balance that cannot be met with the usual diet. In the absence of supplementation, iron deficiency develops. Supplementation with 60 mg of elemental iron per day during the second and third trimesters meets the daily requirement. The Institute of Medicine recommends that supplementation be offered only to women whose serum ferritin level is less than 20 µg/L.¹⁷ Although this is a valid recommendation scientifically, the high cost of the screening limits its applicability.

The fetal compartment preferentially obtains iron, folate, and vitamin B₁₂ from—and at the expense of—the mother.¹⁸⁻²⁰ Maternal iron is transferred to the fetus via serum transferrin. Transferrin binds to receptors in placental syncytiotrophoblast, where the iron is released and subsequently binds to ferritin in placenta cells. It is then transferred to apotransferrin, which enters into the fetal circulation as holo-transferrin. If maternal iron status is low, placental transferrin receptors increase to facilitate more uptake of iron by the placenta.²¹

Folate

Folic acid, a water-soluble vitamin, is widely available in the diet. Dietary folates are, in fact, a family of compounds that appear as polyglutamates. In humans, the only source of folate is the diet, and absorption occurs primarily in the proximal jejunum. Before folate can be absorbed, it must be reduced to the monoglutamate form.²² Pancreatic conjugases within the intestine are responsible for this process. The activity of conjugase is decreased by use of anticonvulsants, oral contraceptives, alcohol, or sulfa drugs.²³ Therefore, in addition to an absolute diminution in dietary intake, the combination of increased need (e.g., multiple pregnancy, hemolytic anemia) and decreased absorption can lead to folate deficiency.^{20,24,25}

The folate requirement of 50 µg/day for a nonpregnant woman increases to 300 to 500 µg/day during pregnancy.^{13,26} Because adequate folate intake before and during the first weeks of pregnancy reduces the occurrence of neural tube defects, all women considering pregnancy should consume 400 µg of folate per day.²⁷ One study estimated that a folate supplementation of 400 µg/day would reduce the risk of neural tube defects by 36%, and that 5 mg/day would reduce the risk by 85%.²⁸ If a previous pregnancy was complicated by a neural tube defect, the mother's intake of folate should be 4 mg/day in the next

pregnancy, starting at least 4 weeks before conception and continuing through the first 3 months of pregnancy.^{27,29} When folate depletion occurs, the usual sequence of events is a decreased serum folate, hypersegmentation of polymorphonuclear leukocytes, a decrease in RBC folate, the appearance of ovalocytes in the blood, development of an abnormal marrow, and, finally, anemia.²²

Vitamin B₁₂

Vitamin B₁₂, also abundantly available in the diet, is bound to animal protein. Absorption requires hydrochloric acid and pepsin to free the cobalamin molecule from protein. Intrinsic factor is also essential for absorption. After absorption, transport occurs via binding to transcobalamin II. Most of the vitamin B₁₂ is stored in the liver, and individuals typically have a 2- to 3-year store available.⁵

Morphologic Classification of Anemia

Microcytic Anemia

The microcytic anemias are characterized by abnormal Hb synthesis with normal RBC production. A logical progression of diagnostic steps requires, first, that iron deficiency anemia be ruled out. If iron deficiency anemia is diagnosed rather than ruled out, it is important to consider gastrointestinal bleeding as the cause, although it is rare in pregnant women. This can be accomplished by testing the stool for the presence of occult blood with guaiac or other equally sensitive reagent. If a microcytic anemia is not the result of iron deficiency, one must seek another cause, such as hemoglobinopathy, chronic infection, or one of the sideroblastic anemias. For this purpose, the following tests should be considered:

- Hb electrophoresis
- Plasma iron and TIBC
- FEP
- DNA probing for α -genes
- Bone marrow examination

As noted, iron deficiency anemia is associated with decreased serum iron, increased TIBC (>400 μ g/dL), reduced serum ferritin concentration (<30 μ g/L), and elevated FEP. Anemia of chronic disorders is associated with decreased serum iron and elevated FEP but paradoxically normal or increased ferritin and decreased TIBC. If the serum iron and TIBC are normal or increased and FEP is normal, the patient usually has thalassemia or a sideroblastic anemia. Hb electrophoresis and DNA probes are used to define the thalassemias, and ring sideroblasts are present in the bone marrow of individuals with hereditary or acquired sideroblastic anemia.

Normocytic Anemia

Because of the diverse nature of normocytic anemia, it is the most difficult type to evaluate. The reticulocyte count varies according to whether RBC production is increased, normal, or decreased. If erythropoiesis is increased, one must differentiate between hemorrhage and an increased rate of destruction. The blood smear may reveal a type of RBC shape that can be virtually diagnostic. Fragmented cells are seen in microangiopathic hemolysis—as in the HELLP syndrome

(hemolysis, elevated liver enzymes, low platelets) and thrombotic thrombocytopenic purpura—and in association with prosthetic heart valves. Other types of poikilocytes identified include sickle cells, target cells, stomatocytes, ovalocytes, spherocytes, elliptocytes, and acanthocytes.

The Coombs test differentiates immune from nonimmune causes of hemolysis. Immune hemolysis is related to alloantibodies, drug-induced antibodies, and autoantibodies. Nonimmune causes of hemolysis include various hemoglobinopathies, hereditary disorders of the RBC membrane (spherocytosis and elliptocytosis), hereditary deficiency of an RBC enzyme, and the porphyrias. Acquired nonimmune hemolysis is caused by either PNH or lead poisoning.

Bone marrow examination is essential for the evaluation of patients who have hypoproliferative anemias with normal iron studies. If erythropoiesis is megaloblastic, folate or vitamin B₁₂ deficiency is a likely cause. If it is sideroblastic, both acquired and hereditary forms of sideroblastic anemia must be considered.

Finally, if erythropoiesis is normoblastic, etiologic mechanisms fall into two major categories. The first category has myeloid-to-erythroid production ratios greater than 4:1 and includes aplasia, bone marrow infiltration, effects of chronic diseases, and endocrine disorders such as hypothyroidism and hypopituitarism. In the second category, there is ineffective erythropoiesis, usually associated with a myeloid to erythroid production ratio lower than 2:1.

Macrocytic Anemia

Macrocytic anemia is associated with either (1) an increased rate of RBC production and release of less than fully mature RBCs or (2) disorders of impaired DNA synthesis. Early use of a bone marrow examination is helpful in pointing the investigation in the correct direction. If maturation is megaloblastic, abnormal serum vitamin B₁₂ and RBC folate levels allow a diagnosis of vitamin B₁₂ or folate deficiency. If a diagnosis of folate deficiency is confirmed, the various causes of decreased deconjugation of the polyglutamate and malabsorption must be considered. If anti-intrinsic factor antibodies are present, a diagnosis of pernicious anemia is ensured. If anti-intrinsic factor antibodies are absent, a Schilling test is required to differentiate between pernicious anemia and a small-bowel malabsorption syndrome. The Schilling test is performed by oral loading with cobalt 58—labeled cobalamin. Urinary excretion of cobalamin measured over 24 hours is then assessed. If abnormal excretion is noted (<10%), the test is repeated with ⁵⁸Co-labeled cobalamin bound to intrinsic factor. If pernicious anemia is present, excretion will normalize; if malabsorption is the cause, excretion will remain reduced.

Anemia and Perinatal Morbidity and Mortality

Fetal Effects of Maternal Anemia

Although it has been traditionally taught that significant maternal anemia is associated with suboptimal fetal outcome, data supporting this concept are scarce. Most recent studies, including a meta-analysis, reported a significant relationship between anemia early in pregnancy and preterm delivery but no significant association with small-for-gestational-age (SGA) neonates.³⁰⁻³³ Earlier studies reporting on maternal anemia and poor fetal outcome produced conflicting data.³⁴⁻³⁷ Studies in sheep showed that fetal oxygen consumption is maintained

until the maternal Hct was reduced by more than 50%.³⁸ Therefore, maternal anemia needs to be severe to affect the fetus.

Elevated Hb early in pregnancy has also been associated with poor perinatal outcome, including stillbirth and SGA neonates.^{39,40} In a case-control study, women with stillbirths had a significantly higher incidence of Hb higher than 14.5 g/dL than did control women without stillbirths.⁴⁰ Although the mechanism for this association is unknown, the authors hypothesized that high Hb may be a marker of inadequate plasma-volume expansion and hence reduced blood flow to the intervillous space. An alternate hypothesis was offered by Sagen and associates, who believed that these data were evidence of chronic hypoxia.³⁹

In Africa, Asia, and Latin America, the relative risk of maternal mortality with severe anemia (Hb < 4.7 g/dL) was significantly elevated at 3.5.⁴¹ In a case series of 130 women with a Hb less than 5 g/dL in the third trimester in India, more than half had a preterm delivery, and more than 25% had postpartum hemorrhage, sepsis, or a stillbirth. Further, eight women died.⁴² However, these studies and others are fraught with confounders, including hemorrhage at delivery and lack of access to care, so it is difficult to know whether the key factor associated with these deaths was the baseline anemia. Therefore, although profound maternal anemia can have adverse effects on the fetus, the margin of safety appears to be large. It may be that the prevalence of severe anemia is too low in industrialized countries to see consistent associations with poor fetal or maternal outcomes.

Although there is no association between maternal third-trimester Hb and cord-blood Hb, maternal Hb and/or ferritin were significantly associated with cord-blood ferritin.^{21,43} In several studies, the umbilical cord-blood ferritin levels of infants whose mothers were iron deficient were reduced, compared with those of infants whose mothers were not iron deficient.^{16,44} Yet, infants whose ferritin levels were low were not anemic and had normal iron kinetics, and their serum ferritin values were not in the iron-deficient range. In a study of newborns of women with severe folate deficiency, Pritchard and colleagues found normal neonatal levels of folate.¹³ Even more interesting, Colomer found that 1-year-old infants had a 5.7-fold increased risk of anemia if their mothers were anemic at delivery, compared with nonanemic mothers, even after the data were controlled for feeding practices and socioeconomic status.⁴⁵ In another interesting trial, iron supplementation in women who were not anemic in the first trimester was associated with a significant reduction in the incidence of birth weight less than 2500 g and in incidence of SGA neonates.⁴⁶ This trial randomized nonanemic women to receive 30 mg ferrous sulfate or placebo by 20 weeks' gestation. Almost 17% of the placebo-treated women but only 4% of the iron-treated women had low-birth-weight neonates, and 18% and 7%, respectively, had babies that were SGA. These provocative results, indicating that improved iron reserves enhance fetal growth independent of anemia status, may be generalizable only to populations with a high incidence of smoking, because 36% to 40% of the women in each group smoked. However, another randomized trial of routine versus indicated (Hb < 10 g/dL) treatment with iron revealed no difference in perinatal outcome or long-term outcome, including subsequent pregnancies.⁴⁷

Genetic Implications

Many of the hemolytic anemias are inherited as either autosomal-dominant or recessive traits. Therefore, once the correct diagnosis has been made, the genetic implications should be thoroughly discussed with the patient and her partner. If appropriate, the discussion should include antenatal diagnosis.

Specific Anemias

Space does not allow a detailed discussion of the diagnosis and treatment of literally hundreds of different anemias. Instead, a scheme of diagnostic studies that are useful in evaluating any anemia and a discussion of specific anemias that are commonly seen during pregnancy are presented.

Iron Deficiency Anemia

Iron deficiency is the cause of 75% of all anemias in pregnancy, and its prevalence may be as high as 47%.⁴⁸⁻⁵⁰ Clinical symptoms include easy fatigue, lethargy, and headache. Pica, which may involve the ingestion of clay, dirt, ice, or starch, is a classic manifestation of iron deficiency and was significantly associated in one study with lower maternal Hb but not with adverse pregnancy outcomes.⁵¹ Clinical findings include pallor, glossitis, and cheilitis. Koilonychia has been associated with iron deficiency anemia but is a rare finding. The laboratory characteristics of iron deficiency anemia are a microcytic, hypochromic anemia with evidence of depleted iron stores, low plasma iron, high TIBC, low serum ferritin, and/or elevated FEP. If a bone marrow examination is performed, stainable iron is found to be markedly depleted or absent. Although iron supplementation has not been shown to alter perinatal outcome, the Centers for Disease Control and Prevention strongly recommends screening and treatment of iron deficiency anemia in pregnancy.^{6,52,53} The rationale is that treatment maintains maternal iron stores and may be beneficial for neonatal iron stores.⁶

The specific treatment is oral iron, most commonly ferrous sulfate, 325 mg one to three times daily. Other iron preparations are more expensive and do not offer any advantage over ferrous sulfate if equal amounts of elemental iron are given. Reticulocytosis should be observed after 7 to 10 days of therapy, and the Hb can rise by as much as 1 g/wk in severely anemic individuals. Absorption from the gastrointestinal tract can be enhanced by the administration of 500 mg of ascorbic acid with each dose of iron. Gastrointestinal side effects associated with iron therapy include nausea, vomiting, abdominal cramps, diarrhea, and constipation. These symptoms correspond to the dose of elemental iron ingested; if symptoms are troublesome, the dose of iron should be reduced. Ferrous sulfate syrup (300 mg/5 mL) is an effective way of tailoring the dose to the patient's tolerance. Once the anemia has resolved, the patient should continue to receive iron therapy for an additional 6 months to replace iron stores.

Parenteral administration of iron is rarely indicated and should be reserved for patients with a malabsorption syndrome and those who refuse to take oral iron and are significantly anemic (Hb < 8.5 g/dL).⁵⁴ There are currently three parenteral forms of iron approved for use in the United States: iron dextran, sodium ferric gluconate, and iron sucrose.⁵⁵ These are usually given intramuscularly or intravascularly, and, because severe anaphylaxis can occur in 1% of patients, a test dose should be administered first. In the absence of any reaction, daily injections of 2 mL (100 mg) can be administered until the full dose is reached. Iron dextran contains 50 mg of iron per milliliter and comes in 2-mL ampules. The required dose of iron dextran needed to correct anemia and replenish stores can be calculated as follows⁵⁶:

1. Milligrams of Fe needed = Hb deficit (in g/dL) × lean body wt (lb) + 1000, where the Hb deficit is calculated for women as 12 minus the patient's Hb value

2. Milliliters of iron dextran needed = mg of Fe needed ÷ 50 mg/mL

Iron sucrose and sodium ferric gluconate preparations appear to have fewer adverse events, including anaphylaxis, in part because of lower molecular weights.⁵⁵⁻⁵⁷ In a recent study, oral iron was compared with intravenous iron sucrose in a randomized trial of pregnant women with Hb values of 8 to 10 g/dL.⁵⁸ The increase in Hb (2 g/dL) was the same in both groups at day 30. In another, partially randomized study comparing oral iron with intramuscular iron dextran in anemic women, there was no significant difference in term Hb levels but a significant increase in ferritin in the group treated with intramuscular iron, compared with orally treated women.⁵⁹ In contrast, another randomized trial comparing oral to intravenous iron sucrose found that the latter was associated with a significantly larger increase in Hb at 2 and 4 weeks and at delivery.⁶⁰ However, at delivery, there was less than 1 mg/dL difference between the mean Hb values in the two groups. The authors reported no serious side effects in either group.

Subcutaneous erythropoietin with or without oral iron therapy or intravenous iron sucrose has been used successfully to treat severe iron deficiency anemia in pregnancy, with no significant risks to the mother.⁶¹⁻⁶³ In one study in women for whom oral iron therapy had failed and who had an Hb value lower than 8.5 g/dL, the addition of erythropoietin to oral iron was associated with normalization of Hb in 2 weeks in 73% of the women.⁶² Darbepoetin alfa, which has a longer half-life than erythropoietin, has also been used to successfully treat anemia after renal transplantation in a pregnant patient.⁶⁴

Megaloblastic Anemia

Megaloblastic anemia is the second most common nutritional anemia seen during pregnancy. Most commonly, folate deficiency is the cause, but a deficiency in vitamin B₁₂ must also be considered. The etiology of these anemias are poor nutrition and or decreased absorption. With the increase in pregnancies occurring after bariatric surgery, it is possible that bariatric surgery may become a common cause of folate or B₁₂ deficiency in pregnancy in the United States.⁶⁵

Patients with folate deficiency present with the typical symptoms of anemia plus roughness of the skin and glossitis. The CBC reveals a macrocytic or normocytic, normochromic anemia with hypersegmentation of the polymorphonuclear leukocytes. The reticulocyte count is normal or low, and the white blood cell and platelet counts are frequently decreased. Bone marrow examination is not usually necessary for diagnosis, but if it is done, megaloblastic erythropoiesis is noted. The RBC folate level is decreased to less than 165 ng/mL (serum folate to less than 2 µg/L), and the vitamin B₁₂ level is normal. Treatment consists of oral folic acid administered in a dose of 1 mg/day. Parenteral folic acid may be indicated for individuals with malabsorption. A reticulocyte response should be seen in 48 to 72 hours, and the platelet count should normalize within a few days. The neutrophils normalize after 1 to 2 weeks.

In addition to anemia, women with vitamin B₁₂ deficiency may also manifest neurologic defects relating to damage to the posterior columns of the spinal cord. It is critical that individuals with vitamin B₁₂ deficiency not be treated with folic acid alone. Such treatment may well improve the anemia but has absolutely no salutary effect on the neuropathy and, in fact, may make it worse. As with folate deficiency, vitamin B₁₂ deficiency is associated with dietary deficiency, an increased requirement, or both. Except in strict vegetarians who avoid all animal products, dietary deficiency is rare.

The most common causes of vitamin B₁₂ deficiency are autoimmune inhibition of intrinsic factor production (pernicious anemia), inadequate production of intrinsic factor after gastrectomy, and the presence of a malabsorption syndrome. The morphologic features of B₁₂ deficiency are similar to those of folate deficiency. In this instance, the serum vitamin B₁₂ level is low and the folate level is normal. Because ineffective erythropoiesis is a prominent feature, evidence of low-grade hemolysis may be present (increased bilirubin and decreased haptoglobin). The measurement of anti-intrinsic factor antibodies is useful. Treatment consists of an intramuscular dose of 1000 µg (1 mg) of vitamin B₁₂ every day for 1 week, then 1 mg every week for 4 weeks, and then 1 mg every month for the remainder of the patient's life in cases of pernicious anemia. A prompt reticulocyte response is anticipated after 3 to 5 days of therapy.

Hereditary Spherocytosis and Elliptocytosis

Spherocytosis is the most common form of inherited hemolytic anemia. The inheritance is autosomal-dominant with variable penetrance. Hereditary spherocytosis (HS) is characterized by a structural defect in the erythrocyte membrane caused by several different molecular defects in the membrane proteins, including spectrin deficiency and ankyrin deficiency.⁶⁶ The classic characteristic is an increased RBC osmotic fragility. The prevalence of the disorder is 2-3/10,000, which implies around 1000 pregnancies annually in women with spherocytosis. A hemolytic crisis can be precipitated by many conditions, such as infection, trauma, and pregnancy itself.⁶⁷ A relationship between increased hemolysis and increased maternal blood volume and splenic blood flow has been proposed. An alternative suggestion is an increased osmotic fragility during the third trimester of pregnancy.⁶⁸

The diagnosis is suspected on the basis of family history and findings in the CBC and reticulocyte count that suggest a hyperproliferative anemia. Confirmation is obtained with the osmotic fragility test. Prenatal care of women with hereditary spherocytosis who have not had a splenectomy requires vigilance for hemolytic crisis and folate supplementation to ensure adequate marrow function.⁶⁹ A hemolytic crisis can be treated conservatively with replacement transfusions or with splenectomy. Because splenectomy is mechanically difficult to accomplish during the third trimester of pregnancy, it is sometimes preceded by delivery. In the absence of severe, untreated anemia, spherocytosis does not contribute to perinatal morbidity or mortality.

Hereditary elliptocytosis, also inherited as an autosomal-dominant trait, is a milder hemolytic state also caused by a structural defect in the RBC wall. The signs and symptoms are similar to those of spherocytosis but are not as severe. Most cases detected during pregnancy have been successfully treated with supportive therapy alone.⁷⁰

Autoimmune Hemolytic Anemia

There are two major types of antibodies responsible for autoimmune hemolytic anemia: warm-reactive and cold-reactive. Most warm-reactive antibodies are of the immunoglobulin G (IgG) class and are directed against some component of the Rh system on the surface of the RBC. In contrast, most cold-reactive antibodies are IgM; they are usually anti-I or anti-i. Autoimmune hemolytic anemia with warm-reactive antibodies is frequently seen in association with various hematologic malignancies (chronic lymphocytic leukemia, lymphoma), lupus erythematosus, viral infections, and drug ingestion. Penicillin and α-methyl dopa have been reported to cause autoimmune hemo-

lytic anemia. Cold-reacting antibodies can be seen in association with mycoplasmal infections, infectious mononucleosis, and lymphoreticular neoplasms.

In a large number of cases, no specific inciting event can be identified.⁷¹ The diagnosis is suspected when a hyperproliferative, macrocytic anemia is identified. The stained smear of peripheral blood often reveals microcytes, polychromatophilia, poikilocytosis, and the presence of normoblasts. Leukocytosis is frequently seen and is a result of marrow hyperactivity. The critical study to confirm the diagnosis is a positive direct Coombs test. There are several case reports in the literature describing pregnancy-induced hemolytic anemia in which no etiology could be discerned, the disease was diagnosed during pregnancy, and spontaneous remission occurred after delivery.^{72,73} The most recent report described a woman who had hemolytic anemia diagnosed in three separate pregnancies that was not responsive to either steroids or intravenous IgG therapy but resolved after delivery in all pregnancies.⁷²

Treatment of autoimmune hemolytic anemia is directed toward both the hemolytic process and the underlying disease. Blood transfusion, corticosteroid therapy, immunosuppression, and splenectomy are the most frequently used measures. In cases with warm-reactive antibodies, corticosteroid should be tried initially, because approximately 80% of patients respond dramatically. Splenectomy is an effective form of treatment in approximately 60% of patients with warm-reactive antibodies. If the disease is refractory to both corticosteroid therapy and splenectomy, a trial of immunosuppression is warranted. The treatment of cold-reactive antibodies depends on the severity of the hemolytic process. In patients with mild anemia, avoidance of cold temperatures is all that is required. Corticosteroid therapy and splenectomy are usually not effective if the majority of the RBC breakdown is intravascular. In patients with severe anemia, a trial of immunosuppression or plasmapheresis should be considered.

Glucose-6-Phosphate Dehydrogenase Deficiency

More than 20 different hereditary RBC enzyme defects have been described, most with an associated hemolytic anemia. Of these, only G6PD deficiency occurs with more than occasional frequency. The genetic locus controlling G6PD synthesis is on the X chromosome, and males with an abnormal gene may suffer hemolysis, especially if they are exposed to oxidant drugs that stress the pentose phosphate pathway of the erythrocyte. Female heterozygotes are generally clinically unaffected by similar exposure. The G6PD activity of the RBCs in heterozygous females is usually intermediate between the activity in hemizygous males and that in normal subjects. However, some female carriers have normal G6PD activity, whereas others have activity that falls within the range seen in affected males. It has been proposed that this is consistent with the Lyon hypothesis, that one of the two X chromosomes of every female cell is randomly inactivated in early embryonic life and continues to be inactive throughout all cell divisions.⁷⁴ Therefore, a few heterozygous women may be severely deficient in G6PD activity, but most have sufficient activity to withstand added stress on this critical metabolic pathway in erythrocytes.

The ethnic groups in which variants of the deficiency occur with greatest frequency are blacks, Mediterranean populations, Sephardic and Asiatic Jews, and selected Asian populations. Of African-American males in the United States, 12% are reported to be deficient in G6PD activity. Most affected individuals are hematologically normal unless they have been exposed to certain drugs or chemicals or have experi-

enced metabolic disturbances or infections that precipitate an acute hemolytic episode. Most affected African Americans carry a variant with these properties. Their hemolytic episodes are relatively mild. Greeks, Sardinians, and Sephardic Jews are more likely to carry G6PD Mediterranean, in which hemolysis is characteristically more severe and favism (hemolysis induced by ingestion of fava beans) occurs. The G6PD-deficient African-American population has not been reported to experience favism.

It is relatively unusual for a pregnant woman to experience severe sequelae of G6PD deficiency. However, Silverstein and associates reported Hct levels lower than 30% in 62% of 180 G6PD-deficient women.⁷⁵ Prudence would argue against exposure of a known carrier to precipitants of hemolysis. Sulfonamides, sulfones, some antimalarials, nitrofurans, naphthalene, probenecid, para-aminosalicylic acid-isoniazid, and nalidixic acid are among the medications and commonly occurring environmental chemicals known to precipitate RBC destruction in at-risk individuals.

One report suggested an increased incidence of low-birth-weight infants born to G6PD-deficient mothers, but no correction for the effects of anemia or urinary tract infection was employed.⁷⁶ Affected male infants born of carrier females have a higher incidence of neonatal hyperbilirubinemia, sometimes severe, than normal infants, and careful observation of those at risk is strongly advised.⁷⁷ The incidence of severe jaundice in G6PD-deficient newborn males is approximately 5%, rising to 50% if there is a history of an icteric sibling.

If a hemolytic episode occurs during pregnancy because of G6PD deficiency in a female heterozygote or the very rare homozygote, management should include prompt discontinuation of any medication or other agent that may be responsible, treatment of any intercurrent illness, and, if clinically indicated, transfusion support. In patients with the variant common among African Americans, even in the male hemizygote, the G6PD activity of young RBCs is much higher than in RBCs that have circulated for weeks and months. Old cells may be totally devoid of activity. Hence, the hemolytic episode, recognized early, is generally relatively mild and can be limited to the oldest population of circulating RBCs if the inciting agent is eliminated. A comprehensive review of G6PD deficiency was published by Beutler.⁷⁴

Aplastic and Hypoplastic Anemia

Aplastic anemia is characterized by pancytopenia in the presence of a hypocellular bone marrow. If it is left untreated, patients usually die from infection or bleeding. Three mechanisms have been postulated to explain the development of aplastic anemia: (1) insufficient stem cells resulting from an intrinsic defect or a reduction in number after exposure to a noxious agent, (2) the presence of a suppressor substance that inhibits the maturation of the myeloid precursors, and (3) development of an autoimmune reaction that causes death of the stem cells.

Agents such as benzene, ionizing radiation, nitrogen mustard, anti-metabolites, antimetabolic agents, certain antibiotics, and toxic chemicals predictably lead to marrow aplasia. In another category are agents such as chloramphenicol, anticonvulsants, analgesics, and gold salts, which induce aplasia only occasionally. Finally, hundreds of agents of various types have been implicated in several cases as causes of aplastic anemia. In about 50% of the cases, however, careful search does not reveal any causative agent.

Holly described eight patients with hypoplastic anemia detected during pregnancy that remitted spontaneously after delivery.⁷⁸ The bone marrow was described as hypocellular with an increase in megakaryocytes. There are now many case reports and series of pregnancy-

associated aplastic anemia, although they present a spectrum of clinical and bone marrow findings that makes it difficult to substantiate the existence of an aplastic anemia specifically related to pregnancy.⁷⁹⁻⁸⁴ Many papers used the criteria delineated by Snyder and coworkers⁸⁴ as evidence that the disease was pregnancy related: identification of the disease after the onset of pregnancy; no other etiology of aplastic anemia; decrease in all blood cell counts and in Hb; and hypoplastic bone marrow. However, recovery from the aplastic anemia was not universally documented after delivery, which raises the question of whether it is truly pregnancy related.^{80,82}

Patients with aplastic anemia seek medical attention because of symptoms related to profound anemia, bleeding, or infection. The CBC reveals pancytopenia with a hypoproliferative reticulocyte count. Examination of the bone marrow reveals hypoplasia with normoblastic erythropoiesis. Severe aplastic anemia is fatal for more than 50% of affected patients.⁸⁵

Bone marrow transplantation is now the treatment of choice, and long-term survival of 50% to 70% of patients can be expected. Alternatives include antithymocyte globulin, immunosuppressive therapy, and other supportive therapy described later in this section.⁸⁶ Survivors have had successful pregnancies after bone marrow transplantation.⁸⁷⁻⁹⁰ The largest series examined pregnancy outcomes in 146 pregnancies occurring after treatment for aplastic anemia in 41 women.⁸⁹ The outcomes in cases treated with total-body irradiation and bone marrow transplantation were compared with those in cases treated with high-dose chemotherapy and bone marrow transplantation. The data demonstrated no increase in the incidence of congenital anomalies in infants. However, total-body irradiation was associated with an increased risk of spontaneous abortion. Twenty-five percent of the pregnancies ended with a preterm delivery or delivery of a low-birth-weight infant. A more recent paper described pregnancy outcomes of 36 women with aplastic anemia who had been treated with immunosuppression before their pregnancy.⁹¹ Only 11 of these women had complete remission before they became pregnant, and 19% of the total group had a relapse of their aplastic anemia during pregnancy that required transfusion. Two women died, one of whom also had PNH, and two women had eclampsia. The majority of the pregnancies resulted in live births, with a 14% prematurity rate. Several patients were treated with cyclosporine or corticosteroids during their pregnancy.

During pregnancy, supportive therapy remains the major objective, because bone marrow transplantation is still relatively contraindicated in pregnancy. In recent years, with modern supportive therapy, the maternal mortality rate has been 15% or less, and more than 90% of patients survive in remission.^{80,82} Treatment consists of maintenance of Hb levels through periodic transfusion, prevention and treatment of infection, stimulation of hematopoiesis with androgens, splenectomy, intravenous immune globulin (IVIG), and intravenous steroids.⁹² Two case reports described successful pregnancies with a combination of RBC and platelet transfusions, cyclosporine, human granulocyte colony-stimulating factor, high-dose intravenous prednisone, and intravenous immunoglobulin.^{79,83} In a series of 14 women diagnosed during pregnancy, all of whom were treated with transfusions only, there were no deaths, and 10 of the women had normal pregnancy outcomes.⁸² The four abnormal outcomes were spontaneous abortion, preterm delivery, preeclampsia, and intrauterine growth restriction (IUGR). Androgen therapy can be effective at stimulating erythropoiesis; however, androgens are contraindicated during pregnancy unless the fetus is demonstrated to be male. Androgenic agents commonly used include the anabolic steroids, oxymetholone, nandrolone decanoate, or testosterone enanthate. Adrenocorticosteroids have

also been widely used with some benefit. However, the remission rate with steroids is only 12%.

Because of anecdotal reports of complete remission after pregnancy termination, it is tempting to consider therapeutic abortion. However, thorough examination of the available literature indicates that abortion or premature termination of pregnancy is not associated with a more favorable outcome. The only reason to terminate pregnancy prematurely is inability to treat the patient satisfactorily during pregnancy with transfusion alone and a consequent need to proceed to marrow transplantation.

Paroxysmal Nocturnal Hemoglobinuria

PNH was named for its characteristic nighttime hemolysis with dark early-morning urine. Hemolysis in PNH occurs as a result of a somatic mutation in the phosphatidylinositol glycan class A (*PIGA*) gene on the X chromosome. This enzyme mediates formation of phosphatidylinositol anchors for various transmembrane proteins, including inhibitors of the complement proteins.⁹³ These latter proteins normally are present in the RBC and protect against complement activation. Their reduction renders RBCs susceptible to intravascular hemolysis by complement. PNH usually begins insidiously, and there is no familial tendency. Considerable variability exists in severity of the disease, and the classic presentation of hemoglobinuria is seen in only 25% of patients. Exacerbations of the hemolytic process are precipitated by infection, menstruation, transfusion, surgery, and ingestion of iron.

The most serious complications are marrow aplasia, thrombosis, and infection. Thrombosis accounts for 50% of deaths in nonpregnant patients and often involves intra-abdominal vessels, including Budd-Chiari syndrome resulting from hepatic vein thrombosis.^{94,95} Although anemia is the most prominent hematologic feature of PNH, leukopenia and thrombocytopenia also occur frequently. The diagnosis is based on tests including the sucrose hemolysis and acidified serum lysis tests, which demonstrate the sensitivity of the patient's RBCs to complement.

There are two excellent reviews of PNH in pregnancy.^{93,96} A review of 20 case reports and series encompassing 33 pregnancies in 24 women revealed several interesting features. One third of these cases were diagnosed for the first time during pregnancy, and 12% of the pregnancies were complicated by thromboembolism with three fourths of the patients having Budd-Chiari syndrome or hepatic vein thrombus.⁹⁶ Half of these women died. In addition, there were two maternal deaths from infection, which means that the maternal mortality rate in this summary of 24 women with PNH was 17%. In addition, 73% had anemia or hemolysis during pregnancy, and 27% developed thrombocytopenia. In another review, the most common complication was venous thrombosis.⁹³ Although at least two pregnant or puerperal women developed a thromboembolism despite receiving thromboprophylaxis, experts continue to recommend thromboprophylaxis.^{93,96} This may be particularly challenging if the patient develops thrombocytopenia. There is one case report of a successful labor epidural placement in a woman with PNH and a platelet count of 64,000/mL.⁹⁷

The optimal treatment of PNH is replacement of the abnormal stem cells with cells capable of producing the normal cellular components. This has been accomplished by bone marrow transplantation. The major therapeutic modalities during pregnancy are iron therapy, transfusions, corticosteroids, and androgen treatment (if the fetus is male).^{93,98,99} Iron can be administered orally to replace the considerable amount lost in the urine. However, in patients with significant iron deficiency, such treatment may lead to a burst of erythropoiesis,

with delivery of a cohort of cells susceptible to the lytic action of complement. If a hemolytic episode follows iron therapy, it should be treated with either suppression of erythropoiesis by transfusion or suppression of hemolysis with corticosteroids. When acute hemolytic episodes occur, treatment is aimed at diminishing hemolysis and preventing complications.

Hemoglobinopathies

The hemoglobinopathies can be broadly divided into two general types. In the thalassemia syndromes, normal Hb is synthesized at an abnormally slow rate. In contrast, the structural hemoglobinopathies occur because of a specific change in the amino acid content of Hb. These structural changes may have either no effect or profound effects on the function of Hb, including instability of the molecule, reduced solubility, methemoglobinemia, and increased or decreased oxygen affinity.

Thalassemia Syndromes

The thalassemia syndromes are named and classified by the type of chain that is inadequately produced. The two most common types are α -thalassemia and β -thalassemia, both of which affect the synthesis of Hb A. Reduced synthesis of γ or δ chains and combinations in which two or more globin chains are affected are relatively rare. In each instance, the thalassemia is a quantitative disorder of globin synthesis.

α -Thalassemia

In patients with α -thalassemia, one or more structural genes are physically absent from the genome. The various α -thalassemia genotypes are summarized in Figure 42-2. In blacks, the most common two-gene deletion state consists of one gene missing on each chromosome. In Asians, most often both genes are missing from the same chromosome. In the homozygous stage, all four genes are deleted and no chains are produced. In such cases, the fetus is unable to synthesize normal Hb F or any adult hemoglobins. This deficiency results in high-output cardiac failure, hydrops fetalis, and stillbirth.¹⁰⁰

The most severe form of α -thalassemia compatible with extrauterine life is Hb H disease, which results from deletion of three α genes. In these patients, abnormally high quantities of both Hb H (β_4) and Hb Barts (γ_4) accumulate. Because Hb H precipitates within the RBC, the cell is removed by the reticuloendothelial system, leading to a moderately severe hemolytic anemia. In α -thalassemia minor (also called α -thalassemia-1), two genes are deleted, resulting in a mild hypochromic, microcytic anemia that must be differentiated from iron deficiency. A single gene deletion (α -thalassemia 2) is clinically undetectable and is called the “silent carrier” state.

The diagnosis of α -thalassemia is presumptive by exclusion of iron deficiency and β -thalassemia. Although α -thalassemia-1 minor does not present a hazard to the adult, there are serious genetic implications when a mating of two individuals with the trait occurs. Under these circumstances, one must make a specific diagnosis by using restriction endonuclease techniques or a DNA probe before undertaking antenatal diagnosis.¹⁰¹

β -Thalassemia

β -Thalassemia is autosomal-recessive and is more common in people of Mediterranean, Middle Eastern, and Asian descent. The underproduction of β -globulin chains is caused by point mutations with single nucleotide substitution or oligonucleotide addition or deletion.¹⁰² The

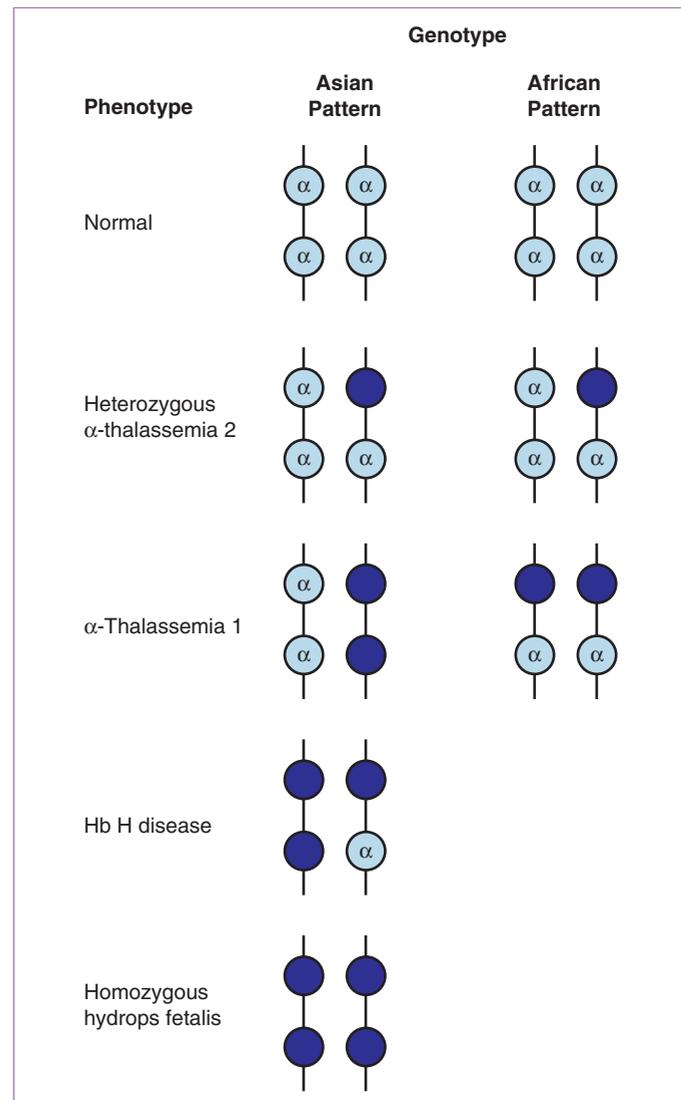

FIGURE 42-2 Genotypes of the various α -thalassemia syndromes. Hb H, hemoglobin H.

β -globin gene is on chromosome 11. In homozygous β -thalassemia, α -chain production is unimpeded, and these highly unstable chains accumulate and eventually precipitate; markedly ineffective erythropoiesis and severe hemolysis result in a condition known as β -thalassemia major or Cooley anemia. There is variation in severity depending on whether homozygous for reduced (β^+) or absent (β^0) β -globin synthesis (see Table 42-4). The fetus is protected from severe disease by α -chain production. However, this protection disappears rapidly after birth, with the affected infant becoming anemic by 3 to 6 months of age. The infant has splenomegaly and requires blood transfusions every 3 to 4 weeks. Death typically occurs by the third decade of life and is usually secondary to myocardial hemochromatosis. Female infants surviving until puberty are usually amenorrheic and have severely impaired fertility.^{103,104}

β -Thalassemia minor (also called β -thalassemia trait) results in a variable degree of illness, depending on the rate of β -chain production. The characteristic findings include a relatively high RBC membrane rigidity, moderate to marked microcytosis, and a peripheral smear resembling that observed in iron deficiency. Hb electrophoresis char-

TABLE 42-4 HEMATOLOGIC AND CLINICAL ASPECTS OF THE THALASSEMIA SYNDROMES

Condition	Hemoglobin (Hb) Pattern*				Clinical Severity
	Hb Level	Hb A ₂	HB F	Other Hb	
Homozygotes					
α -Thalassemia	↓↓↓↓	0	0	80% Hb Barts, remainder Hb H and H Portland, some Hb A	Hydrops fetalis

acteristically shows an elevation of Hb A₂. β -Thalassemia trait does not impair fertility, and the incidence of prematurity, low-birth-weight infants, and infants of abnormal size for gestational age is identical to that in normal women.^{105,106} Nineteen women with β -thalassemia major or intermedia (e.g., the compound heterozygous state) were followed through 22 pregnancies; 21 viable infants were delivered.¹⁰⁷ These patients all had intensive treatment, including transfusions and iron-chelating agents, if necessary, before pregnancy or if their Hb concentration was greater than 7 g/dL. In addition, all women had a pre-pregnancy cardiac echocardiogram showing a left ventricular ejection fraction greater than 55%. These results suggest that women with well-managed, stable β -thalassemia can do very well during pregnancy.¹⁰⁷ The clinical characteristics and hematologic findings of the various thalassemias are summarized in Table 42-4.

Because of increased Asian immigration, the number of β -thalassemia cases in the United States has risen, so maternal screening of appropriate women is important.¹⁰⁸ In California, cases of β -thalassemia major, Hb E/ β -thalassemia, and other combined structural Hb abnormalities are more common than phenylketonuria or galactosemia.¹⁰⁸ A suggestion for easy antenatal maternal screening for α - and β -thalassemia is shown in Figure 42-3.^{105,109} Prenatal diagnosis, including preimplantation genetic diagnosis, is now available for β -thalassemia by polymerase chain reaction techniques of mutation detection on fetal blood or fetal DNA obtained from amniocentesis or chorionic villus sampling.^{102,110-113}

Structural Hemoglobinopathies

To date, several hundred variants of α , β , γ , and δ chains have been identified. Most differ from normal chains by only one amino acid.

TABLE 42-5 FREQUENCY OF THE MOST COMMON HEMOGLOBINOPATHIES IN ADULT AFRICAN AMERICANS

Hemoglobinopathy	Abbreviated Name	Frequency
Sickle cell trait	Hb SA	1:122
Sickle cell anemia	Hb SS	1:708
Sickle cell-hemoglobin C disease	Hb SC	1:757
Hemoglobin C disease	Hb CC	1:4790
Hemoglobin C trait	Hb CA	1:41
Hemoglobin S- β -thalassemia	Hb S- β -thal	1:1672
Hemoglobin S-high F	Hb S-HPFH	1:3412

The nomenclature and frequency of the most common hemoglobinopathies among African Americans are depicted in Table 42-5.¹¹⁴ Confirmation of a diagnosis of a specific hemoglobinopathy requires identification of the abnormal Hb by means of Hb electrophoresis.

Sickle Cell Trait

Traditionally, women with sickle cell trait have been thought to do well during pregnancy and labor. However, new studies have reported conflicting results about increased morbidities in women with sickle trait.¹¹⁵⁻¹¹⁷ A case-control study from Mississippi, in which women with or without the trait were matched for race, reported a significant decrease in gestational age at birth (33 versus 35 weeks), lower mean birth weight, and an increased rate of fetal death (9.7% versus 3.5%) in the women with sickle cell trait.¹¹⁶ Of interest, 42% of the fetal

deaths in the sickle cell trait group were early deaths (16 to 20 weeks). In contrast, in a large cohort study of all African-American deliveries at one institution that compared those with and without maternal sickle cell trait, the trait was found to have a significant protective effect for preterm delivery at less than 32 weeks (0.9% versus 4.5%).¹¹⁵ This protective effect was even more apparent in women with multiple gestations, with 0% versus 22% delivering before 32 weeks.

Because there is an increased rate of urinary tract infection among women with sickle cell trait, pregnant patients should be repeatedly screened for asymptomatic bacteriuria.¹¹⁸⁻¹²⁰ Recently, in a large case-control study of women with or without sickle cell trait who were matched for race, age, gestational age, and entry into prenatal care, there was no significant difference in the incidence of positive urine cultures (22% versus 19%).¹¹⁷ However, pyelonephritis was significantly more common in the women with sickle cell trait (2.4% versus 0.7%). Another study suggested that the risk of preeclampsia was increased to 25% in those with the trait, compared with 10% in a sickle-negative control group.¹²¹ These patients may become iron deficient, and iron supplementation during pregnancy is indicated.

Sickle Cell Anemia

Patients with sickle cell anemia (SCA) suffer from lifelong complications, in part as a result of the markedly shortened life span of their RBCs. Virtually all signs and symptoms of SCA are secondary to hemolysis, vaso-occlusive disease, or an increased susceptibility to infection (Table 42-6). Clinical manifestations may affect growth and development, with growth restriction and skeletal changes secondary to expansion of the marrow cavity. Painful crises may occur in the long bones, abdomen, chest, or back. The cardiovascular manifestations are those of a hyperdynamic circulation, and pulmonary signs may be secondary to either infection or vaso-occlusion. In addition to painful vaso-occlusive episodes, patients may exhibit hepatomegaly, signs and symptoms of hepatitis, cholecystitis, and painful splenic infarcts. Genitourinary signs include an impairment in concentrating ability (hyposthenuria), hematuria, and pyelonephritis.

Whether pregnancy in women with SCA is associated with more maternal complications is controversial. One comparison of pregnancy outcomes between women with and without SCA revealed no significant differences. Rates of maternal morbidity from SCA were the same during pregnancy as in the nonpregnant state.¹²² However,

TABLE 42-6 CLINICAL MANIFESTATIONS OF SICKLE CELL ANEMIA

another study showed a significant increase in antepartum admissions, preterm labor or preterm premature rupture of membranes, and postpartum infection in women with versus those without SCA.¹²³ In two studies, there was no difference in the incidence of preeclampsia in women with and without SCA.^{123,124} Series examining maternal deaths have been too small to determine whether there is an increased risk with SCA; however, pulmonary embolus or acute chest syndrome or both was the cause in 5 of 7 deaths.¹²⁵

It is not known whether the frequency of painful crises in women with SCA changes with pregnancy. In one large study, the average number of crises per patient per pregnancy was 1 to 2, and other studies have suggested that 20% to 50% of affected pregnant women had crises.^{122,124,126,127} Treatment is largely symptomatic, with the major objectives being to end a painful crisis and to combat infection. Hydration, oxygen therapy, and pain management are the cornerstones of managing a pain crisis. Acute chest syndrome is one of the most severe complications of SCA and can be very difficult to treat. It has been reported to occur in up to 20% of pregnancies.^{122,124,128} Urinary tract and pulmonary infections should be diagnosed promptly and treated vigorously with appropriate antibiotics. Transfusion therapy has been used widely for years in the treatment of symptomatic patients. Partial exchange transfusions or prophylactic transfusions have been advo-

cated.^{129,130} The goal of partial exchange transfusions is to keep the Hb A level higher than 50% and the Hct greater than 25%.¹³¹ A prospective, randomized study of 72 patients with SCA showed no significant difference in perinatal outcome between women who were treated with prophylactic transfusions and those who received transfusions only if their Hb level fell to less than 6 g/dL or the Hct to less than 18%.¹²⁷ However, this study did report a significant decrease in crises during pregnancy, from 50% to 14%, in the group receiving prophylactic transfusions. Sixty-six patients with sickle cell–Hb C disease and 23 with sickle cell– β -thalassemia received transfusions for hematologic reasons only and experienced similar perinatal outcomes.¹²⁷ However, the benefits attained must be balanced against a 25% incidence of alloimmunization and 20% occurrence of delayed transfusion reaction.

Several studies documented no relationship between maternal anemia and risk for IUGR or perinatal death in women with SCA.^{124,132} The use of prophylactic transfusions should be individualized. An excellent review of SCA in nonpregnant individuals suggested that transfusion is indicated for symptomatic acute anemia, severe symptomatic chronic anemia, acute chest syndrome with hypoxia, and surgery with general anesthesia and may be useful for severe protracted pain episodes.¹³³ Most observers believe that the prepregnancy course of a woman is a good index of how she will fare during pregnancy. Although fetal outcomes are generally good in pregnancies complicated by SCA, there continues to be an increased risk of prematurity and IUGR.^{122,123,134,135} The most recent series showed an incidence of IUGR and preterm delivery of 45% each, and both were significantly more common in women with SCA than in the control group without SCA.¹²³

Serial ultrasound studies should be done throughout pregnancy to confirm normal fetal growth. There are no prospective studies on the use of antepartum fetal testing in women with SCA, so this should be instituted at the discretion of the physician. In addition, preimplantation genetic diagnosis with polymerase chain reaction assays is available for SCA.¹¹⁰

In general, prenatal vitamins without iron should be given to women who are receiving multiple transfusions. But all women with SCA should have an additional folic acid supplement of 1.0 mg/day prescribed. The pneumococcal vaccine should be given if the patient has not had the vaccine within the past year. During labor and delivery, the patient must remain well oxygenated and hydrated. If an exchange transfusion protocol has been used and the Hb A level is greater than 40%, painful crises are distinctly unusual.¹³⁶ Finally, a recent retrospective study of 40 women with SCA reported that the initial prenatal white blood cell count was significantly higher in those women who subsequently developed SCA-related complications ($11.2 \times 10^9/L$) during their pregnancy than in those who did not develop complications ($8 \times 10^9/L$).¹³⁷

Hemoglobin Sickle C Disease

Women who are doubly heterozygous for both the Hb S and the Hb C genes are said to have Hb SC disease. Hb electrophoresis reveals approximately 60% Hb C and 40% Hb S. Patients with Hb SC disease typically have a normal habitus, a healthy childhood, and a normal life span. If a systematic screening program has not been used, the condition may first be detected in many women during the latter part of pregnancy, when a complication occurs. At the beginning of pregnancy, most women are mildly anemic and splenomegaly is present. Examination of a peripheral blood smear shows numerous target cells. Hb electrophoresis ensures the correct diagnosis.^{138,139}

During pregnancy, 40% to 60% of patients with Hb SC disease present as if they had SCA. In contrast to patients with SCA, those with

Hb SC disease frequently experience rapid and severe anemic crises resulting from splenic sequestration. These patients also have a greater tendency to experience bone marrow necrosis with the release of fat-forming marrow emboli. The clinical manifestations of Hb SC disease are otherwise similar to those of SCA but milder, and the general management of symptomatic patients is identical. Considerations for the management of labor are the same as with SCA. In a recent report, women with Hb SC disease had a significantly increased risk of antepartum admission, IUGR, and postpartum infection compared to women without sickle disease, but these risks were only half as great as those of the women with SCA.¹²³ Similarly, Serjeant and associates reported that the rates of miscarriage, live-born delivery, and newborn weight less than 2500 g in women with Hb SC disease were similar to those in women with normal Hb and significantly better than those in women with SCA.¹⁴⁰ Rates of pain crises, acute chest syndrome, and urinary tract infections were similar in women with Hb SC disease and those with SCA.¹⁴⁰

Hemoglobin S- β -Thalassemia

Patients with Hb S- β -thalassemia are heterozygous for the sickle cell and the β -thalassemia genes, and in general about 10% of sickle cell disease is caused by Hb S- β -thalassemia.¹¹¹ In addition to decreased β -chain production, there is a variably increased production of Hb F and Hb A₂. Because of this variable production rate, Hb electrophoresis reveals a spectrum of Hb concentrations. Hb S may account for 70% to 95% of the Hb present, with Hb F rarely exceeding 20%.¹⁴¹ Because of the thalassemia influence, the Hb S concentration exceeds the Hb A concentration. This is in sharp contrast to patients with sickle cell trait, in whom Hb A levels exceed the concentration of Hb S.

The diagnosis is made in an anemic patient by demonstrating increased Hb A₂ and Hb F levels in association with a level of Hb S exceeding that of Hb A. The peripheral smear reveals hypochromia and microcytosis with anisocytosis, poikilocytosis, basophilic stippling, and target cells. The clinical manifestations of this disorder parallel those of SCA but are generally milder. Painful crises may occur; however, these patients have a normal body habitus and frequently enjoy an uncompromised life span. The role of exchange transfusion should be similar to that in patients with SCA; that is, exchange transfusion should be reserved for the woman who experiences painful crises or whose anemia leads to an Hct lower than 25%.

Hemoglobin C Trait and Disease

Hb C trait is an asymptomatic trait without reproductive consequences. Target cells are found in the peripheral smear, but anemia is not present. Hb C disease, the homozygous state, is a mild disorder that

usually is discovered during a medical evaluation. Mild hemolytic anemia with an Hct in the range of 25% to 35% is characteristic. The RBCs show microspherocytes and characteristic targeting. No increased morbidity or mortality is associated with pregnancy, and no specific therapy is indicated.

Hemoglobin E Disease

The recent immigration of Southeast Asians to the United States has resulted in an increase in the number of individuals with Hb E trait and disease. The clinical and laboratory manifestations of the various Hb E syndromes are outlined in Table 42-7.^{142,143} Most individuals have a mild microcytic anemia that is of no clinical significance, and no treatment is necessary. However, patients who are homozygous for Hb E have a greater degree of microcytosis and are frequently anemic. Target cells are prominent. As with Hb C trait and disease, no specific therapy is required, and reproductive outcome is normal.

Anemias Associated with Systemic Disease

The normal bone marrow has the capacity to increase its RBC production sixfold to eightfold in response to anemia. This compensatory mechanism, which is responsible also for the increase in RBC mass in normal pregnancy, is triggered by tissue hypoxia and mediated by erythropoietin. The response may be absent or blunted in some circumstances, most commonly in chronic disorders. Chronic infections, rheumatoid arthritis, and other inflammatory states are characterized by a mild normocytic, normochromic anemia (or sometimes a hypochromic, microcytic anemia) with low serum iron concentration, low transferrin level, inappropriately low reticulocyte count, and generous but poorly utilized stores of reticuloendothelial iron. Although the bone marrow is normally cellular, it does not respond appropriately to the mildly accelerated RBC destruction typical of chronic inflammation. Studies thus far have not determined whether the defect in erythropoiesis can be attributed to inadequate erythropoietin secretion. In the absence of pregnancy, the Hb concentration in these chronic states is frequently 9 to 10 g/dL, and the Hct concentration is approximately 30%. The hydremia of pregnancy may lower these values somewhat.

A similar but frequently more complicated anemia accompanies renal failure. Here, more often perhaps than in chronic inflammatory states, blood loss and hemolysis are contributory factors, and the serum iron and transferrin changes noted earlier are less regular. In

TABLE 42-7 VARIOUS GENOTYPES OF HEMOGLOBIN E AND THEIR PHENOTYPIC EXPRESSION*

Hb, hemoglobin; MCV, mean corpuscular volume.

many of these situations, diminished erythropoietin is important in the pathogenesis.

Renal failure and chronic inflammation are rare in pregnancy, so management of the associated anemias is seldom a clinical problem in obstetric patients. Occasionally, however, it is the anemia that calls attention to the underlying disease. These anemias do not respond to hematinic agents or steroid hormones (unless the adrenal steroids play some role in controlling the underlying disease, as in rheumatoid arthritis or lupus). Erythropoietin is useful in treating chronic renal disease and can often obviate the need for repeated RBC transfusion.¹⁴⁴

Chapter 43

Malignancy and Pregnancy

David Cohn, MD, Bhuvanewari Ramaswamy, MD, and Kristie Blum, MD

Cancer occurring during pregnancy is not rare. Approximately 1 of 1000 pregnant women is diagnosed with a new malignancy each year in the United States.¹ Cancer is one of the leading causes of nonaccidental deaths in the United States in women between the ages of 15 and 34, and it is the leading cause of death in the women between the ages of 35 and 54 years.² The most common malignancies in women 15 to 34 years old are malignant melanoma, breast cancer, leukemia, cervical cancer, central nervous system tumors, and non-Hodgkin lymphoma. Lung, colorectal, and ovarian cancer also are common in 35- to 54-year-old women.¹ Melanoma is estimated to occur in 1 of 1000, cervical cancer in 1 of 2000, Hodgkin lymphoma in 1 of 3000, breast cancer in 1 of 3000, ovarian cancer in 1 of 18,000, and leukemia in 1 of 75,000 pregnancies. The current social trend of delaying pregnancy into the later reproductive years will result in more cancers being diagnosed during gestation.

The management of cancer in pregnancy is challenging, posing ethical and medical dilemmas. Limited prospective data are available, which hinders the decision-making process. The goal of cancer therapy in pregnant women is to provide the best cancer care for the patient while minimizing the potential harm to the fetus.

Cancers in pregnancy are often categorized by the time of diagnosis: those discovered during the antenatal period, at the time of delivery, or up to 1 year after birth. More than 50% of cancers complicating pregnancy are found within 1 year after delivery, and more than 25% are found in the antenatal period. Few are found at delivery.³

When a malignant neoplasm is diagnosed in pregnancy, the health of the mother and fetus must be considered. When cancer is diagnosed early in a desired pregnancy, the clinical situation is complex. If delaying treatment will not affect the maternal prognosis, treatment may be deferred until the fetus has achieved maturity. If the prognosis is expected to worsen with delayed treatment, the risks and benefits of more immediate treatment must be weighed against the risks to the pregnancy and the fetus. Given the complex management involved in the care of a pregnant patient with cancer, a multidisciplinary team is essential to ensure that the mother, family, and all members of the health care team are well informed about the risks, benefits, and alternatives of the treatment choices and modalities. In addition to the medical aspects of the care, management must be individualized to balance the ethical, moral, spiritual, and cultural issues that complicate such a diagnosis.

Factors such as the hormonal milieu, increased vascularity, altered lymphatic drainage, and immune adaptations in pregnancy have historically been thought to increase the risk of malignancy and to increase the likelihood of a more aggressive course with poorer outcomes than

would be expected in a nonpregnant woman. However, there is no evidence to suggest that pregnancy directly or indirectly affects the incidence or outcome of cancer. This chapter addresses the issues related to the diagnosis and care for a pregnant patient with cancer.

Ovarian and Cervical Malignancies

Ovarian Cancer

Epidemiology, Diagnosis, and Tumor Types

One of 18,000 pregnancies is complicated by an ovarian malignancy.⁴⁻⁶ Approximately 1 of 1000 pregnant women undergo exploratory surgery to evaluate an adnexal mass, and 1% to 3% of these masses are malignant.^{7,8} This incidence is lower than among nonpregnant women, probably because pregnancy occurs in younger women, in whom most ovarian masses are corpus luteum cysts or other benign simple cysts and most ovarian neoplasms are teratomas or cystadenomas.⁹⁻¹¹ Most ovarian malignancies found in pregnancy are germ cell tumors, but the incidence of epithelial ovarian malignancies identified during pregnancy may increase as women defer childbearing into later in their reproductive years.

Rarely, a woman presents with an advanced ovarian malignancy requiring extensive cytoreduction. If the malignancy is diagnosed when the fetal prognosis allows delivery or the patient does not wish to continue the pregnancy, immediate surgical exploration for cytoreduction and subsequent adjuvant treatment should be undertaken. If the pregnancy is desired and the fetus cannot be delivered, management is complex. In selected patients, antepartum bilateral oophorectomy and cytoreduction can be performed, with the pregnancy continuing and adjuvant treatment delayed until delivery. Management must be individualized for each patient based on her desire for future fertility, gestational age, and extent of disease. In selected patients, antepartum neoadjuvant (before surgery) chemotherapy administered until fetal maturity, followed by cytoreductive surgery at abdominal delivery, may be considered.

Germ cell cancers are the most common ovarian malignancy diagnosed in pregnancy; up to 30% of malignancies in pregnancy are dysgerminomas. They most often manifest with torsion. The serum level of maternal lactate dehydrogenase (LDH), the tumor marker for dysgerminomas, is not altered by pregnancy, and it can serve as a marker for the disease during pregnancy.¹²

TABLE 43-1 COMPONENTS OF COMPREHENSIVE SURGICAL STAGING OF GYNECOLOGIC CANCERS

<p>Sampling of pelvic cytology or ascites</p> <p>Ipsilateral salpingo-oophorectomy</p> <p>Hysterectomy and contralateral salpingo-oophorectomy (eliminated in selected patients)</p> <p>Peritoneal biopsies (e.g., anterior and posterior cul-de-sac, pelvic side walls, abdominal gutters, diaphragms)</p> <p>Biopsies of adhesions or other abnormalities</p> <p>Omentectomy</p> <p>Bilateral pelvic lymphadenectomy</p> <p>Bilateral aortic lymphadenectomy</p>
--

Standard management of a suspected ovarian dysgerminoma during pregnancy is surgery. Unilateral oophorectomy for diagnosis with comprehensive surgical staging (Table 43-1) and preservation of the contralateral ovary and uterus is recommended. Because 15% of dysgerminomas are bilateral, inspection of the contralateral ovary with biopsy or removal of abnormalities should be performed for therapeutic and prognostic reasons. Wedge resection or biopsy of a normal-appearing contralateral ovary is unnecessary because of the risk of increased adhesion formation and possible infertility. Patients with advanced dysgerminoma require chemotherapy with bleomycin, etoposide, and cisplatin (BEP regimen).

The prognosis for women with early-stage dysgerminoma is excellent. With advanced disease, approximately 10% of tumors will recur, but most are cured with chemotherapy or radiation therapy. The cure rate for women with early-stage disease is excellent.

Endodermal sinus tumors (i.e., yolk sac tumors) of the ovary are rare, aggressive tumors that confer a poor prognosis. These tumors are marked by increased serum levels of maternal α -fetoprotein (AFP), which may be elevated in normal and abnormal pregnancies. Nevertheless, an extremely elevated AFP level in an apparently normal pregnancy may be associated with an endodermal sinus tumor. Because of their aggressive nature, surgery is indicated for the diagnosis of an endodermal sinus tumor, and adjuvant chemotherapy is administered to all women with this diagnosis.

Sex cord–stromal tumors (mainly granulosa cell tumors and Sertoli-Leydig cell tumors) are rare ovarian cancers in reproductive-age women and therefore rare in pregnancy. Independent of pregnancy, these tumors manifest with evidence of hormone excess (i.e., virilization or hyperestrogenism). During pregnancy, they more commonly manifest with hemorrhagic rupture leading to hemoperitoneum. Management includes unilateral oophorectomy and surgical staging. Adjuvant therapy is reserved for patients with advanced or recurrent disease.

For patients with ovarian cancer diagnosed during pregnancy, oncologic outcomes appear to be similar to those for patients who are not pregnant. However, the therapeutic plan must be modified by pregnancy in some circumstances.

Management of Adnexal Masses Occurring during Pregnancy

In the United States, 10% of women undergo surgery for an ovarian mass during their lifetime, and up to 20% of these masses are identified as malignant.¹³ The common use of obstetric ultrasound has led to increased discovery of adnexal masses complicating gestation. Masses

once found at the time of abdominal delivery, during the postpartum period, or later are now incidentally detected during a first or second trimester ultrasound examination. Approximately 0.2% to 2% of pregnancies are complicated by an adnexal mass, and 1% to 3% of these are malignant.^{4,9,14-18} These estimates are uncertain because many masses incidentally discovered may regress, are not reported, or may not require or receive any intervention. Although many ovarian masses diagnosed during pregnancy are benign cysts that undergo spontaneous regression by the second trimester, some of these masses persist through the second trimester and beyond, potentially causing pregnancy-related complications and requiring surgical evaluation and intervention.

Approximately 75% of adnexal masses complicating pregnancy are simple cysts measuring less than 5 cm in diameter, and the remaining one fourth are simple or complex masses that exceed 5 cm in diameter. During pregnancy, 70% of ovarian masses spontaneously resolve by the early second trimester, becoming undetectable by 14 to 15 weeks' gestational age.^{9,16} Functional cysts are the most common, and dermoid cysts (i.e., benign cystic teratomas) are the most common neoplasm encountered in pregnancy. Other common benign masses include paraovarian cysts, endometriomas, leiomyomas, and benign neoplasms such as cystadenomas.⁸⁻¹¹

Adnexal masses larger than 8 cm in diameter are more often complicated by pain, torsion, rupture, or internal hemorrhage than smaller lesions. Preterm labor, preterm premature rupture of membranes, obstruction of labor, and fetal death have rarely been observed.¹⁹⁻²¹ Ovarian torsion occurs most commonly in the late first or early second trimester, when the uterus is growing out of the true pelvis and in the puerperium and when the uterus undergoes rapid involution. If clinical signs or symptoms consistent with torsion, rupture, or hemorrhage occur, emergent surgery is indicated independent of gestational age. In the case of an ovarian tumor larger than 8 cm in diameter in a woman who does not undergo surgery, the clinician and patient must be aware of the increased risk of complications and their symptoms.

In the non-emergent setting, the radiographic and ultrasonographic characteristics of the mass commonly have been used to guide management. In masses that appear simple and cystic in nature and are less than 6 cm in diameter, the risk of malignancy is low (<1%); these can be observed without surgery.^{9-11,19} Surgical exploration should be performed for masses that persist into the second trimester, are rapidly enlarging, exceed 8 cm in diameter, or appear malignant.¹³ Because levels of cancer antigen 125 (CA 125) levels usually are elevated during the beginning of pregnancy and persist throughout pregnancy, serum testing is unreliable for evaluating the risk of an epithelial malignancy. If the source of the mass is not clear, magnetic resonance imaging can be employed to differentiate ovarian from extraovarian masses.

Surgical exploration for an ovarian mass is optimally undertaken at 16 to 20 weeks' gestation, when physiologic cysts have regressed and, if an oophorectomy is required, when the placenta has become hormonally functional and independent of the corpus luteum. If the mass is discovered in the late third trimester, evaluation, management, and surgical exploration may be deferred until or after delivery in some circumstances. If delivery is abdominal, diagnosis and potential staging can be undertaken at the time of cesarean section; if delivery is vaginal, surgery may be postponed, depending on the nature and appearance of the mass.

Cervical Cancer

According to the National Cancer Institute, an estimated 11,070 new cases of cervical cancer are expected to be diagnosed in the United

States in 2008, with an estimated 3870 deaths from the disease.²² Invasive cervical cancer in pregnancy is uncommon, comprising only approximately 1% of total cervical cancers diagnosed, but pre-invasive cervical neoplasia is common in reproductive-age women, occurring in 5 to 50 cases per 1000 pregnancies.²³⁻²⁵ The incidence of cervical cancer has declined because of implementation of the Papanicolaou (Pap) smear to screen for cervical dysplasia and cancer. The practicing obstetrician-gynecologist is more likely to encounter an abnormal Pap smear than invasive cervical cancer during pregnancy. Although Pap smears and routine screening are readily available in most developed countries, most women diagnosed with cervical cancer have not had appropriate screening. Pregnancy and prenatal care affords an opportunity to screen and treat many patients who would otherwise not access the health care system.

Cervical Intraepithelial Neoplasia

As many as 5% of pregnancies may be complicated by an abnormal Pap smear result.²⁵ Cervical cytology and physical examination are the principal forms of cervical cancer screening during pregnancy. Although endocervical curettage should be avoided during pregnancy to prevent direct or indirect injury to the pregnancy, an endocervical brush should be employed to increase the adequacy of the smear. This can increase the incidence of spotting after collection, but it appears to have no effect on the risk for serious adverse outcomes related to the pregnancy.²⁶ During pregnancy, the goal of evaluation of an abnormal Pap smear result and cervical dysplasia is determination of the extent of neoplasia; the aim is to rule out invasive cancer and allow therapy for pre-invasive disease to be deferred until after delivery.

The Bethesda system is the standard classification system for cervical neoplasia. It is used to guide the management of patients with abnormal cervical cytology. Atypical squamous cells of uncertain significance (ASC-US) should be managed as in the nonpregnant state. Options include repeat cytologic examination at a close interval follow-up visit, immediate colposcopy, or triage with high-risk human papillomavirus (HPV) testing. Patients with an ASC-US Pap results without evidence of HPV infection can be evaluated after delivery. ASC smears in which a high-grade lesion cannot be excluded (ASC-H) usually are managed with colposcopy, although some clinicians use HPV status to triage these smears. Women who are found to have low- or high-grade squamous intraepithelial lesions (LSILs or HSILs) should undergo colposcopy to evaluate the extent and severity of neoplasia.²⁷

Pap smears revealing atypical glandular cells (AGCs), although rare in pregnancy, also warrant colposcopic examination. Pregnancy complicates the cytologic interpretation of AGC, because sloughed decidual cells, endocervical gland hyperplasia, and cells demonstrating an Arias-Stella reaction, all of which are benign, can occur in normal pregnancy. Compared with nonpregnant patients, for whom AGC is associated with malignancy in as many as 25% of cases, AGC found in pregnancy is less likely to indicate malignancy. However, the inability to perform an endocervical curettage and endometrial sampling limits the evaluation of AGC during pregnancy.

Colposcopic evaluation in pregnancy is facilitated by the eversion of the transformation zone. The procedure should be performed whenever indicated by the cytology results, regardless of pregnancy. The purpose of colposcopy in pregnancy is to exclude the presence of malignancy. Biopsies should be performed for any suspicious lesions seen at the time of colposcopic evaluation. Biopsies should be done only for the most suspicious areas, and taking many samples at one examination should be avoided.²⁸ Colposcopic diagnostic accuracy, with or without biopsy, is 95% to 99%, and complications are rare.²⁹ The most common complication associated with colposcopically

directed biopsy is hemorrhage resulting from the increased vascularity of the cervix during pregnancy. Bleeding can be stopped by direct pressure to the site, with application of Monsel's (ferric subsulfate) solution, silver nitrate, vaginal packing, and rarely, suture ligation of vessels. Colposcopy and biopsy do not jeopardize the pregnancy as long as endocervical curettage is avoided. Observation without therapy is appropriate for pregnant women with cervical dysplasia if invasive cervical cancer has been excluded by colposcopy (with or without biopsies).²⁹⁻³⁴ This approach is supported by the American College of Obstetricians and Gynecologists (ACOG).³⁵ Inadequate colposcopic evaluation is indication for further evaluation with a cone biopsy in the nonpregnant patient, but pregnant women with an unsatisfactory initial colposcopic result may undergo repeat colposcopy in 6 to 12 weeks. Because the transformation zone undergoes further eversion as pregnancy progresses, a later examination may be satisfactory.³⁶ Treatment for cervical dysplasia such as laser therapy, cryotherapy, loop electrosurgical excision procedure (LEEP), and cone biopsy may therefore be deferred until the postpartum period. In women with biopsy-proven dysplasia identified during pregnancy who have no evidence of invasion by colposcopy, management may consist of serial colposcopy examinations with intermittent cervical cytology and expectant management of the pregnancy. Because regression of cervical dysplasia after pregnancy has been reported, withholding definitive treatment of this disease (in the absence of invasive cervical cancer) is appropriate. At 6 months after delivery, almost 70% of cervical intraepithelial neoplasia (CIN) II and III lesions resolved,³³ which is higher than the rate for the nonpregnant population.^{33,37} For this reason, delay of definitive therapy until after delivery is appropriate in a patient without evidence of invasive cervical cancer; however, the maximum interval from delivery until postpartum evaluation and management of cervical dysplasia has not been determined. Cervical cytology, colposcopy, directed biopsies, and endocervical curettage usually are performed around the 6-week postpartum evaluation.

In the pregnant state, LEEP and cone biopsies should be reserved for the exclusion of invasive disease. Risks of these procedures in pregnancy include cramping, bleeding, infection, premature preterm rupture of membranes, spontaneous abortion, preterm labor, and pregnancy loss. Complication rates are similar for LEEP and cone biopsy.³⁸ If a LEEP or cone biopsy is indicated to rule out malignancy, the safest time to perform them seems to be in the middle of the second trimester, between 14 and 20 weeks, or after fetal maturity is documented. In an effort to minimize preterm delivery after cone biopsy, some physicians have advocated concurrent MacDonalld cerclage at the time of cone biopsy. Although there were no complications in the largest study of this strategy, only 17 patients were evaluated.³⁹

For patients with cervical dysplasia diagnosed during pregnancy without any clinical evidence of invasive cervical cancer, the route of delivery is not affected by the dysplasia. However, some physicians have documented an increased rate of spontaneous remission of cervical cancer after vaginal delivery compared with cesarean delivery⁴⁰; others have not found this to be the case.⁴¹

Cervical Carcinoma

The occurrence of cervical carcinoma in pregnancy is rare, comprising only 1% of all cervical cancers diagnosed annually. However, because cervical cytology and examination are typically performed at the first prenatal visit, cervical cancer is one of the most common cancers diagnosed during pregnancy. Manifestation of cervical cancer during pregnancy is similar to that outside pregnancy, and most women present without symptoms. When detected in pregnancy, cervical cancer is usually stage I disease due to increased surveillance. The most

common symptom of cervical cancer in pregnancy is bleeding, especially after coitus. It is imperative for clinicians caring for pregnant women to recognize that vaginal bleeding is not necessarily related to the pregnancy and can be caused by other illnesses.

Pregnancy was once believed to alter the course of cervical cancer compared with nonpregnant cohorts, but there is no difference in survival or disease characteristics when matched cohorts are studied.^{37,42,43} However, when compared with nonpregnant counterparts, pregnant women with cervical cancer are much more likely to have stage I disease, and most have stage IB disease.^{42,44-47} Because of the physiologic and anatomic changes of pregnancy, induration or nodularity at the inferior cardinal ligament is less prominent, leading to underestimation of the stage and degree of tumor involvement. Nonetheless, pregnancy does not affect the survival rate for cervical cancer. The overall survival rate is 80% compared with 82% in nonpregnant patients.⁴⁸

According to the International Federation of Gynecology and Obstetrics (FIGO), clinical staging of cervical cancer can include intravenous pyelography, chest radiography, cystoscopy, and sigmoidoscopy. Although not included in the FIGO staging system, intravenous contrast-enhanced computed tomography (CT) has often been used for staging and treatment planning. The use and timing of these staging studies during pregnancy must be considered carefully because of the ionizing radiation used with CT and fluoroscopy (for barium enema and cystoscopy; see Table 43-2). Chest radiography is acceptable during pregnancy with appropriate abdominal and pelvic shielding. In some case reports, magnetic resonance imaging (MRI), which has been shown to be safe during pregnancy, has been used to define the extent of extracervical tumor spread.^{49,50}

After a stage has been established, management must be individualized. A multidisciplinary team, which may include a perinatologist, neonatologist, radiation oncologist, and gynecologic oncologist, must be recruited to counsel the patient regarding treatment options related to the stage, fetal status, and gestational age and to determine her desire to continue her pregnancy. In certain circumstances, treatment of the cancer is recommended despite the potential lethality of the therapy on the pregnancy. In others, treatment can be delayed until after delivery or until a gestational age when delivery will not produce significant morbidity.

In pregnant women with a cervical biopsy suggesting microinvasive cervical cancer, a cervical cone biopsy must be performed to definitively establish the diagnosis. Women with stage IA1 cervical cancer (<3 mm of invasion, <7 mm of tumor breadth) can be followed with periodic colposcopy and cytology, and the infant can be delivered when obstetrically indicated. Definitive management is deferred to the intrapartum (with cesarean hysterectomy) or postpartum period. Surgical treatment for stage IA1 cervical cancer may include cervical conization (with negative margins) or extrafascial hysterectomy, depending on the desire for future fertility. Cone biopsy during pregnancy carries additional risks over that performed outside of pregnancy. The timing of cone biopsy during pregnancy is controversial, with some physicians reporting fetal loss rates approximating 25% when conization is performed during the first trimester,⁵¹ whereas others have described the relative safety of early conization.⁵² Most agree, however, that the rates of fetal loss are less than 10% in the second trimester and nonexistent in the third trimester. Blood loss associated with cone biopsy increases with increasing gestational age. For that reason, care must be taken in determining when a cone biopsy should be performed during pregnancy. Limited data exist regarding the role of the LEEP during pregnancy.^{38,53} The initial investigation of this technique was associated with maternal and fetal morbidity, blood transfusion, inadequate spec-

imens, and residual disease in the conization specimen.³⁸ Further investigation of the relative safety and efficacy of LEEP compared with knife conization in pregnancy is required. When “microinvasive” cervical cancer is suggested by a cervical biopsy or invasive disease is suspected at colposcopy but not confirmed on biopsy, cervical conization is necessary, regardless of the duration of pregnancy. The procedure is optimally performed in the operating room, with a knife, after the period of organogenesis has passed and after appropriate counseling about the risks of fetal loss and transfusion. After conization with negative margins in a woman with confirmed pre-invasive disease or microinvasive carcinoma, follow-up colposcopy and possibly cytology can be used to monitor disease progression during pregnancy, with no alteration in the intrapartum management. In women who have completed childbearing, cesarean hysterectomy or postpartum hysterectomy can be considered. Although controversial, patients with cervical adenocarcinoma in situ or stage IA1 cervical adenocarcinoma with negative cone biopsy margins probably can be managed conservatively during their pregnancy, because most studies demonstrate a low risk of parametrial and lymphatic metastasis with early invasive cervical adenocarcinoma.⁵⁴⁻⁵⁶ However, there is a paucity of data regarding this disease during pregnancy.⁵⁷ Women with positive margins for dysplasia after conization during pregnancy must be counseled regarding the risk of current invasive disease, with management based on the risk and benefits of observation, repeat conization, or definitive therapy for possible invasive cervical cancer during pregnancy.

In women with stage IA2 or IB cervical cancer, identical oncologic outcomes have been reported with radiation therapy or radical hysterectomy and lymphadenectomy in addition to adjuvant radiation therapy (possibly with concurrent radiosensitizing chemotherapy). The advantage of primary surgical management includes the ability to preserve ovarian function and to avoid the potential negative impact on sexual function imparted by radiation therapy. The diagnosis of a stage IA2 or IB cervical cancer during pregnancy does not change the potential therapies recommended. The initiation of treatment is the critical issue in the management of early cervical cancer during pregnancy, specifically related to the potential risk of delay of definitive therapy on cancer outcomes to minimize fetal morbidity and mortality. Case reports and small case series suggest that a moderate delay in definitive therapy is associated with oncologic outcomes similar to those treated promptly. Sood and colleagues³⁸ described 11 women whose definitive treatment for stage IA and IB cervical cancers was delayed by an average of 16 weeks (range, 3 to 32 weeks). All 11 women remained without evidence of disease and without apparent negative outcomes related to the delay in definitive therapy during pregnancy. These and other reports of small series with a variety of treatment strategies suggest that a moderate delay of definitive therapy does not incur excessive risk. For this reason, women who are diagnosed with early cervical cancer at or beyond 20 weeks of their pregnancy are commonly offered the option of delaying therapy until delivery later in pregnancy or after birth. Women diagnosed with an early cervical cancer before 20 weeks should be informed of the risk of adverse oncologic outcomes related to delay of definitive therapy for their cervical cancer. However, the degree of risk is uncertain given the small number of patients for whom this management strategy has been reported. Thorough documentation of the risks of a decision to delay definitive treatment is imperative.

Immediate treatment options include radiation therapy or radical hysterectomy and lymphadenectomy for stage IA2 or IB disease. Irradiation usually leads to spontaneous abortion at a dose of 4000 cGy; evacuation of the uterus before therapy or in the absence of miscarriage from radiation therapy can be considered. For women who

choose to delay therapy for fetal development, coordination of care with the perinatologist, neonatologist, and gynecologic oncologist is critical to determine the appropriate gestational age for delivery that balances the maternal oncologic risks with the fetal risks of prematurity. Delivery, depending on the clinical extent of the cancer, followed by pelvic irradiation in 2 to 3 weeks is one option. Alternatively, cesarean delivery followed immediately by radical hysterectomy and lymphadenectomy is often recommended for reproductive-age women with early cervical cancer to preserve ovarian and vaginal function compared with radiation therapy. At surgery, it may be appropriate to move the ovaries out of the potential radiation field (i.e., oophoropexy) in women who may need postoperative adjuvant teletherapy.

For women with advanced cervical cancer who present in the second half of pregnancy, delay of therapy for fetal maturity carries a small but unquantifiable risk of adverse cancer outcome. Cesarean delivery (to avoid delivery through a cervical tumor⁵⁹) followed by radiation therapy with concurrent chemotherapy usually is recommended. In the first trimester and early second trimester, delay of therapy may increase the risk of a poor oncologic outcome, and it is therefore recommended to begin treatment at the time of diagnosis with ultimate sacrifice of the pregnancy as an unavoidable outcome. Evacuation of the uterus can be performed before irradiation or after radiation therapy if spontaneous miscarriage does not ensue. The anatomic distortion that occurs in pregnancy must be considered when planning radiotherapy to ensure the appropriate treatment fields. Patients who refuse immediate therapy for advanced cervical cancer during the first half of a pregnancy must be counseled regarding the potential impact on tumor growth and spread and the worsened prognosis. In selected patients, neoadjuvant chemotherapy (to decrease the risk of cancer progression during pregnancy) can be considered with definitive chemoradiotherapy initiated after delivery. However, there are limited data to support this management strategy.⁶⁰⁻⁶²

For women who delay definitive therapy for their cervical cancer until the postpartum period, the mode of delivery remains controversial. For early-stage disease, there is no consensus on whether vaginal delivery affects survival and prognosis. However, delivery through a bulky and friable cervical cancer leads to the potential risk of hemorrhage. Cervical cancer may recur at the episiotomy site, typically within 6 months of delivery.^{63,64} For these reasons, vaginal delivery should be reserved for appropriately counseled and carefully selected women with intraepithelial lesions and early-stage cancers. Women with cervical cancer who have delivered vaginally with episiotomy who later develop a lesion in the episiotomy should undergo biopsy to rule out recurrence at this site. For women with early cervical cancer whose primary therapy will be surgical, abdominal delivery with concurrent hysterectomy (i.e., extrafascial hysterectomy or radical hysterectomy and lymphadenectomy, depending on the tumor stage) is recommended.

In selected women with early cervical cancer, radical excision of the cervix (i.e., radical trachelectomy) and lymphadenectomy can be considered for definitive treatment of stage I cervical cancer with the potential to maintain future fertility. This procedure is usually performed independent of pregnancy, but it has been reported during pregnancy.⁶⁵ After radical trachelectomy, oncologic outcomes appear favorable in women with small squamous lesions without lymphovascular invasion. Although most women who attempt pregnancy after radical trachelectomy are able to conceive, pregnancy rates are decreased because of cervical dysfunction. The risk of preterm delivery is increased after radical trachelectomy, although most women deliver at term. Overall, approximately 2% develop recurrence, and 56% deliver a viable pregnancy (28% are term, and 28% are preterm).⁶⁶⁻⁷¹

Treatment of Cancer during Pregnancy

Radiation Therapy

Radiation during pregnancy may be used for diagnosis or therapy. Diagnostic radiation for cancer during pregnancy, in the form of x-rays, is used in chest radiography, CT for evaluation or staging of a cancer, and fluoroscopic techniques such as intravenous pyelography (IVP), retrograde pyelography, and barium enema. Radiographic imaging is often necessary for cancer during pregnancy. The known risks of diagnostic radiation have to be balanced with the expected benefits of such imaging. Units of radiation are expressed as rad, gray (Gy), milligray (mGy), or centigray (cGy). These interchangeable terms are units of absorbed dose and reflect the amount of energy deposited into a mass of tissue. One gray equals 100 rad. As it relates to pregnancy, the absorbed dose is the dose received by the entire fetus. Diagnostic radiation doses are less than 1 mGy (<0.1 cGy), and therapeutic radiation for cervical cancer delivers more than 4000 cGy to the fetus.

Because there is no dose of diagnostic radiation that is completely safe for the fetus, radiography should be avoided if possible during fetal development and minimized at all times during pregnancy. However, fetal tolerance to the level of radiation encountered in diagnostic procedures is greater than generally understood. Rarely does diagnostic radiography exceed the threshold of fetal tolerance during a pregnancy (Table 43-2). At the time of conception, exposure of 10 cGy usually results in embryologic death. If the embryo survives, radiation-induced noncancer health effects are unlikely. At all stages of gestation, radiation-induced noncancer health effects are not detectable for fetal doses below 5 cGy. From 16 weeks' gestation to birth, radiation-induced

TABLE 43-2 APPROXIMATE FETAL DOSES FROM COMMON DIAGNOSTIC RADIOGRAPHIC PROCEDURES

noncancer health effects are unlikely below 50 cGy. The risk of childhood cancer from prenatal radiation exposure is related to the amount of prenatal radiation exposure above the usual background. At a dose up to 5 cGy, the incidence of childhood cancer is 0.3% to 1%; at a dose of 5 to 50 cGy, the incidence is 1% to 6%; and at a dose higher than 50 cGy, the incidence is more than 6%.⁷² At a dose of 5 to 50 cGy between 8 and 15 weeks after conception, growth retardation and mental retardation can occur, with severe mental retardation occurring in up to 20% of cases. At this dose, there are no noncancer health effects expected with exposure at 16 weeks to term. At doses higher than 50 cGy, these noncancer health effects are expected to be more severe and more common than with lower doses, and the health effects can occur even with exposure from 16 to 25 weeks. After 25 weeks, prenatal radiation exposure with doses higher than 50 cGy leads to fetal death in a dose-dependent manner.^{73,74} Given the rarity of diagnostic radiation dosages beyond the thresholds of fetal exposure, therapeutic abortion is rarely recommended for this reason alone. When many radiographic studies are required, the fetal radiation dose should be monitored. Increased use of MRI and ultrasonography, imaging modalities that do not employ ionizing radiation, may avoid concerns related to the fetal risks of imaging studies.

Therapeutic radiation for cervical cancer during pregnancy is lethal to a fetus. Radiation exposure while the fetus is in the uterus leads to fetal death, usually followed by spontaneous abortion. Pelvic radiotherapy for cervical cancer leads to sterility as a result of the direct cytotoxic effect on the endometrium and ovarian injury by standard pelvic doses for treating this cancer (usually more than 4500 cGy). The threshold values for permanent and temporary sterility have not been clearly defined, but the risk of sterility is related to ovarian reserve (i.e., age at exposure) and dose. In women 40 years of age or older, 600 cGy can induce menopause. Adolescent girls treated with 2000 cGy fractionated over 5 to 6 weeks have a 95% likelihood of permanent sterility. With conventional therapeutic doses of radiation for cervical cancer, any field that includes the ovaries will cause sterility. Although the uterine effects cannot be avoided, transposing the ovaries out of the pelvic radiation field can preserve function in many women undergoing pelvic radiotherapy for cervical cancer.

Chemotherapy

The teratogenic effect of chemotherapy is inarguable. The effects of chemotherapeutic medications vary according to their mechanism of action and the gestational age of the fetus during their administration. Although there are few data regarding the use of cytotoxic chemotherapy during pregnancy for the treatment of gynecologic cancers, there is considerable literature about the use of these agents for treatment of pregnant women with lymphomas and leukemias. These data indicate that fetal exposure to chemotherapeutic agents within 2 weeks after conception leads to spontaneous abortion or no effect, with subsequent normal development. Chemotherapeutic agents kill rapidly dividing cells nonselectively in carcinomas and the embryo or fetus.^{11,75} The most susceptible period is the first trimester, when organogenesis occurs.⁷⁶ During organogenesis, exposure to most cytotoxic chemotherapeutics carries a high incidence of congenital malformations.⁷⁷ Numerous uncontrolled, observational reports describe good fetal and maternal outcomes with administration of chemotherapy during the second and third trimesters⁷⁸⁻⁸² but increased intrauterine growth restriction, low birth weight, spontaneous abortion, and preterm labor are also reported.^{77,80,83}

Chemotherapy around the time of delivery may cause concerns because of the risks of maternal myelosuppression with resultant neu-

troponia and thrombocytopenia. Furthermore, there may not be sufficient time for excretion of chemotherapy agents and their active metabolites from the fetus in time for delivery. The infant, after separation from the excretory function of the placenta and without mature hepatorenal excretion mechanisms, may experience adverse effects after birth. Other factors, such as maternal nutritional status, can alter protein-binding and serum free-drug concentration, and the expanded plasma volume experienced during pregnancy also affects the pharmacokinetics of a chemotherapeutic agent. To minimize the maternal and fetal risks associated with chemotherapy in proximity to delivery, a careful delivery plan with input from the obstetrician, perinatologist, neonatologist, and oncologists involved must be made.

If chemotherapy for a gynecologic cancer is required during pregnancy, ovarian function is usually preserved, and future fertility should not be jeopardized. Long-term follow-up of children who were exposed to anti-neoplastic agents in utero found that exposed offspring usually have normal birth weights, educational performance, and reproductive capacity.⁸⁴⁻⁸⁷

Surgical Principles

Pregnant women are not immune to processes that require surgical intervention. Because of their relative youth and general good health, pregnant women tolerate surgical procedures well, and obstetric outcomes are usually good after uncomplicated surgical procedures. Among 5405 women undergoing non-obstetric surgical procedures, most were performed in the second trimester.⁸⁸ The rates of stillbirth and congenital anomalies were not different from those for pregnancies not associated with surgery, but low birth weight and preterm delivery were more common. An increased risk of preterm delivery has been reported after surgery in the first trimester, and it was increased with longer procedure times.⁸⁹ If surgery is required during pregnancy, it should be performed when possible during the second trimester and under controlled circumstances. Urgent procedures performed in pregnancy should be carried out in an efficient, effective manner. In particular, abdominal surgery during pregnancy carries increased fetal risk compared with extra-abdominal surgery.

Laparoscopic surgery is feasible and relatively safe during pregnancy.⁹⁰⁻⁹⁴ Laparoscopic procedures are associated with less pain in the postoperative period, reduced use of analgesics and tocolytics, and overall shorter length of bed rest and hospitalization compared with laparotomy. The most common indications for laparoscopic surgery during pregnancy are cholecystectomy, evaluation of an adnexal mass, and appendectomy.⁹⁵ Surgical risks inherent to minimally invasive surgery do not appear to be increased in pregnancy, and laparoscopic techniques in pregnant patients should not differ greatly from that of open procedures. As with open procedures, fetal heart tones should be obtained before and after the procedure. Continuous intraoperative fetal heart rate monitoring, if technically feasible, may be helpful to ensure satisfactory uterine blood flow in procedures when maternal blood loss is anticipated. A sustained fall in fetal heart rate may indicate decreased uterine perfusion that can be restored by repositioning the patient to relieve aortocaval compression or by expanding the intravascular volume. Nasogastric or orogastric decompression can be used to minimize insertion of ports into the stomach, and the patient should be placed in a leftward tilt to minimize aortocaval compression. The pneumoperitoneum should be established through an open technique to minimize the risk of uterine perforation or laceration. Although rare, insertion of the Veress needle to establish the pneumoperitoneum into the uterus has led to fetal loss through the development of a pneumoamnion.⁹⁶ Ancillary ports should be placed carefully. Because

of an intra-abdominal space that is progressively compromised, laparoscopy usually should be avoided after the late second trimester; however, this situation should be evaluated on a case-by-case basis. One possible risk of laparoscopy is that the developing fetus may be exposed to acidosis caused by maternal absorption of the carbon dioxide gas with subsequent hypercarbia and serum conversion to carbonic acid. Studies of fetal sheep in response to insufflation have demonstrated that these animals have adequate compensatory response and placental reserve to tolerate insufflation, although one pregnant ewe died during establishment of the pneumoperitoneum.^{97,98} There have been no human reports of fetal loss attributable to acidosis caused by pneumoperitoneum, and this risk may be theoretical. With any surgical approach during pregnancy (open or minimally invasive), the gravid uterus should be manipulated as little as possible to minimize the risk of spontaneous preterm labor, ruptured membranes, or other complications. Prophylactic tocolytics at the time of surgery in the second trimester do not decrease the risk of preterm labor or preterm delivery in these patients, but it may be beneficial in the third trimester.⁸⁹

Gestational Trophoblastic Neoplasia

Gestational trophoblastic neoplasia (GTN) is a spectrum of pregnancy-related conditions that have the potential for local invasion, distant metastasis, and death from disease. These conditions arise from abnormal fertilization and manifest as a missed abortion, as a miscarriage, or are concurrent with or follow a normal gestation. During the past 50 years, significant strides have been made in the diagnosis and treatment of GTN, and it is the most successfully treated gynecologic cancer and one of the most curable solid tumors in women. The full discussion of the diagnosis and treatment of GTN is beyond the scope of this text but can be found in texts of gynecologic oncology.

GTN is described here as it relates to ongoing pregnancies. As a pregnancy-related cancer, GTN can be diagnosed and followed with serum levels of β -human chorionic gonadotropin (β -hCG). Using transvaginal ultrasonography, an intrauterine pregnancy can be diagnosed when the β -hCG level is 1500 to 2000 IU/mL (for singleton gestations). The threshold for transabdominal ultrasonography is higher—approximately 6500 IU/mL. When an abnormal pregnancy is diagnosed, GTN must be considered. The histologic spectrum of GTN includes partial and complete molar pregnancies, gestational choriocarcinoma, and placental-site trophoblastic tumors. Molar pregnancy occurs in 1 of every 1000 pregnancies in the United States, and it is more common in women at the extremes of age for reproduction. Women most often present with amenorrhea, followed by vaginal bleeding in the first trimester. With the increasing use of transvaginal ultrasound in early pregnancy, it is rare for molar pregnancies to manifest later in the course of the disease, when hyperthyroidism, severe hyperemesis, and hypertension may occur. Often, patients complain of passage of vesicles from the uterus. These vesicles are usually seen on transvaginal ultrasound, and in the absence of a gestational sac or fetal parts, a diagnosis of partial molar pregnancy is usually made. Clinically, the uterus is larger than expected because of the molar pregnancy or the resultant ovarian thecal lutein cysts. Included in the differential diagnosis of a positive serum β -hCG level in the absence of an intrauterine or extrauterine pregnancy must be that of phantom β -hCG syndrome,⁹⁹ in which circulating serum factors such as heterophilic antibodies or nonactive forms of β -hCG interact with the β -hCG

antibody to create false-positive β -hCG results. These findings may lead to inappropriate initiation of therapy for GTN. This false β -hCG reading can be excluded by running a simultaneous urine sample for β -hCG, because these serum factors are not excreted in the urine. Alternatively, the serum can be serially diluted, with the expectation of a linear decrease in β -hCG levels in the case of a true-positive result. Because not all β -hCG testing platforms are susceptible to this false-positive result, the use of an alternative platform may exclude phantom β -hCG syndrome.^{99,100}

Molar pregnancy may coexist with a normal gestation in 1 of 20,000 to 100,000 pregnancies.¹⁰¹ Coordinated care among the obstetrician, perinatologist, neonatologist, and gynecologic oncologist must ensue. These pregnancies are associated with a higher incidence of complications such as fetal death, vaginal bleeding, pre-eclampsia, and persistent GTN after evacuation. Historically, early pregnancy termination has been recommended to avoid subsequent complications. However, in the largest reported series,¹⁰¹ 60% of women who chose to continue a normal pregnancy coexistent with a complete molar pregnancy experienced spontaneous abortion or fetal demise before 24 weeks, and 40% delivered a live infant at 24 weeks or later (most after 32 weeks). The rate of persistent GTN requiring chemotherapy was not different in women undergoing early pregnancy termination compared with those who did not terminate and no different from that experienced by patients with a singleton complete molar event in this series.¹⁰¹

Pregnancy and Solid Tumors

Breast Cancer in Pregnancy

Gestational or pregnancy-associated breast cancer is defined as breast cancer that is diagnosed during pregnancy, in the first postpartum year, or any time during lactation. Physiologic changes in the breast make the diagnosis of breast cancer during pregnancy a challenge. Nevertheless, any discrete lump felt in the breast should be investigated further by a specialist breast team.

Epidemiology

Breast cancer is one of the most common malignancies encountered in pregnant women. The reported incidence ranges from 1.3¹⁰² to 3.3² cases per 10,000 live births. Although only 0.2% to 3.8% of breast cancers diagnosed in women younger than age 50 are pregnancy associated, almost 10% to 20% of breast cancers diagnosed in women in their 30s are discovered during pregnancy.^{103,104} This pattern of prevalence is likely to change in the future with an increase in gestational breast cancers as more women delay childbearing.

Clinical Presentation and Diagnosis

The most common clinical presentation of breast cancer in pregnant and nonpregnant women is a painless lump in the breast. Occasionally, refusal by an infant to nurse from a lactating breast may signify an occult carcinoma, and it has been described as the milk rejection sign.¹⁰⁵ The physiologic changes in the breast during pregnancy and lactation result in engorgement and increased nodularity, which makes it a challenge for the patient and clinician to identify these tumors by palpation. Such challenges result in diagnostic delays of 2 months or longer, which in part is responsible for the advanced stage at diagnosis in pregnant or lactating women. In a mathematical model assessing tumor progression over time, a 1-month delay in the treatment of primary tumor increased the risk of axillary metastases by 0.9% to 1.8%.¹⁰⁶ Clinicians therefore should perform a thorough

breast examination at the initial prenatal visit and without hesitation thereafter.

The differential diagnosis of a breast mass in a pregnant or lactating woman is provided in Table 43-3. Although 80% of breast biopsies obtained from pregnant women are benign, it is important to biopsy any lump that is present for 2 to 4 weeks.¹⁰⁷

IMAGING

Mammography has a high false-negative rate during pregnancy, with sensitivity rates ranging from 63% to 78% in some studies.^{108,109} Mammography during pregnancy is safe because the average glandular dose to the breast for a two-view mammogram (200 to 400 mrad) results in a negligible radiation dose of only 0.4 mrad to the fetus.^{110,111} Radiation exposure is expressed as gray (Gy) units (1 Gy = 1000 mGy = 100 rad; 1 rad = 10 mGy). Fetal exposures less than 5 rad (50 mGy) are not thought to cause malformation (see Chapter 20),⁶² and mammography still has a place in the evaluation of a breast mass in pregnancy.

Ultrasound is usually the preferred imaging modality to evaluate a breast mass in a pregnant woman. It is inexpensive, safe for the fetus, and can distinguish between solid and cystic lesions in 97% of patients.¹¹²⁻¹¹⁴ If lymph nodes are palpable, axillary sonography with ultrasound-guided fine-needle aspiration biopsy should be done as part of staging evaluation.

The American Cancer Society recommends screening MRI for women who have an approximately 20% to 25% or greater lifetime risk of breast cancer,¹¹⁵ but there are no published data regarding the use of MRI to diagnose breast cancer during pregnancy. Although gadolinium-enhanced MRI is more sensitive than mammography for detecting invasive breast cancer, its use in pregnant women is limited by its passage across the placenta and reported association with fetal abnormalities in rats. MRI therefore is not recommended for the diagnosis of breast cancer during pregnancy. For postpartum women at the time of diagnosis, gadolinium-enhanced breast MRI may be considered if necessary.^{110,116} MRI may be used for staging evaluation in a pregnant woman as long as contrast is avoided (staging evaluation is discussed later).

BIOPSY

Core-needle biopsy is the preferred method of tissue confirmation in pregnant women with suspected breast cancer.¹⁰⁷ This can be performed under local anesthesia and has no risks unique to pregnancy. Although fine-needle aspiration can be used, the proliferative changes induced by pregnancy may result in an indeterminate score requiring additional evaluation for diagnosis.^{117,118} The accuracy of interpreta-

tion of fine-needle aspiration biopsy depends on an experienced pathologist who is aware that the woman is pregnant.

One of the known, albeit rare, complications of such biopsies during lactation is the development of milk fistula.¹¹⁹ Suspending breastfeeding before the biopsy decreases the incidence of milk fistula.

STAGING

Evaluation. The tumor, node, and metastasis (TNM) staging system of the American Joint Committee on Cancer is appropriate for pregnant and nonpregnant women with breast cancer. Women with gestational breast cancer often present with later-stage disease than women who are not pregnant, which is attributable to the delay in diagnosis. A thorough history and physical examination of the breast and axilla are required to determine whether the woman needs a comprehensive staging workup.

Axillary Staging. Clinically palpable lymph nodes should be evaluated by ultrasound-guided fine-needle aspiration biopsy for pathologic confirmation. Sentinel lymph node biopsy has emerged as the standard technique in staging clinically node-negative women with early-stage breast cancer. Sentinel lymph node biopsy has not been fully evaluated in gestational breast cancer. Isosulphan blue dye should not be administered to pregnant women. Some small studies have reported that the use of double-filtered technetium sulfur colloid to map sentinel lymph nodes in pregnancy is safe, but no supporting larger studies have been reported.^{110,120,121} Sentinel lymph node biopsy is not recommended in women with gestational breast cancer outside of a clinical trial.¹²²

Distant Metastases. The three most common sites of distant metastases in breast cancer are the lung, liver, and bone. As with nonpregnant women, women with gestational breast cancer who are asymptomatic and are clinically node negative do not require further formal staging because the yield in such patients is low. Complete radiologic staging evaluation should be considered in women with symptoms, women with clinically palpable nodes, and women with T3 or T4 lesions. Chest radiographs can be performed safely in pregnancy with abdominal shielding. Chest CT scans should be avoided. If further evaluation of the chest is required, MRI (without gadolinium) of the thorax is preferred. Abdominal ultrasound is the safest method to look for liver metastases in pregnancy, although MRI without contrast can be done if necessary.¹¹⁰ CT of the abdomen and pelvis is not preferred in pregnant women because fetal radiation exposure approximates 250 mrad. For bony metastasis, low-dose bone scans or MRI without contrast of the thoracic and lumbar spine is recommended.¹²³ Baker and colleagues¹²⁴ reported a “low-dose” bone scan with a fetal exposure of only 0.08 rad, compared with the standard 0.19 rad of conventional bone scan. Maternal hydration and frequent voiding is required to reduce the fetal exposure to radiation resulting from accumulation of radionuclides in the maternal bladder. Plain skeletal radiographs including the spine and pelvis are acceptable and safe options for evaluation of bone with less than 1 rad (0.01 Gy) of exposure to the fetus. The other alternative to identify metastatic bony lesions is non-contrast MRI of thoracic and lumbar spine. MRI is also the most sensitive and safe way to scan the brain for metastatic lesions.

Among the blood tests routinely obtained, alkaline phosphatase is not helpful. The level normally doubles or even quadruples during pregnancy, and it therefore cannot be used as an indicator for metastases.¹²⁵

Pathology of Gestational Breast Cancer

Most breast cancers in pregnancy are poorly differentiated, infiltrating, ductal carcinomas.¹²⁶ Women with breast cancer in pregnancy have

larger tumors and more frequent nodal involvement, metastasis, and vascular invasion.^{104,127,128} Women with gestational breast cancers have a higher incidence of inflammatory breast cancer and are 2.5 times more likely to have distant metastatic disease.¹²⁹ Breast cancers that have estrogen or progesterone receptors are less common (25%) during pregnancy compared with the rate of 55% to 60% in nonpregnant premenopausal women.^{103,112,126,127} The high levels of circulating estrogen and progesterone in pregnancy may bind all the hormone receptor sites or downregulate them, resulting in negative receptor status in hormone binding assay. One series suggested that the proportion of hormone receptor positive tumors in pregnant women is closer to the nonpregnant state when immunohistochemical methods are used.¹³⁰ Amplification of the *HER2* gene or increased expression of its ERBB2 protein (i.e., the oncoprotein fragment p105 is used in assays) is observed in approximately one fourth of breast cancers. Few studies have reported the incidence of this gene amplification in pregnant women with breast cancer, but most have quoted a higher incidence. For example, one series found that 7 (58%) of 12 gestational breast cancers were HER2 positive compared with 16% of age-matched nonpregnant controls.¹³⁰ However, the percentage of HER2-positive tumors was similar to that for nonpregnant breast cancer patients in a prospective series of pregnant breast cancer patients.¹²⁶

Treatment

The treatment of breast cancer during pregnancy should closely follow the guidelines recommended for women who are not pregnant. Treatment should be administered with a curative intent with minimal delay. Therapeutic decisions should be individualized, taking into consideration the gestational age, stage of the disease, and the preferences of the patient and her family. Abortion is usually not recommended but may be considered for an individual patient during treatment planning. Care by her obstetrician, perinatologist, and oncology team

should be coordinated as described previously for women with leukemia, lymphoma, or solid tumors.

LOCOREGIONAL TREATMENT

Surgery is the definitive treatment for pregnancy-associated breast cancer. Mastectomy with axillary dissection is traditionally considered the best choice for stage I, II, and some stage III breast cancers when the patient chooses to continue the pregnancy.^{131,132} Mastectomy eliminates the need for breast radiation therapy in stage I and II disease and therefore minimizes the risk associated with fetal radiation exposure. If breast reconstruction is desired, it should be delayed until after delivery because prolonged surgery may increase fetal complications.

Breast-conservation surgery is a treatment option for women diagnosed in the late second trimester or early third trimester. Lumpectomy with axillary dissection is feasible in pregnancy. In such cases, radiation therapy to the entire ipsilateral breast is delayed until after delivery.¹³³ In women who present with locally advanced-stage disease, neoadjuvant chemotherapy can be considered before definitive surgery. The feasibility of breast-conservation surgery depends on the clinical response (Fig. 43-1).

Axillary dissection is an essential component of treatment and staging because nodal metastases are commonly found in pregnancy-associated breast cancer. Choice of systemic therapy also depends on comprehensive staging of the nodal involvement. Although sentinel lymph node biopsy is the preferred method of axillary staging in women with clinically node-negative breast cancer, the safety and reliability of this procedure in pregnant women have not been established. Sentinel lymph node biopsy is not recommended for pregnant women with early-stage breast cancer.¹²²

Adjuvant radiation therapy improves local control of breast cancer and survival. The risks of teratogenicity and induction of childhood malignancies and hematologic disorders complicate but do not

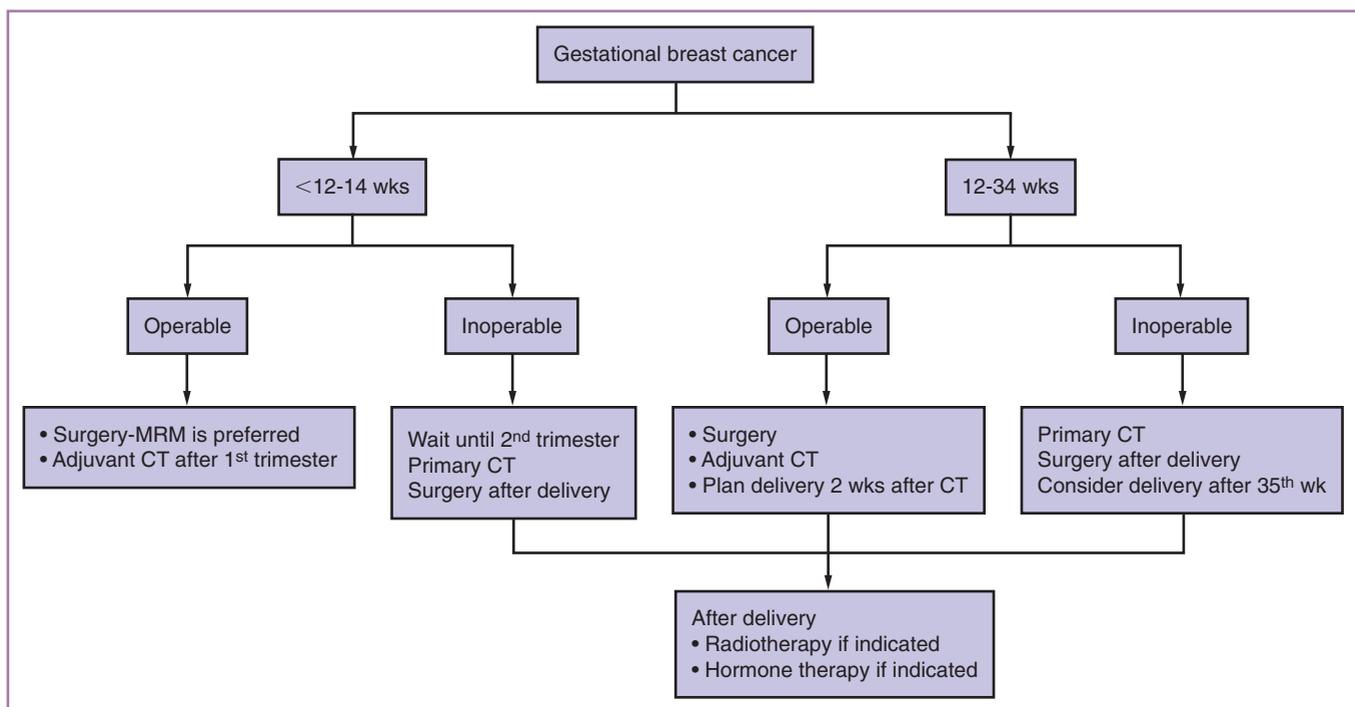

FIGURE 43-1 Algorithms for treatment of breast cancer in pregnancy. Neoadjuvant chemotherapy can be considered before definitive surgery for women who present with locally advanced stage disease. Breast conservation surgery depends on the clinical response to therapy. CT, chemotherapy; MRM, modified radical mastectomy.

preclude the use of radiation therapy in the management of breast cancer in pregnancy.¹³⁴ In selected and appropriately counseled women, radiotherapy of breast cancer is possible with fetal doses that fall below the customary threshold for malformations of 5 rad. The excess childhood cancer risk has been estimated as 6.57 cases per 10,000 children per rad per year.¹³⁵ For a typical treatment regimen approximating 50 Gy (5000 rad), radiation of the maternal breast or chest wall has been estimated to expose the fetus to as little as 0.1% to 0.3% of the total dose, or 0.05 to 0.15 Gy of the total dose,¹²¹ or as much as 3.9 to 15 rad in the first trimester and 20 rad in late third trimester.¹³⁶ Some experts do not recommend radiation therapy during pregnancy,^{137,138} but each patient should be counseled based on her own circumstances.

SYSTEMIC THERAPY

Adjuvant chemotherapy is recommended for all premenopausal patients with node-positive breast cancer or with tumors greater than 1 to 2 cm in diameter that are poorly differentiated. Most of the pregnancy-associated breast cancers fit in this category. All chemotherapeutic agents used in breast cancer have been categorized by the U.S. Food and Drug Administration as category D or X, indicating that teratogenic effects have occurred in humans (see Chapter 20). Information regarding the effects of chemotherapy administered during pregnancy is largely compiled from case reports and small case series. Dosing of chemotherapy during pregnancy is complicated by increased plasma volume, increased hepatorenal clearance, decreased serum albumin, and decreased gastric emptying, which increases absorption.¹³⁹

Chemotherapy exposure during the first trimester, the period of organogenesis, carries the greatest risk for spontaneous abortion, fetal death due to chromosomal, and congenital abnormalities. Chemotherapy is usually deferred during this period as long as the health of the mother is not compromised because of the treatment delay.¹⁴⁰⁻¹⁴²

The incidence of congenital malformation is low if chemotherapy is administered to women in second or third trimester.^{123,127,128,131,139,143} One review reported a 1.3% risk of fetal malformation for 150 women given chemotherapy in the second or third trimester, compared with a risk of 16% in first-trimester chemotherapy.¹⁴⁴ However, approximately 50% of infants exposed to chemotherapy in the second or third trimester manifest intrauterine growth retardation, prematurity, and low birth weight.^{145,146} The most commonly used regimen in gestational breast cancer is doxorubicin with cyclophosphamide (AC regimen) with or without 5-fluorouracil (FAC regimen). The only prospective study of chemotherapy in pregnant women with breast cancer was conducted with the FAC regimen in a cohort of 24 women and used the same doses administered to nonpregnant women.¹³² Chemotherapy was not given in the first trimester, and the study reported no birth defects in the infants. The median gestational age in this study was 38 weeks. It is unclear whether in utero exposure to anthracyclines is cardiotoxic to the fetus.

Methotrexate should be avoided in all stages of pregnancy because of the possibility of third spacing in the amniotic fluid and its abortifacient and teratogenic effects.^{142,144} Although several case reports have shown the safety of administering taxanes during pregnancy, the long-term effects are unknown.^{147,148} The current international guidelines for the use of chemotherapy in gestational breast cancer do not recommend the use of taxanes.¹⁴⁹ No data are available on the use of dose-dense therapy in pregnancy, and it is not recommended. Chemotherapy should be avoided for 3 to 4 weeks before delivery to avoid infectious complications due to transient myelosuppression.

Addition of trastuzumab to adjuvant chemotherapy has made a significant impact on disease-free and overall survival in women with HER2-overexpressing breast cancers. Only four case reports of the use of trastuzumab in pregnancy have been published.¹⁵⁰⁻¹⁵⁴ Reversible oligohydramnios and reversible maternal heart failure were described. No fetal abnormalities have so far been reported.

For women who have hormone receptor-positive breast cancer during pregnancy, therapy with tamoxifen or other selective estrogen receptor modulators is deferred until after delivery. These agents have been associated with vaginal bleeding, spontaneous abortion, birth defects, and fetal death.¹⁵⁵⁻¹⁵⁷ Long-term effects of tamoxifen on female offspring are unknown.

Use of antiemetics such as promethazine, ondansetron, or dexamethasone is considered safe during pregnancy. Granulocyte colony-stimulating growth factor and erythropoietin have been safely used in pregnant patients, and their use should follow the general guidelines.

Monitoring of Pregnancy and Timing of Delivery

Pregnant women with breast cancer should be monitored closely by their obstetrician and oncologist. Gestational age should be accurately determined to plan the timing of chemotherapy and delivery. If possible, delivery should be planned 3 to 4 weeks after chemotherapy, allowing time for the recovery of cell counts. The timing of delivery is related to the maternal condition, need for further therapy, and expected neonatal and infant outcomes. As a general rule, women receiving chemotherapy should be cautioned against breastfeeding while receiving chemotherapy.

Termination of Pregnancy

Early termination of pregnancy does not improve the outcome of breast cancer in pregnancy.¹⁵⁸ Some series suggest inferior outcomes in pregnant women with breast cancer who undergo elective termination compared with those who continue with the pregnancy.¹⁵⁹ Termination decisions should be individualized and depend on the patient's willingness to accept a possible risk to the fetus from cancer therapy, her overall prognosis, and the ability to care for the offspring.

Prognosis of Breast Cancer Associated with Pregnancy

The prognosis of breast cancer occurring during pregnancy has changed over the years. Current reports suggest similar survival of women with gestational breast cancers compared with age- and stage-matched control groups.^{128,158,160} In 1994, Petrek and associates¹⁶¹ reported a 5-year survival rate of 82% for pregnant and nonpregnant women with node-negative breast cancer, 47% for node-positive pregnant women, and 59% for node-positive nonpregnant women.¹⁶¹ There are, however, other case-control studies that showed decreased survival for pregnant women with breast cancer.^{129,162}

Follow-up after Breast Cancer

Women with breast cancer occurring during pregnancy should be monitored for recurrence and long-term side effects of cancer therapy according to the guidelines recommended by the American Society of Clinical Oncology and the National Comprehensive Cancer Network (NCCN) for all women with breast cancer.

Pregnancy after Breast Cancer

The impact of future pregnancy in young women with breast cancer is uncertain. Three large, registry-based studies have concluded that women who become pregnant after successful treatment of breast

cancer do not have worse prognosis with regard to their cancer.^{143,163-165} Reports that the outcome of early breast cancer is improved in women with a subsequent pregnancy suggest a possible antitumor effect of pregnancy.¹⁶⁶⁻¹⁶⁸ Most recurrences of breast cancer occur within the first 2 years after initial treatment, and oncologists therefore recommend a delay of 2 to 3 years before contemplating pregnancy.¹⁶⁹

Malignant Melanoma in Pregnancy

Malignant melanoma occurs in 2.8 of 1000 deliveries¹⁷⁰ and accounts for 8% of all gestational malignant tumors. Concerns regarding the possible relationship between melanoma and pregnancy arose from early reports of poor outcome of melanoma in pregnant women.¹⁷¹ Melanoma occurring during pregnancy may be more advanced and is more likely located in sites associated with poorer prognosis.¹⁷²⁻¹⁷⁴ Head, neck, and truncal lesions occurred in 43% of pregnant patients, compared with 38% of nonpregnant controls, but other reports found no increase in poor prognostic locations in pregnancy.¹⁷⁵ Pregnancy has been associated with increased tumor thickness in some reports.¹⁷⁵⁻¹⁷⁷ There may be a hormonal induction of proliferation of the cancerous melanoma cells in pregnancy, but no specific pregnancy-related hormone has been identified. The effect of pregnancy on tumor site and thickness remains unclear.

Historically, melanoma in pregnancy has been associated with a poorer prognosis, with several controlled studies reporting a decrease in survival rates compared with those for nonpregnant women.^{173,174,178,179} However, when matched for site and stage, no significant difference in survival is observed. Trapeznikov and coworkers¹⁷⁹ reported the only study showing a difference in survival rate despite matching by age, tumor site, and stage. At 10 years of follow-up, there was a statistically different survival rate of 26% for the pregnant group and 43% for the nonpregnant group in this study.¹⁷⁹

Other studies have not observed any significant differences in survival rates in pregnant women, but some report a shorter disease-free survival for pregnant women,^{175-177,180,181} perhaps because of the shorter follow-up period in these studies. Three large, case-control studies of the prognosis of melanoma diagnosed during pregnancy did not show any difference in survival.¹⁸²⁻¹⁸⁴ O'Meara and colleagues¹⁸⁴ used the records from the California Cancer Registry between 1991 and 1999 and reported no difference in survival between 303 patients with pregnancy-associated melanoma and 1799 age-matched nonpregnant controls.

Surgery is the only effective cure for melanoma. Recommendations should be based on the same prognostic factors established for a nonpregnant patient. In a pregnant woman diagnosed with early-stage melanoma, there is no reason to delay surgery. Chemotherapy does not offer sufficient benefit to the mother to warrant risk to the fetus. In pregnant women presenting with metastatic disease, the decision regarding termination of pregnancy and initiating systemic therapy should be individualized according to the prognosis and the patient's wishes. Although melanoma is not the most common malignancy manifesting in pregnancy, it is the most common cancer to metastasize to the placenta.

Colon Cancer in Pregnancy

Colorectal cancer in pregnancy presents a diagnostic, therapeutic, and ethical challenge. Colorectal cancer in pregnancy is a rare event, with a reported incidence of 0.008% (1 in 13,000) pregnancies.¹⁸⁵ Approximately 300 cases have been reported in the literature. The mean age of diagnosis of colorectal cancer in pregnancy is 31 years (range, 16 to 48 years).¹⁸⁶ The management of colorectal cancer in pregnancy raises

several ethical and medicolegal issues because the treatment goals for the mother often conflict with the interests of the fetus. The diagnosis is particularly difficult because the common signs and symptoms of colon cancer are often attributed to the pregnancy. This results in advanced stages of the disease at diagnosis, with a correspondingly poor prognosis. Enhanced awareness among the medical community is needed to diagnose colon cancer earlier in pregnancy and thereby improve outcomes. A team approach involving experts in obstetrics, neonatology, gastrointestinal surgery, and medical oncology is required for optimal management.

Clinical Presentation

Common presenting signs and symptoms of colon cancer include abdominal pain, anemia, nausea, vomiting, constipation, abdominal mass, weight loss, and rectal bleeding. Many of these symptoms occur normally in pregnancy, and others, such as weight loss and an abdominal mass, can be masked by pregnancy.¹⁸⁷ This diagnostic challenge often leads to delayed diagnosis and evaluation and to a poor prognosis for colorectal cancer in pregnancy. A review of 41 cases of colorectal cancer in pregnancy demonstrated that all the patients presented with Duke class B or greater disease.¹⁸⁶

Predisposing Factors

Colorectal cancer is rare in young patients, and colorectal cancer in pregnancy designates a special group of young women who must have predisposing factors leading to this condition. Predisposing factors for colon cancer include hereditary nonpolyposis colorectal cancer (HNPCC) (i.e., Lynch syndrome), familial adenomatous polyposis, Gardner's syndrome, Peutz-Jeghers syndrome, and long-standing inflammatory bowel disease. However, in their review of 19 pregnant patients with colorectal cancer, Girard and coworkers¹⁸⁵ attributed these predisposing factors to only four patients.

Factors such as steroid hormones, TP53 protein abnormality, and cyclooxygenase-2 (COX-2) enzyme levels have been implicated in colorectal cancer in pregnancy. Between 20% and 54% of colon cancers have estrogen receptors, and some studies have also demonstrated progesterone receptors.¹⁸⁸ The role these hormones play in the progression of colon cancers has been related to the interaction between their receptors and other growth-signaling pathways.¹⁸⁹ However, data to support an etiologic role of hormone receptors in colon cancer and circulating hormones are conflicting.

Diagnosis

Colonoscopy is the procedure of choice to obtain a biopsy and confirm a diagnosis in a nonpregnant patient with suspected colorectal cancer. However, pregnancy is a relative contraindication to colonoscopy. Possible adverse effects of colonoscopy in pregnant women include placental abruption from mechanical pressure to the uterus, fetal exposure to potential teratogenic medications, and fetal injury resulting from maternal hypoxia or hypotension.¹⁹⁰ The patient and her family should be fully informed about all potential risks to the mother and fetus, and informed consent should be obtained. The risks may be minimized with gentle abdominal compression during colonic intubation, use of meperidine instead of benzodiazepines, administering oxygen to the mother, and antenatal fetal monitoring.¹⁹¹

Pregnant patients with persistent gastrointestinal symptoms should be evaluated by a specialist gastroenterologist with sigmoidoscopy as an alternate to colonoscopy. Most cases of colorectal carcinomas in pregnancy are rectal carcinomas; 86% of colorectal carcinomas diagnosed in pregnancy were below the peritoneal reflection in one review.¹⁷³ The serum level of carcinoembryonic antigen (CEA) is a

reliable laboratory test used for the diagnosis, prognosis, and monitoring of the colorectal cancer in pregnancy.¹⁹² Unfortunately, it is not a useful tool for screening because of its low sensitivity and specificity. Abdominal CT used for staging of colon cancer is contraindicated in pregnancy. Alternatives include ultrasound and MRI without contrast to assess the extent of the cancer in the abdomen and pelvis in a pregnant woman. Ultrasound has a sensitivity of 75% for detecting hepatic metastatic lesions.

Treatment

Management of colorectal cancer in pregnancy is influenced by the gestational age, tumor stage, and need for elective or emergent surgery. There are no universally accepted guidelines for treatment. Goals of care are prompt initiation of treatment of the cancer and delivery of the infant as soon as neonatal outcomes are optimized. When colorectal cancer is diagnosed in the first 20 weeks of pregnancy, the recommended treatment is surgical removal of the tumor. Colon cancer is rarely detected before 20 weeks' gestation, which explains the paucity of data on fetal outcome after colonic or rectal resections. Anecdotal reports have described birth of normal infants after such resections. Because of the controversial data regarding the risks of such resections to the pregnancy, termination of pregnancy and resection of the tumor constitute the recommended treatment.¹⁹³ Delaying surgery until after delivery may result in significant tumor progression and is not recommended.

When the diagnosis is made after 20 weeks of pregnancy, surgery may be delayed until the fetal prognosis has improved. However, delay can result in progression of the cancer, increasing the mother's risks. The patient should be fully informed about these risks before making a decision to postpone surgery.

Colorectal cancer in pregnancy may be complicated by ovarian metastases, which are reported in 25% in pregnant patients but only 3% to 8% in nonpregnant patients.^{194,195} Prophylactic bilateral salpingo-oophorectomy simultaneous with resection is recommended by some, but it is associated with an increased risk for spontaneous abortion. Bilateral wedge biopsies of the ovaries may be performed during surgery for pathologic examination and subsequent removal if the ovaries are involved.¹⁹⁶

Adjuvant chemotherapy is recommended for stage II or III colorectal cancer. Chemotherapy cannot be administered in the first trimester but can be considered in the second or third trimesters. The most commonly used agent is 5-fluorouracil, but its use in pregnancy has been associated with fetal abnormalities.¹⁹⁷ Irinotecan, oxaliplatin, bevacizumab, and cetuximab are all newer agents used in the management of colorectal cancer, but experience with these agents in pregnancy is not well documented. Adjuvant radiation therapy is indicated in the management of Dukes B and C rectal cancers, but it is contraindicated in pregnancy. Radiation therapy should be employed postoperatively after delivery or elective abortion.

Prognosis

Colorectal cancer in pregnancy is associated with a poor prognosis. There are no reports of 5-year survivors of colorectal cancer diagnosed in pregnancy. Despite the poor prognosis, the stage-for-stage survival of women with colorectal cancer in pregnancy is similar to that of the general population.¹⁸⁶ Delay in diagnosis and advanced-stage disease at presentation most likely explain the overall poor prognosis in pregnancy. Gestational colon cancer also appears to worsen the pregnancy outcomes. Woods and associates¹⁹⁸ reported that 78% of pregnancies in women with colon cancer resulted in live births; deaths were attributed to prematurity and intrauterine demise.

Hematologic Malignancies during Pregnancy

Diagnosis and management of acute and chronic leukemias, non-Hodgkin lymphoma (NHL), and Hodgkin lymphoma (HL) arising within the setting of pregnancy are difficult. Approximately 1 of 1000 to 6000 pregnancies¹⁹⁹ and 1 of 75,000²⁰⁰ pregnancies are complicated by lymphoma or leukemia, respectively. Because hematologic malignancy during pregnancy is rare and clinical trials in pregnancy are complicated by ethical dilemmas, there are few data to guide decisions about imaging, therapy, maternal toxicities, and gestational and postnatal complications.

Therapeutic options include observation, radiotherapy, chemotherapy, and termination of pregnancy. Several retrospective studies suggest that chemotherapy can often be safely administered during the second and third trimesters of pregnancy, and it should be considered in women with potentially curable and life-threatening leukemias and lymphomas.^{199,200} In women with aggressive and curable hematologic malignancies, delay in therapy can prevent remission, contribute to future disease relapse, and hasten maternal death.²⁰⁰ Chemotherapy during the second and third trimesters should therefore be considered for pregnant women with acute leukemia, HL, and Burkitt and diffuse, large B-cell NHL. When chemotherapy poses a high risk to the fetus (e.g., in the first trimester in women with few clinical manifestations) or when the hematologic malignancy is incurable (e.g., indolent NHL, chronic leukemias), fetal toxicity can be limited by deferring treatment until later stages of the pregnancy or by using palliative chemotherapy or steroids during pregnancy. Regardless of the therapeutic approach, the management of a pregnant patient with a hematologic malignancy requires careful coordination and collaboration among medical oncologists, perinatologists, and neonatologists.

Hodgkin Lymphoma in Pregnancy

Epidemiology, Diagnosis, and Staging

HL is the fourth most common malignancy complicating pregnancy.²⁰¹ The relative frequency of HL in pregnancy is a function of the high incidence of HL in persons 15 to 34 years old. HL typically manifests as enlarging lymphadenopathy, favoring the lymph nodes of the neck, mediastinum, and axilla. A contiguous pattern of spread of HL between lymphatic channels of the upper neck, chest, and mediastinum has been described,²⁰² with lymph node involvement tracking from the neck to the mediastinum and axilla before involvement of intra-abdominal nodes or the spleen. Patients with mediastinal adenopathy often notice increasing shortness of breath or cough, symptoms common in normal pregnancies, which may delay diagnosis in pregnant women. Isolated subdiaphragmatic lymphadenopathy rarely occurs.

Diagnosis of HL requires excisional or core-needle biopsy, because the malignant Reed-Sternberg cells are often missed on fine-needle aspiration. Staging for HL follows the Ann Arbor staging system (Table 43-4) and usually requires CT of the chest, abdomen, and pelvis; bone marrow biopsy; and ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG-PET). Bone marrow biopsy can be performed safely during pregnancy, but the fetal risks associated with ionizing radiation preclude the use of abdominal pelvic CT and PET in pregnant women. Typical staging of pregnant patients consists of a CT chest with appropriate abdominal shielding and the use of abdominal

TABLE 43-4 ANN ARBOR STAGING SYSTEM FOR HODGKIN LYMPHOMA AND NON-HODGKIN LYMPHOMA

Stage*	Description
I	Involvement of a single lymph node region or lymphoid structure or involvement of a single extralymphatic site (I _E)
II	Involvement of two or more lymph node regions on the same side of the diaphragm, which may be accompanied by localized, contiguous involvement of an extralymphatic site or organ (II _E)
III	Involvement of lymph node regions on both sides of the diaphragm, which may also be accompanied by involvement of the spleen (III _S) or by localized contiguous involvement of an extralymphatic site or organ (III _E)
IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues, with or without lymph node involvement

*The absence or presence of fever (>38 °C), unexplained weight loss (>10% of body weight), or night sweats should be indicated by the suffix letters A or B, respectively (e.g., IIA, IIIB).

MRI to detect intra-abdominal adenopathy. Because multiagent chemotherapy is used to treat early-stage and advanced-stage HL, accurate staging is less critical for the pregnant patient because the chemotherapy treats disease above and below the diaphragm. Few patients receive radiotherapy alone.

PET has been incorporated into response definitions for HL and aggressive NHL.²⁰³ The use of PET improves the sensitivity of traditional staging methods, and its results have prognostic significance during therapy.²⁰⁴⁻²⁰⁶ However, because it is contraindicated during pregnancy, PET scan can be delayed until the completion of therapy and after delivery. Although a pretherapy PET scan can facilitate the interpretation of post-therapy PET scans, a PET scan is not required at diagnosis for the management of patients with classic HL because it is routinely avid for FDG.²⁰³ At the conclusion of therapy, a PET scan is essential for persons with HL to confirm a complete remission of a disease for which residual mediastinal masses may represent fibrosis or persistent disease. PET negativity correlates with disease-free survival.²⁰⁴⁻²⁰⁶ Although a PET scan cannot be used to stage a pregnant patient, it is performed for all patients after delivery on completion of therapy.

Therapy

Therapeutic options for pregnant patients with HL depend on clinical features, maternal wishes, fetal risks, the gestational age at diagnosis, and potential complications. Pregnancy was associated with poor patient outcomes in HL, late presentation, minimal response to therapy, and short progression-free and overall survival times.²⁰⁷⁻²⁰⁹ However, these reports were likely confounded by delayed diagnosis and inferior therapy, because later series incorporating multiagent chemotherapy regimens into the treatment of pregnant patients demonstrated response and survival outcomes comparable to those for nonpregnant patients.^{208,210-213}

CHEMOTHERAPY

During the first trimester, in women with painless adenopathy and without respiratory compromise or B symptoms (e.g., fevers, night

sweats, weight loss >10% [see Table 43-4]), therapy may be deferred until after the first trimester to minimize the risk of fetal teratogenicity from chemotherapy. In women with symptoms, palliative measures such as corticosteroids or single-agent chemotherapy (i.e., vinblastine) may be necessary to control symptoms until the second trimester. Chemotherapy in the first trimester has been associated with fetal malformations, an increased risk of spontaneous abortion, and stillbirth.²¹⁴⁻²¹⁸ In particular, antimetabolites (e.g., fluorouracil, gemcitabine, fludarabine, cytarabine) or alkylating agents (e.g., busulfan, chlorambucil, cyclophosphamide, ifosfamide) should be avoided in the first trimester because of their teratogenic effects.^{199,218-220} Fortunately, the front-line chemotherapy regimen commonly used to treat HL is doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD), consisting of antitumor antibiotics and antimicrotubule agents. In some series, ABVD has been administered during the first trimester without fetal complications.^{84,221} However, because data to support the safe use of ABVD in the first trimester are limited and the potential for teratogenesis is significant, ABVD should be offered only during the first trimester after appropriate counseling when the health of the mother is at risk due to rapidly progressive disease. Palliative treatment of symptoms with steroids, single-agent treatment with vinblastine, or delayed therapy until the second trimester are preferable options.

Therapy for HL during the second and third trimester consists primarily of chemotherapy. ABVD appears safe in the second and third trimesters of pregnancy,^{84,221} and because HL is potentially curable, the regimen should be offered to all patients unless delivery is expected within 2 to 3 weeks. Prolonged treatment delays may ultimately affect the prognosis of the mother and increase the risk for future relapse. Unlike the first trimester, in which the potential fetal effects of chemotherapy include malformations and demise, multiagent chemotherapy in the second and third trimesters primarily results in lower birth weights, with rare reports of cardiac toxicity related to anthracycline (Adriamycin) therapy and neonatal myelosuppression complicated by respiratory distress or enterocolitis.^{218,222} One trial correlated cardiac toxicity with higher doses of the anthracycline, with a dose per cycle of Adriamycin exceeding 70 mg/m² associated with a 30-fold increase in fetal events.²¹⁸ Fortunately, with the ABVD regimen, the Adriamycin dose per cycle is only 50 mg/m². In at least one series with long-term follow-up of 3 to 19 years, children born to women who received chemotherapy in their first, second, and third trimesters did not experience neurologic, psychologic, or immunologic effects, and they did not develop secondary malignancies.²²¹ These reports offer some reassurance that standard doses of ABVD are likely safe in the second and third trimesters of pregnancy.

RADIOTHERAPY

Before the advent of the ABVD chemotherapy, radiotherapy with abdominal shielding was occasionally employed for the treatment of pregnant women with early-stage HL confined to the neck, mediastinum, or axilla. However, radiotherapy as a single modality has fallen out of favor in treating nonpregnant and pregnant patients because chemotherapy alone or combined-modality regimens (e.g., ABVD and involved field radiotherapy) have become the standard of care for early-stage and advanced-stage HL. Combined-modality regimens are more effective than radiation alone in early-stage HL, require limited doses and fields of radiation, and may have fewer late toxicities than previously employed extended fields of radiation.²²³ Because most pregnant women cannot be adequately evaluated for intra-abdominal involvement because PET scans and abdominal CT are contraindicated, radiotherapy alone may undertreat patients with undetected

stage III or IV disease. Extended fields and higher doses of radiation have been associated with second malignancies, including breast and lung cancers, and with late cardiovascular disease in HL survivors.²²⁴⁻²²⁶ Radiotherapy fields encompassing the mediastinum or axilla ultimately include breast tissue and potentially increase the risk for late secondary breast cancers, particularly in women younger than 30 years old.²²⁴ Radiotherapy alone therefore is only considered for selected patients (pregnant and nonpregnant) with stage I or II HL confined to the neck without B symptoms. In this setting, fetal exposure usually is less than 0.1 Gy (10 rad) with abdominal shielding.^{227,228} Mediastinal radiation or mantle field irradiation (neck and mediastinum) typically leads to fetal radiation doses of 0.03 to 0.25 Gy, exceeding the recommended fetal radiation exposure of 0.1 Gy. When this dose is required for therapy, chemotherapy should be employed during pregnancy and, if necessary, radiotherapy delayed until after delivery.^{227,228} Despite the fetal and maternal risks associated with radiotherapy, some patients will ultimately require radiotherapy for early-stage disease as part of combined-modality therapy regimens or to treat sites of initially bulky disease, where radiotherapy can minimize the risk of relapse.²²⁹ In these patients, ABVD chemotherapy is offered during the second and third trimesters of pregnancy, with radiotherapy withheld until the postpartum period.

Non-Hodgkin Lymphoma in Pregnancy

Epidemiology, Diagnosis, and Staging

The incidence of NHL during pregnancy is low, although the incidence of NHL in the general population has been steadily rising since the 1980s, increasing the likelihood of diagnosis during pregnancy.²³⁰ Studies of NHL during pregnancy are complicated by the number of subtypes of NHL—at least 30 using the World Health Organization classification system of lymphoid malignancies²³¹—including B-cell, T-cell, NK-cell, and plasma cell neoplasms. As a result, the presenting features of the disease depend on the histologic subtype. Aggressive B-cell NHL subtypes (i.e., diffuse, large B-cell; primary mediastinal B-cell; and Burkitt lymphomas)^{207,232,233} more commonly occur during pregnancy because these diseases more frequently affect younger patients than indolent or T-cell subtypes. However, indolent NHL, including follicular and marginal zone lymphomas, T-cell lymphoma, and multiple myeloma, have been reported during pregnancy.²³⁴⁻²⁴⁵

Diffuse, large B-cell lymphoma is perhaps the most common NHL during pregnancy, followed by Burkitt lymphoma. Diffuse, large B-cell lymphoma comprises 30% to 40% of all NHLs and can occur at any age. Common clinical presentations include lymphadenopathy, a mediastinal mass, involvement of a single extranodal site (e.g., bones, lung, liver), and B symptoms.^{199,231} Primary mediastinal large-cell lymphoma is a clinical variant of diffuse, large B-cell lymphoma that has a female predominance, a large anterior mediastinal mass associated with dense fibrosis, and often involvement of other extranodal sites.^{231,246} A patient's presenting features often are related to compressive symptoms from the mediastinal mass, including dyspnea on exertion or superior vena cava syndrome.

Burkitt lymphoma is uncommon in adults, representing only 1% to 2% of all NHL subtypes, but it accounts for 30% to 50% of all childhood lymphomas.²¹⁸ The median age of adult patients at presentation is 30 years, and as a result, Burkitt lymphoma is the second most common NHL manifesting during pregnancy.²⁴⁷ Burkitt NHL frequently manifests in extranodal sites, often with intra-abdominal masses arising from the mesenteric lymph nodes, bowel, kidney, liver, spleen, or ovaries. A high incidence of breast, cervical, uterine, and

ovarian involvement by Burkitt NHL is reported in pregnant patients.^{233,244,248-252} Involvement of these organs is observed in nonpregnant patients with Burkitt lymphoma; however, the increased blood flow to the breast, ovary, cervix, and uterus during pregnancy may also contribute to this presentation.

Similar to HL, the diagnosis of NHL during pregnancy requires core-needle or excisional biopsy because fine-needle aspiration is often insufficient to confirm the subtype of NHL.²⁵³ Routine staging of NHL, as in HL, follows the Ann Arbor staging system (see Table 43-4) and requires CT scans of the chest, abdomen, and pelvis; bone marrow biopsy; and occasionally a PET scan. Bone marrow biopsy, CT of the chest (with abdominal shielding), and MRI of the abdomen are typically employed for the pregnant patient with NHL to minimize fetal radiation exposure. PET, which is routinely performed for patients with aggressive NHL to determine therapeutic response and prognosis,²⁰³⁻²⁰⁶ can be deferred until the end of therapy and after delivery.

Therapy

Historically, coincident pregnancy at the time of a diagnosis of NHL was associated with poor patient outcomes.^{207,208,254-256} This may be attributed to the higher frequency of aggressive NHL subtypes in pregnant patients and to a reluctance to treat pregnant patients with the multiagent chemotherapy regimens necessary for long-term cure. The rarity of NHL and the variety of subtypes of NHL have made accurate assessment of outcomes during pregnancy difficult because of the unique prognosis, clinical outcome, and therapeutic approach for each NHL subtype. In retrospective series, pregnancy did not adversely influence patient outcomes when multiagent chemotherapy was administered during the second and third trimesters.^{217,232,257}

TREATMENT OF DIFFUSE, LARGE B-CELL NON-HODGKIN LYMPHOMA

Chemotherapy is the mainstay of therapy for most aggressive NHL subtypes. In nonpregnant patients with diffuse, large B-cell lymphoma, an approach of three to six cycles of rituximab, cyclophosphamide, Adriamycin, vincristine, and prednisone (RCHOP regimen) with additional involved radiotherapy for early-stage or bulky NHL is potentially curative. RCHOP has been safely administered during the second and third trimesters of pregnancy, with limited toxicity to the mother or fetus, with the exception of decreased birth weight and fetal B-cell depletion.^{258,259} Rituximab, an anti-CD20 monoclonal antibody, specifically targets malignant and normal B cells bearing CD20. This agent can deplete normal B cells in treated patients for 3 to 6 months; however, this has not been associated with an increased incidence of infections.²⁶⁰ This same B-cell depletion is observed in infants whose mothers receive rituximab while pregnant, and the effect may persist for up to 4 months after birth with no consequent increase in infections.²⁵⁹

Because of the potential teratogenic effects of chemotherapy in the first trimester, combination chemotherapy with RCHOP is usually reserved until later trimesters for pregnant women with diffuse, large B-cell and primary mediastinal large-cell NHL. However, both are potentially curable malignancies, and therapy in the second and third trimesters should be considered after appropriate counseling. Deferring all therapy until after delivery can potentially compromise outcome because these aggressive lymphomas progress quickly, and the likelihood of cure decreases with advanced stages. For women with symptoms during the first trimester, palliative steroids may be administered until later stages of pregnancy, when chemotherapy administration is less risky. Radiotherapy is frequently administered after

chemotherapy for women with early-stage or bulky disease, and it can be delayed until after delivery.

TREATMENT OF BURKITT NON-HODGKIN LYMPHOMA

Treatment of Burkitt NHL during pregnancy is quite challenging. This malignancy is curable in up to 84% of young patients, but Burkitt lymphoma has a doubling time of 25 hours and can rapidly progress to involve the bone marrow or central nervous system, making observation until after delivery almost impossible. Alkylating agents, anti-metabolites, antimicrotubule agents, and antitumor antibiotics are all incorporated into typical Burkitt lymphoma regimens, which include methotrexate, Adriamycin, cyclophosphamide, vincristine, ifosfamide, cytarabine, etoposide, and intrathecal chemotherapy.²⁴⁷ Treatment with less aggressive regimens, including RCHOP, may adversely affect patient outcome. Therapy after relapse is frequently ineffective. Patients who relapse or progress during initial treatment require stem cell transplantation. Optimal and immediate treatment at diagnosis with multiagent chemotherapy is critical and potentially curative.

Although some series have reported safely administering these multiagent regimens containing cyclophosphamide, doxorubicin, etoposide, vincristine, methotrexate, ifosfamide, and cytarabine (i.e., CODOX-M/IVAC regimen) during pregnancy,²⁵⁷ such series are limited. Other physicians have recommended palliating the patient with RCHOP until delivery, at which time aggressive, multiagent regimens can be administered.²⁵⁸ These approaches may result in increased risk to the fetus or a increased risk of relapse for the mother. All options, including termination of the pregnancy, must be weighed. Potential toxicities and disease outcomes must be discussed with the mother and the obstetric, oncology, and pediatric physicians. Treatment options during pregnancy for women with Burkitt NHL must be determined on an individual basis, but if the pregnancy is allowed to continue, strong consideration should be given to administration of multiagent chemotherapy with a clear understanding of the potential fetal risks associated with this approach, because this malignancy is potentially curable and can progress within days. However, because of the limited data regarding toxicities associated with these multiagent regimens, including profound and prolonged myelosuppression, termination of pregnancy is often recommended.

Leukemia in Pregnancy

Epidemiology and Diagnosis

Acute leukemia complicates about 1 in 75,000 pregnancies.^{200,261} Several subtypes of acute leukemia are recognized. They are separated on the basis of their cell of origin (i.e., myeloid and lymphoid) and cytogenetic abnormalities.²³¹ The most commonly encountered acute leukemias during pregnancy include acute myeloid leukemia (AML), acute promyelocytic leukemia (APL), and acute lymphoid leukemia (ALL). Presenting features include elevated white blood cell counts, neutropenia, anemia, thrombocytopenia, disseminated intravascular coagulation with associated bleeding or thrombosis (in APL) and occasionally lymphadenopathy (in ALL). The diagnosis of acute leukemia during pregnancy requires peripheral blood examination and bone marrow biopsy with flow cytometry and cytogenetic analysis.

Therapy

In a retrospective review of 37 women presenting with acute leukemia during pregnancy, the median age at diagnosis was 30 years (range, 19 to 45 years), and the gestational age at diagnosis was 23 weeks (range,

5 to 37 weeks).²⁶¹ Twenty-four percent of patients presented during the first trimester, 27% in the second, and 49% during the third. Four (11%) of these cases were APL, 6 (16%) were ALL, and 27 (73%) were AML. In all cases, chemotherapy was initiated immediately, with therapeutic abortion recommended to the women presenting in the first trimester. Multiagent chemotherapy consisted of anthracycline (i.e., idarubicin or Adriamycin) and cytarabine for AML; anthracycline, cytarabine, and all-*trans*-retinoic acid for APL; and anthracyclines, vincristine, cyclophosphamide, prednisone, and asparaginase for ALL. Ninety-two percent achieved a complete remission, and the 3-year disease-free survival reached 65%, which was similar to the rate for the nonpregnant population. Overall, 11 infants who were exposed to chemotherapy during the second or third trimesters were delivered, and all developed normally, with no growth or developmental abnormalities or infectious complications.

A second large case series described the outcomes of 51 pregnant women diagnosed with acute leukemia between 1968 and 1986.²⁶² In this series, AML accounted for 51% of cases, ALL for 33%, and APL for 8.5%, with 26% of patients presenting during the first trimester, 32% during the second, and 42% in the third. For the 43 women diagnosed in the second and third trimesters, 1 spontaneous abortion, 1 elective abortion, 2 stillbirths, 1 low-birth-weight infant, 18 premature births, and 20 term deliveries were reported. Only one congenital malformation (i.e., adherence of the iris to the cornea) occurred, and 3 of 39 infants had transient cytopenias. For 15 women treated during the first trimester, three infants had low birth weights, seven infants were premature, one was stillborn, two were delivered at term, and three abortions occurred. One infant had esophageal atresia and anomalous inferior vena cava and eventually developed a neuroblastoma and thyroid carcinoma at age 14.

Fetal risk was highest with chemotherapy exposure in the first trimester; however, combination chemotherapy must be considered for acute leukemia patients who are pregnant because of the likelihood of rapid disease progression and maternal complications without therapy. Potential risks from acute leukemia and its treatment during pregnancy include preterm delivery, low birth weight, disseminated intravascular coagulation, and maternal or fetal bleeding and infection because of thrombocytopenia and neutropenia.

Chapter 44

Renal Disorders

David J. Williams, PhD, and John M. Davison, MD

Among the many physiologic changes that occur in normal pregnancy, few are as profound as those affecting the urinary system.¹ These healthy alterations and various diagnostic pitfalls for the unwary clinician are discussed in Chapter 7. Improvements in our knowledge about gestational physiology in antenatal care generally, technology for fetal surveillance, and neonatology services have meant better care and outcomes for women with renal problems and their newborns.^{2,3} With this in mind, this chapter focuses on urinary tract infection (UTI), acute and chronic renal disease in pregnancy, and the management of pregnant women on dialysis or with renal allografts.

Urinary Tract Infection

The incidence of asymptomatic bacteriuria (i.e., significant growth of a uropathogen in the absence of symptoms) is 2% to 10%, which is the same during pregnancy as it is in sexually active nonpregnant women.⁴ However, the structural and immunologic changes to the urothelium of the renal tracts during pregnancy⁵ make it more likely that a lower UTI will ascend to cause acute pyelonephritis.^{4,5} During pregnancy, 12.5% to 30% of women with untreated asymptomatic bacteriuria develop acute pyelonephritis,^{4,6-8} a serious infection with significant morbidity for the mother and fetus.

Diagnosis of Urinary Tract Infections

During pregnancy, symptoms suggesting a UTI are dysuria and offensive-smelling urine. Others usually associated with a UTI are urinary frequency, nocturia, urge incontinence, and strangury (i.e., the urge to pass urine having just done so), but these symptoms are also found in healthy pregnant women.

Microscopy and culture of a freshly voided midstream urine sample allow quantification of pyuria (i.e., leukocytes in the urine) and growth of a urinary pathogen. A bacterial UTI is the most common cause of pyuria and is considered significant if microscopy of a sample of unspun midstream urine reveals more than 10 leukocytes per microliter. Urine culture is conventionally recognized as significant if there is growth of more than 10^5 colony-forming units per milliliter (CFU/mL) of a single recognized uropathogen, in association with pyuria.⁹ Low counts of bacteriuria¹⁰ (2^4 to 10^4 CFU/mL) may still be significant if symptomatic women have a high fluid intake or are infected with a slow-growing organism. If left untreated, most symptomatic women with low-count bacteriuria will have 10^5 CFU/mL 2 days later.⁹ During pregnancy, the most common uropathogens are bowel commensals,

Escherichia coli (70% to 80%), *Klebsiella*, *Proteus*, *Enterobacter*, and *Staphylococcus saprophyticus*.

If urine from a symptomatic pregnant woman is cloudy and positive on dipstick testing for nitrite (produced by most uropathogens) and leukocyte esterase (produced by white blood cells), a UTI is likely and empiric treatment can be started.⁹ These urine sticks are not sensitive enough to be used for screening for asymptomatic bacteriuria in early pregnancy,¹⁰ and microscopy and culture of a clean catch midstream urine sample is necessary. Hematuria and proteinuria are unreliable indicators of a UTI, but they are important signs of renal disease (discussed later).

Asymptomatic Bacteriuria

Maternal and Fetal Risks

During pregnancy, untreated asymptomatic bacteriuria will develop into acute pyelonephritis in up to 30% of women, but if treated, less than 1% of pregnant women develop pyelonephritis.^{4,6,7} A systematic review of 14 studies confirmed that antibiotic treatment of asymptomatic bacteriuria significantly reduced the incidence of pyelonephritis compared with placebo or no treatment (odds ratio [OR], 0.25; 95% confidence interval [CI], 0.14 to 0.48).¹¹ After successful treatment of asymptomatic bacteriuria, monthly screening of midstream urine is necessary, because about 30% of women will have a relapse of bacteriuria, making them vulnerable to acute pyelonephritis again.⁴

Asymptomatic bacteriuria has been associated with an increased risk of preterm delivery and low birth weight.¹² Treatment of asymptomatic bacteriuria has been shown to reduce the incidence of low-birth-weight infants (OR, 0.66; 95% CI, 0.49 to 0.89)¹¹ but have no effect on preterm delivery.⁶ It has been suggested that the underlying renal pathology, which is commonly associated with bacteriuria, is responsible for poor pregnancy outcomes.⁶ Additional good-quality studies are needed to settle this issue.

Management of Asymptomatic Bacteriuria

Contrary to much published advice, not all pregnant women need to be screened for asymptomatic bacteriuria. There are two main reasons. First, the prevalence of asymptomatic bacteriuria varies between populations, and where it is low (<2.5%), it is hard to justify the cost-effectiveness of screening. In populations in which the prevalence of asymptomatic bacteriuria is more than 5%, the case for screening is much stronger.⁷ Second, approximately 1% to 2% of the 90% to 98% of asymptomatic women who test negative for bacteriuria in the first

trimester will develop a symptomatic UTI.^{8,13} This means that one third of all women who develop a UTI in late pregnancy would have been missed on first-trimester screening.^{8,13} Women at increased risk for pyelonephritis or renal impairment should be screened for asymptomatic bacteriuria every 4 to 6 weeks throughout pregnancy.

Treatment of Urinary Tract Infections

There is no consensus about the optimal treatment of asymptomatic bacteriuria¹⁴ or the empiric treatment of symptomatic UTIs in pregnancy.¹⁵ Most urinary infections during pregnancy (approximately 75%) are caused by *E. coli*, which is usually sensitive to nitrofurantoin (89%), trimethoprim with or without sulfamethoxazole (87%), ampicillin (72%), or cephalosporins.^{16,17} Until well-structured trials are done, the most cost-effective treatment for asymptomatic bacteriuria or a first episode of cystitis is nitrofurantoin monohydrate macrocrystals (100 mg twice daily for 3 days) or trimethoprim (200 mg twice daily for 3 days).¹⁷ Nitrofurantoin should be avoided after the onset of labor in patients with glucose-6-phosphate dehydrogenase deficiency, although no well-documented cases of hemolysis in neonates have been recorded,¹⁸ and trimethoprim should be avoided in the first trimester because it is a folic acid antagonist associated with an increased risk of neural tube defect.¹⁹

Screening for recurrent infections should begin 1 week after completion of initial treatment and then be done every 4 to 6 weeks for the remainder of pregnancy. Recurrent infections or a first infection in a pregnant woman at high risk for pyelonephritis should be treated with a 7- to 10-day course of an antibiotic that reflects antibacterial sensitivities.¹⁷ Women who have had two episodes of asymptomatic bacteriuria or cystitis should be considered for low-dose antibiotic prophylaxis—guided by the sensitivities of the most recent infective organism—for the remainder of pregnancy and until 4 to 6 weeks after birth.²⁰ Suitable regimens for long-term antibiotic prophylaxis include nitrofurantoin (50 to 100 mg each night), amoxicillin (250 mg each night), cephalexin (125 to 250 mg each night), or trimethoprim (100 to 150 mg each night).²⁰ These women should also be investigated for structural abnormalities of the renal tracts or renal calculus using ultrasonography.

Acute Pyelonephritis

The same uropathogens that cause asymptomatic bacteriuria and cystitis are responsible for acute pyelonephritis.²¹ The prevalence of asymptomatic bacteriuria in a pregnant population dictates the incidence of acute pyelonephritis. Screening and treating a high-risk population for asymptomatic bacteriuria reduces the incidence of acute pyelonephritis to less than 1%.^{8,11} Unless acute pyelonephritis is treated promptly, there is considerable maternal and fetal morbidity.²¹

Maternal Symptoms and Signs

Most women with acute pyelonephritis present in the second or third trimester.²¹ More than 80% of women present with backache, fever, rigors and costovertebral angle tenderness, and about one half have lower urinary tract symptoms, nausea, and vomiting.²¹ Bacteremia occurs in 15% to 20% of pregnant women with acute pyelonephritis,²¹ and a small proportion of these women will develop septic shock and increased capillary leak, leading to pulmonary edema.²² It is important, however, to differentiate the hypotension due to reduced intravascular volume (i.e., fever, nausea, and vomiting) from that caused by septic shock. Women with pyelonephritis at risk for serious complications are those who present with the highest fever (>39.4 °C) and tachycardia

(>110 beats/min) at 20 weeks' gestation or later and who have received tocolytic agents and injudicious fluid replacement.²³

Fetal Risks

Acute pyelonephritis can trigger uterine contractions and preterm labor.²⁴ Antibiotic treatment of pyelonephritis reduces uterine activity, but patients with recurrent infection or marked uterine activity are at increased risk for preterm labor.²⁴ Because uterine activity often occurs in the absence of cervical change and because tocolysis with β -mimetics aggravates the cardiovascular response to endotoxemia,²³ tocolytic therapy should be used with care and only in those with cervical changes.²⁵

Management of Acute Pyelonephritis

Women suspected of acute pyelonephritis from their history, symptoms, and signs should be admitted to the hospital. Laboratory tests should include a full blood cell count, serum creatinine concentration, levels of electrolytes, and urine culture. If there are systemic symptoms or septic shock, a blood culture may be useful. Pregnant women with pyelonephritis and septic shock need intensive care. For these women, assessment of the state of hydration is critical and often requires invasive hemodynamic monitoring with a central venous pressure line. This can optimize fluid balance, aiming for a urine output greater than 30mL/hr to minimize renal impairment and reduce the risk of pulmonary edema. Intravenous antibiotics should be started empirically (discussed later) until the sensitivities of blood and urine cultures are known. These women often have transient renal impairment, thrombocytopenia, and hemolysis, suggesting that the alveolar capillary endothelium is damaged by endotoxin.²² A blood film and lactate dehydrogenase concentration can be used to diagnose hemolysis.

Trials investigating the outpatient management of pyelonephritis in pregnancy have identified a group of women who can be managed at home.²⁵ These women should be less than 24 weeks' gestation, be relatively healthy, and understand the importance of compliance. They should have an initial period of observation in the hospital to demonstrate an ability to take oral fluids and receive intramuscular cefuroxime or ceftriaxone. After satisfactory laboratory tests, they can go home and are seen again within 24 hours for a second intramuscular course of cephalosporin. They then start a 10-day course of oral cephalexin (500 mg four times daily) or appropriate antibiotic with regular outpatient follow-up.²⁴ Following this regimen, 90% of women will improve as outpatients, and 10% will require hospital admission because of sepsis or recurrent pyelonephritis. Women with acute pyelonephritis who are beyond 24 weeks' gestation should be admitted for at least 24 hours to observe the maternal condition as described earlier and to monitor uterine activity and the fetal heart rate.²⁵

Gram-negative bacteria causing pyelonephritis in pregnancy are often resistant to ampicillin,²⁶ and intravenous cefuroxime (750 mg to 1.5 gm, depending on severity of condition, every 8 hours) is an effective first choice until culture sensitivities are known.¹⁵ Women allergic to β -lactam antibiotics can be given intravenous gentamicin (1.5 mg/kg every 8 hours) for the initial treatment of acute pyelonephritis. A single-dose regimen (7 mg/kg every 24 hours) should be avoided during pregnancy to reduce the very small risk of cranial nerve VIII damage to the fetus.¹⁷ Serum concentrations of gentamicin should be measured and dose adjustments made according to identified levels. Intravenous antibiotics should be continued until the patient has been afebrile for 24 hours. Oral antibiotics should then be given for 7 to 10 days, according to bacterial sensitivities, or if not available, as if for symptomatic lower UTI.¹⁷

Failure of these measures to improve the maternal clinical condition within 48 to 72 hours suggests an underlying structural abnormality. Ultrasonography is an easy but inconclusive way of excluding stones. If clinical suspicion is high, a plain abdominal radiograph can identify 90% of renal stones, and a one-shot intravenous urogram (IVU) at 20 to 30 minutes can identify the remainder.²⁵ The risk to the fetus from radiation of one or two radiographs is minimal, especially when compared with the clinical benefit of identifying an obstructed, nonfunctioning kidney. Urinary tract obstruction can also be detected using magnetic resonance urography, especially during the second and third trimesters.²⁷

After one episode of pyelonephritis, pregnant women should have monthly urine cultures to screen for a recurrence.²⁵ The risk of recurrent pyelonephritis can be reduced with antimicrobial prophylaxis chosen according to the sensitivities of initial bacterial infection^{20,28} or with nitrofurantoin (100 mg every night) continued until 4 to 6 weeks after delivery.²⁵

Acute Renal Failure in Pregnancy

Acute renal failure has become a rare but serious complication of pregnancy. In early pregnancy, acute renal failure is associated with septic abortion (a complication largely confined to the developing world) and dehydration related to hyperemesis gravidarum. Around the time of delivery, acute renal failure is most commonly caused by gestational syndromes such as preeclampsia and abruptio placentae (Table 44-1). However, pregnancy is a prothrombotic state that is associated with heightened inflammation²⁹ and major changes to the vascular endothelium,³⁰ particularly the glomerular capillary endothelium.³¹ These physiologic changes predispose pregnant women to acute glomerular capillary thrombosis. Whereas nonpregnant patients who suffer an acute prerenal insult (e.g., hemorrhage, dehydration, septic shock) may develop transient acute tubular necrosis if inadequately treated, the same prerenal insult in pregnancy is more likely to develop into renal cortical necrosis with permanent renal impairment. This is even more likely to occur if a prerenal insult coexists with a pregnancy-related condition that induces a consumptive coagulopathy or endothelial damage (e.g., preeclampsia).

Management is aimed at identification and correction of the precipitating insult and optimal fluid resuscitation, which is best guided by monitoring the central venous pressure and pulmonary artery wedge pressure. If oliguria persists despite euolemia with deteriorating renal function or fluid overload, fluid restriction followed by renal replacement therapy is indicated.

TABLE 44-1 CAUSES OF ACUTE RENAL FAILURE IN PREGNANCY

Most common causes	Severe preeclampsia Placental abruption
Causes in early pregnancy	Septic abortion Hyperemesis gravidarum Ovarian hyperstimulation syndrome
Rare causes	Amniotic fluid embolus Hemolytic uremic syndrome/ thrombotic thrombocytopenic purpura Acute fatty liver of pregnancy Acute obstruction of renal tracts

Preeclampsia

Preeclampsia and the Kidney

Preeclampsia rarely causes acute renal failure severe enough to require dialysis.³² In a cohort of South African women with severe preeclampsia and renal impairment, 7 (10%) of 72 required temporary dialysis, and none developed chronic renal failure.³² All women with severe preeclampsia who needed dialysis had hemorrhage, which often was caused by abruptio placentae.³² Preeclampsia causing mild transient renal impairment (serum creatinine up to 125 $\mu\text{mol/L}$ or 1.41 mg/dL) is common, but with appropriate management, there should be complete recovery of renal function.

Women with preexisting renal disease are more vulnerable to preeclampsia, especially when it is associated with chronic hypertension³³ (see Chapter 35). A meta-analysis of trials investigating the effectiveness of low-dose aspirin (50 to 150 mg/day) in pregnant women with moderate to severe renal disease revealed a significant reduction in the risk of preeclampsia and perinatal death.³⁴

Conversely, 2% to 5% of women with preeclampsia are later found to have underlying renal disease,³⁵ but if preeclampsia is severe, up to 20% of women will have chronic kidney disease (CKD).³⁶ Women who have had preeclampsia should therefore be checked for persistent postpartum hypertension and proteinuria. Gestational hypertension usually resolves within 3 months of delivery, but severe proteinuria due to preeclampsia can take up to 12 months to disappear. Women who have had preeclampsia are more likely to have persistent microalbuminuria compatible with microvascular disease and are at increased risk for cardiovascular disease in later life.^{37,38}

Women who develop high levels of proteinuria (>10 g/24 hr) tend to have earlier-onset preeclampsia and deliver at an earlier gestational age compared with preeclamptic women who have less marked proteinuria (<5 g/24 hr).³⁹ After correction for prematurity, however, massive proteinuria (>10 g/24 hr) has no significant effect on neonatal outcome.³⁹ Increasing proteinuria is not therefore an indication for delivery. We suggest that pregnant women who develop a proteinuria level of more than 1 to 3 g in 24 hours accompanied by other maternal risk factors for thrombosis should be considered for thromboprophylaxis with enoxaparin (40 mg SC each day) or Fragmin (5000 units SC each day).

The diagnosis of preeclampsia is difficult if there is chronic hypertension and preexisting proteinuria, especially because these two parameters become increasingly marked in late pregnancy. Hyperuricemia and intrauterine growth restriction are common features of preeclampsia and chronic renal impairment, but the presence of increased levels of hepatic transaminases and thrombocytopenia support a diagnosis of preeclampsia.⁴⁰

Preeclampsia: Management of Renal Impairment and Fluid Balance

The cure for severe preeclampsia is delivery of the infant and placenta. Delivery may halt the general progression of preeclampsia, but postpartum maternal renal function usually deteriorates before improving.³² It is advisable to recommend delivery for women who have preeclampsia and an increase in the serum creatinine concentration from about 70 $\mu\text{mol/L}$ (0.79 mg/dL) to more than 120 $\mu\text{mol/L}$ (1.36 mg/dL) to prevent ongoing renal impairment.

Fluid balance is critical to the management of acute renal failure during pregnancy. Too little intravascular fluid leads to prerenal failure, which is especially damaging to chronically impaired kidneys, whereas too much fluid risks pulmonary edema, adult respiratory distress syn-

drome, and maternal death.⁴¹ Transient oliguria (<100 mL over 4 hours) is a common observation in the first 24 hours after a healthy pregnancy. If a preeclamptic woman is not obviously hypovolemic and has a serum urea level of 5 mmol/L or less and serum creatinine level of 90 μ mol/L or less, repeated fluid challenges to increase urine output are unnecessary and increase the maternal risk of pulmonary edema. Women with severe preeclampsia and renal impairment (i.e., serum creatinine level of more than 120 μ mol/L or 1.36 mg/dL) should have their fluid balance guided by a central venous pressure catheter or, when available, a pulmonary artery flotation catheter on a high-dependency unit familiar with this equipment.⁴² The rate of fluid replacement should take account of central venous filling pressure, pulmonary wedge pressure, hourly urine output, and insensible losses. After the patient is euvolemic, the rate of intravenous fluid replacement should equal the previous hours' urine output plus insensible losses; this is usually 30 mL/hr if the patient is afebrile. The amount of intravenous fluid replacement can be reduced after the mother can take oral fluid and her renal impairment starts to improve. Intravenous fluid regimens that stick to a fixed hourly replacement can lead to fluid overload in oliguric women and to reduced intravascular volume in those having a diuresis. Fluid replacement should include blood to replace blood losses and then isotonic sodium chloride or compound sodium lactate (i.e., Hartmann's solution). Dextrose solutions are hypotonic and lead to maternal hyponatremia (5% dextrose contains only 30 mmol/L of NaCl, compared with 150 mmol/L of NaCl in a 0.9% sodium chloride solution).

Low-dose "renal" dopamine infusion (3 μ g/kg/min) was previously used to increase renal blood flow in people with acute renal failure, but it is no longer thought to be beneficial. It is recommended that once hypovolemia has been corrected, as judged by the central venous pressure or pulmonary wedge pressure, preeclamptic women with oliguria (<200 mL/12 hr) and a serum urea level higher than 14 mmol/L (39 mg/dL) and serum creatinine level higher than 500 μ mol/L (5.65 mg/dL) may benefit from a furosemide infusion (5 mg/hr) in an effort to prevent fluid overload and hemodialysis.⁴³

After acute tubular necrosis is established with oliguria and a rising serum creatinine level despite adequate intravascular volume and blood pressure, fluid intake should be restricted to avoid fluid overload. In these circumstances, dialysis is indicated. There are no good studies that have followed up women with acute renal failure related to preeclampsia, but those with the most severe renal impairment will undoubtedly be left with a degree of permanent renal impairment that may not manifest until later life.³²

Hypertension due to preeclampsia is caused by vasoconstriction around a reduced plasma volume.⁴⁰ For this reason and despite the lack of evidence from randomized trials, women with severe preeclampsia often receive plasma volume expansion before therapeutic vasodilation. Unless there are signs of pulmonary edema (i.e., basal crackles and $PO_2 < 95\%$ on air), 500 mL of colloid or crystalloid given over 30 to 60 minutes or 250 mL per hour until the pulmonary wedge pressure is 10 to 12 mm Hg can improve maternal and fetal well-being in cases of severe preeclampsia.^{45,46} A vasodilator given alone can cause profound hypotension that may threaten maternal renal, cerebral, and uteroplacental blood flow.

Hemolytic Uremic Syndrome and Thrombotic Thrombocytopenic Purpura

Hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP) are similar syndromes (designated HUS/TTP).

They are characterized by microangiopathic hemolytic anemia and thrombocytopenia. The congenital and acquired forms of HUS/TTP are more common in late pregnancy.⁴⁶ Women with HUS/TTP develop platelet thrombi attached to von Willebrand factor multimers in end-organ microvessels. This typically results in a multiorgan disorder with abdominal ischemia and renal or neurologic impairment.⁴⁷ A plasma metalloprotease (ADAMTS13), which normally cleaves von Willebrand factor multimers to prevent microthrombi, is deficient in some women with congenital HUS/TTP,⁴⁸ and antibodies that neutralize ADAMTS13 have been found in women with acquired HUS/TTP.⁴⁹

HUS/TTP is more common in women (approximately 70% of cases) and more common in association with pregnancy (approximately 13% of cases).⁴⁶ During pregnancy, the levels of ADAMTS13 fall progressively.⁵⁰ This may explain why women with a congenital deficiency of ADAMTS13 or with other risk factors for thrombosis (e.g., obesity, thrombophilia) are predisposed to peripartum HUS/TTP.

Hemolytic Uremic Syndrome, Thrombotic Thrombocytopenic Purpura, and Preeclampsia

Preeclampsia shares many similarities with HUS/TTP. Both syndromes occur most frequently in the third trimester or immediately after delivery. It is, however, important to differentiate them, because management is different. Women with HUS/TTP often present with gastrointestinal or neurologic abnormalities,⁴⁶ and they are more likely to have severe renal impairment, hemolysis, and thrombocytopenia compared with women who have preeclampsia. Because disseminated intravascular coagulation (DIC) is rare in HUS/TTP, the prothrombin time and kaolin clotting time are usually normal.⁴⁷ Women with preeclampsia are also more likely to have elevated levels of hepatic transaminases, heavy proteinuria, and abnormal clotting compared with women with HUS/TTP.⁴⁰ However, in many women, the distinction between preeclampsia and HUS/TTP can be determined only by the course of the illness after delivery,⁵¹ but acute renal failure due to preeclampsia usually becomes transiently worse before improving.³²

Management of Hemolytic Uremic Syndrome and Thrombotic Thrombocytopenic Purpura

Maternal survival from HUS/TTP greatly improved since treatment with plasmapheresis (i.e., infusion of fresh plasma and removal of old plasma).⁵² Until recently, it was unclear why plasmapheresis worked, but the discovery of antibodies to ADAMTS13 (removed with old plasma) and a congenital deficiency of ADAMTS13 (replenished with infusion of fresh plasma) gives reason to this process. However, severe deficiency of ADAMTS13, which is not a routine laboratory measurement, is not present in all cases of HUS/TTP, and plasmapheresis is effective in pregnant women who have milder deficiencies of ADAMTS13.⁵³

Steroids are often added to the plasma exchange regimen and are a rationale choice for acquired HUS/TTP with an autoimmune pathology, but there are no randomized, controlled trials of their use. Antiplatelet regimens with aspirin and dipyridamole may also be beneficial in conjunction with plasma exchange.⁵⁴ Conversely, administration of platelets to thrombocytopenic patients with HUS/TTP can result in a precipitous decline in clinical status.

Acute Renal Cortical Necrosis

In the developed world, acute renal cortical necrosis (ARCN) has become a rare complication of pregnancy. The reduced incidence of

septic abortion and improved management of peripartum obstetric emergencies have prevented prerenal impairment developing into acute tubular necrosis and then renal cortical necrosis. In the developing world, however, obstetric emergencies are still responsible for most cases of ARCN.⁵⁵ Acute renal failure after septic abortion or peripartum obstetric emergencies developed into ARCN in 20% of women after a prolonged period of acute tubular necrosis.⁵⁶

ARCN is most commonly caused by abruption of the placenta with hemorrhage, amniotic fluid embolus, and sepsis associated with DIC.⁵⁷ After hemorrhage or sepsis with hypotension, prerenal failure without adequate resuscitation leads to acute tubular necrosis. If anuria persists for longer than a week, ARCN should be suspected. A definitive diagnosis can be made with renal biopsy, but it is often missed because of the patchy nature of cortical necrosis. Selective renal angiography can confirm the diagnosis, but it introduces another nephrotoxic agent and is usually unnecessary. Because of the serious nature of the precipitating illness and the limited availability of renal replacement therapy in the developing world, the maternal mortality rate is still high.⁵⁶

For women who survive the acute illness, renal function usually returns slowly over the next 6 to 24 months. Long-term renal function depends on the extent of cortical necrosis, which is often incomplete. Hyperfiltration through remnant glomeruli usually leads to a subsequent progressive decline in renal function.

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy (AFLP) causes reversible peripartum liver and renal impairment in 1 of 5000 to 10,000 pregnancies.⁵⁸ The diagnosis is based on clinical and laboratory findings of impaired liver, renal function, and clotting function, rather than on histologic or radiologic evidence of a fatty liver.⁵⁸ Women with AFLP usually present with nausea, vomiting, and abdominal cramps. Impaired renal function and reduced plasma antithrombin levels are early findings of AFLP that may precede liver dysfunction.⁵⁸ In established cases of AFLP, depressed function of the liver with prolonged prothrombin time, hypoglycemia, and DIC are more markedly abnormal than levels of liver transaminases, which may only be moderately elevated.⁵⁸ In a series of 28 women with AFLP, other ubiquitous laboratory findings at the time of delivery were elevated levels of serum total bilirubin (mean, 7.5 mg/dL), serum creatinine (mean, 205 mmol/L or 2.3 mg/dL), and uric acid (mean, 11 mg/dL).⁵⁸

A recessively inherited fetal inborn error of mitochondrial fatty acid oxidation may explain up to 20% of AFLP cases.⁵⁹ Mitochondrial fatty acid oxidation is important for normal renal and liver function and may therefore explain the dual vulnerability of these organs in women with AFLP.

In women with AFLP, maternal renal impairment is aggravated by hypotension from hemorrhage, which is most likely to follow an emergency operative delivery.^{58,60} The combination of renal dysfunction, hemorrhage, and DIC resulting from liver failure during pregnancy or after delivery requires intensive care with a multidisciplinary team of hepatologists, nephrologists, intensive care specialists, and obstetricians. Management is supportive and aimed at maintaining adequate fluid balance for renal perfusion, replacing blood, correcting the coagulopathy with fresh frozen plasma and possibly with antithrombin concentrate and fresh platelets. Hypoglycemia should be corrected with 10% dextrose solutions. Temporary dialysis may be necessary, but with good supportive care, recovery of normal renal and liver function is usual.⁵⁸ Perinatal survival in association with AFLP is improving, but it depends on the early recognition of the maternal condition, close fetal surveillance, timely delivery, and excellent neonatal care.

Nephrotoxic Drugs during Pregnancy

Nonsteroidal anti-inflammatory drugs (NSAIDs), including the more selective cyclooxygenase-2 (COX-2) inhibitors, when given to the mother in the peripartum period, reduce renal blood flow and have been associated with acute renal impairment in the mother and fetus.⁶¹ Women with reduced intravascular volume, especially with preexisting renal impairment, are particularly vulnerable and should be prescribed NSAIDs with caution. Aminoglycosides are also nephrotoxic and should be prescribed with care and attention to drug plasma levels in women with mild renal impairment.

Acute Renal Obstruction in Pregnancy

The renal tracts may be obstructed during pregnancy by renal calculi (discussed later), congenital renal tract abnormalities, or a gestational overdistention syndrome. Women born with congenital obstructive uropathies at the pelviureteral junction (PUJ) or vesicoureteric junction (VUJ) are at increased risk of urine outflow obstruction in the second half of pregnancy, even if they have had surgical correction in childhood.⁶² Congenital abnormalities of the lower urinary tracts, including the bladder and urethra, are varied and usually require extensive surgical correction in childhood. During pregnancy, these women are at increased risk for recurrent urine infections and, less commonly, for outflow obstruction requiring temporary nephrostomy or a ureteric stent.⁶³

Women with a single kidney and urologic abnormalities are particularly vulnerable to develop post-renal failure in relation to gestational obstruction of their solitary kidney. An incomplete obstruction can cause renal impairment with an apparently good urine output. High backpressures compress and damage the renal medulla, leading to a loss of renal concentrating ability and production of dilute urine that is passed through an incomplete obstruction. It is also important for the obstetrician to remember that a congenitally single kidney is often associated with other abnormalities of the genital tracts, such as a unicornuate uterus.⁶⁴

During pregnancy, the renal tracts can rarely and spontaneously become grossly overdistended. If untreated, overdistention occasionally can lead to rupture of the kidney or renal tracts.⁶⁵ Women with overdistention of the renal tracts initially present with severe loin pain, most commonly on the right side and radiating to the lower abdomen. The pain is positional and inconstant; it is characteristically relieved by lying on the opposite side and tucking the knees up to the chest. A palpable tender flank mass may suggest renal tract rupture.⁶⁵ Rupture of the kidney almost always occurs in a previously diseased kidney, usually in association with a benign hamartoma or renal abscess.⁶⁵ Urinalysis can reveal gross or microscopic hematuria. A renal ultrasound can detect a hydronephrotic kidney with a grossly dilated pelvicaliceal system. Occasionally, a urinoma is evident around the kidney, indicating rupture of the renal pelvis that can sometimes seal spontaneously.

The pain from the overdistention syndrome varies from mild to very severe. Women with mild symptoms can usually be managed with advice on positional relief and regular analgesia. Women with severe unremitting pain, hematuria, and grossly distended renal tracts on ultrasound in the absence of structural or infected masses usually have immediate pain relief after decompression of the system with a ureteric stent or nephrostomy. Rupture of the kidney necessitates immediate surgery and almost invariably an emergency nephrectomy.⁶⁵

Chronic Kidney Disease

Normal Pregnancy and Renal Assessment

The glomerular filtration rate (GFR), measured as 24-hour creatinine clearance, increases by more than 50% shortly after conception. Serum creatinine (and urea nitrogen levels, which average 70 $\mu\text{mol/L}$ (0.8 mg/dL) and 5 mmol/L (13 mg/dL), respectively, in nonpregnant women, decrease to mean values of 50 $\mu\text{mol/L}$ (0.6 mg/dL) and 3 mmol/L (9 mg/dL) in pregnant women. Near term, a 15% to 20% decrement in GFR occurs, which affects serum creatinine levels minimally.

Serum creatinine values of 80 $\mu\text{mol/L}$ (0.9 mg/dL) and urea nitrogen of 6 mmol/L (14 mg/dL), which are acceptable in nonpregnant subjects, are suspect in pregnant women. However, the physician should use caution in assessing renal function by serum creatinine levels alone, because the creatinine is filtered and secreted by the kidney, and the ratio of creatinine to inulin clearance normally falls to between 1.1 and 1.2. As renal disease progresses, a greater portion of urinary creatinine is formed as a result of secretion (clearance ratios rise to between 1.4 and 1.6 when the serum creatinine level is 1.4). The GFR may be overestimated by 50%.

Formulas (e.g., the Cockcroft-Gault formula) that use serum creatinine in relation to age, height, and weight to calculate GFR should not be used in pregnancy because weight or body size does not reflect kidney size. The use of estimated GFR (eGFR) from the Modification of Diet in Renal Disease (MDRD) formula, whereby the serum creatinine value is adjusted for age, gender, and race, cannot be recommended for use in pregnancy because it significantly underestimates the GFR.⁶⁶ Ideally, evaluation of renal function in pregnancy should be based on the clearance of creatinine rather than its serum concentration. Creatinine levels may increase by up to 12 $\mu\text{mol/L}$ (0.15 mg/dL) shortly after ingestion of cooked meat (because cooking converts preformed creatine into creatinine), and the timing of the blood sample during a clearance period must take into account meals and their content.

Renal Dysfunction and Preconception Counseling

CKD is often clinically and biochemically silent until renal impairment is advanced. Symptoms are unusual until GFR declines to less than 25% of normal, and more than 50% of renal function can be lost before the serum creatinine level rises above 120 $\mu\text{mol/L}$ (1.36 mg/dL). However, women who become pregnant with a serum creatinine level above 125 $\mu\text{mol/L}$ (1.4 mg/dL) are at increased risk for an accelerated decline in renal function and poor pregnancy outcome.⁶⁷⁻⁷⁰

CKD is universally classified into five stages according to the level of renal function (i.e., GFR) (Table 44-2). CKD stages 3 through 5 (GFR < 60 mL/min) affect approximately 1 in 250 women of child-bearing age (20 to 39 years),⁷¹ but due to reduced fertility and an increased rate of early miscarriage, pregnancy in these women is less common. Studies of CKD in pregnancy have mostly classified women on the basis of serum creatinine values, but we estimate that approximately 1 of 750 pregnancies are complicated by CKD stages 3, 4, or 5.^{72,73} Some women are discovered to have CKD for the first time during pregnancy. Approximately 20% of women who develop early preeclampsia (≤ 30 weeks' gestation), especially those with heavy proteinuria, have previously unrecognized CKD.⁷⁴

TABLE 44-2 STAGES OF CHRONIC KIDNEY DISEASE

Stage	Description	GFR*
1	Kidney damage with normal or increased GFR	≥ 90
2	Kidney damage with mildly decreased GFR	60-89
3	Moderately decreased GFR	30-59
4	Severely decreased GFR	15-29
5	Kidney failure	<15 or dialysis

*Glomerular filtration rate (GFR) reported as mL/min/1.73 m².
From the National Kidney Foundation: K/DOQI clinical practice guidelines for chronic kidney disease: Evaluation, classification and stratification. *Am J Kidney Dis* 39(Suppl 1):S1-S266, 2002.

Women with CKD are less able to make the renal adaptations characteristic of and essential to healthy pregnancy. Their inability to boost renal hormones often leads to normochromic normocytic anemia, reduced plasma volume expansion, and vitamin D deficiency.^{75,76} The gestational rise in GFR is impaired in women with moderate renal impairment and usually absent in those with a serum creatinine level higher than 200 $\mu\text{mol/L}$ (2.26 mg/dL).^{68,77,78} If preeclampsia develops there is often a mild deterioration in renal function, but the addition of a prerenal insult, such as significant peripartum hemorrhage, can seriously threaten maternal renal function.

Renal Dysfunction and the Impact of Pregnancy

Mild Renal Impairment: Chronic Kidney Disease Stages 1 and 2

Most women with CKD who become pregnant have mild renal dysfunction, and pregnancy usually succeeds without affecting renal prognosis. However, complications such as preeclampsia, intrauterine fetal growth restriction, and preterm birth are more common (Table 44-3).^{69,68}

A case-controlled study of 360 women with primary glomerulonephritis and only mild pre-pregnancy renal dysfunction (serum creatinine level less than 110 $\mu\text{mol/L}$), minimal proteinuria (<1 g/24 hr), and absent or well-controlled hypertension, showed that pregnancy had little or no adverse effect on long-term (up to 25 years) maternal renal function.⁷⁹ The situation is quite different for women who have moderate to severe renal impairment (CKD stages 3, 4, or 5).

Moderate to Severe Renal Impairment: Chronic Kidney Disease Stages 3 through 5

Small, mainly uncontrolled, retrospective studies have shown that women with the worst pre-pregnancy renal function are at greatest risk for an accelerated decline in renal function caused by pregnancy (see Table 44-3). Proteinuria and hypertension add to this risk.^{68,70,77,80,81} One retrospective series of women with CKD (87 pregnancies) found that those with initially moderate renal impairment (serum creatinine level of 124 to 168 mmol/L or 1.4 to 1.9 mg/dL) had a 40% risk of a pregnancy-related decline in renal function, which persisted after delivery in about one half of those affected, whereas 13 (65%) of 20 women with severe renal impairment (i.e., serum creatinine level higher than 177 mmol/L or 2.0 mg/dL) had a decline in renal function

TABLE 44-3 PRE-PREGNANCY RENAL FUNCTION IN CHRONIC RENAL DISEASE WITH ESTIMATES FOR PREGNANCY OUTCOME (>24 WEEKS) AND IMPACT ON MATERNAL RENAL FUNCTION

Serum Creatinine Level μmol/L (mg/dL)	Loss of Renal Function*							
	IUGR (%)	Preterm Delivery (%)	Preeclampsia (%)	Perinatal Deaths (%)	Pregnancy (%)	Persists after Delivery (%)	ESRF in 1 Year (%)	
<125 (<1.4)	25	30	22	1	2	—	—	
125-180 (1.4-2.0)	40	60	40	5	40	20	2	
>180 (>2.0)	65	>95	60	10	70	50	35	

*Estimates are based on literature from 1985 to 2007, with all pregnancies attaining at least 24 weeks' gestation.

ESRF, end-stage renal function; IUGR, intrauterine growth restriction.

Data from references 67-70, 72, 77, 78, 83, 165-169.

during the third trimester that persisted in almost all and deteriorated to end-stage renal failure in 7 (35%) of 20.^{67,82}

The first *prospective* study to assess the rate of decline of maternal renal function before and after pregnancy in 49 women with pre-pregnancy CKD stages 3 to 5 confirmed these earlier observations.⁷⁰ Specifically, women with a pre-pregnancy GFR less than 40 mL/min/1.73 m² and proteinuria level of more than 1 g in 24 hours, but not either factor alone, showed an accelerated decline in renal function after their pregnancy compared with before pregnancy. Chronic hypertension, which predisposes women to preeclampsia, may explain why those with milder renal dysfunction also have a gestational decline in renal function. This risk is reduced when hypertension is controlled.

Impact of Chronic Kidney Disease on Perinatal Outcome

Maternal hypertension, proteinuria, and recurrent urinary infection often coexist in women with CKD, and it is difficult to apportion the contribution that each factor makes to a poor pregnancy outcome. It appears, however, that each factor is individually and cumulatively detrimental to fetal outcome.^{67,70,76,77} Although women with severe renal impairment have the greatest difficulty conceiving, the highest rate of miscarriage, and poorest fetal outcome, there is a spectrum of poor outcomes, including preeclampsia, fetal growth restriction, preterm delivery, and perinatal death, correlating with the level of renal dysfunction.^{68,69,70,78,83}

Preconception Counseling

Initiating and sustaining pregnancy are related to the degree of functional impairment. Fertility is diminished as renal function falls. When the preconception serum creatinine level exceeds 280 μmol/L (3 mg/L), corresponding to a GFR of less than 25 mL/min, normal pregnancy is unusual; however, successes have been documented in women with moderate to severe disease, including some treated with dialysis because of accelerated maternal renal deterioration.⁸⁴

Ideally, pregnancy is probably best restricted to women with preconception serum creatinine levels below 180 μmol/L (2 mg/dL) and a diastolic blood pressure of 90 mm Hg or less. If the patient has hypertension requiring more than one drug for control, prognosis becomes substantially poorer. Some clinicians extend this limit to 250 μmol/L (2.8 mg/dL), whereas others believe it should be no higher than 140 μmol/L (1.5 mg/dL). Whatever level is used, we reiterate that degrees of impairment not causing symptoms or disrupting homeostasis in nonpregnant individuals can still jeopardize pregnancy. Clinical complications such as hypertension, proteinuria,

and infection increase the risk of complications at all levels of renal impairment.

A question should be asked: Is pregnancy advisable? If a woman with chronic renal disease wishes to have a family, the sooner she starts, the better. In some of these patients, renal function continues to decline with time. Women are not always counseled before conception. A patient with suspected or known renal disease may present already pregnant, and the question then becomes whether to continue the pregnancy.

Ideally, all women with CKD should be made aware of the risks pregnancy may have on their own long-term renal function and pregnancy outcome before they conceive. Folic acid (400 mg daily) should be given as usual around conception until at least 12 weeks' gestation. Low-dose aspirin (50 to 150 mg/day) should be started in early pregnancy to reduce risk of preeclampsia and improve perinatal outcome.³⁴ Regular drugs should be reviewed so that fetotoxic drugs (e.g., angiotensin-converting enzyme [ACE] inhibitors, angiotensin II receptor blockers) can be stopped as soon as pregnancy is confirmed.⁸⁵

There are reports of women with severe chronic renal failure having successful pregnancies managed without dialysis.⁸⁶ In one woman, the serum creatinine level was 700 μmol/L (8 mg/dL) at the time of spontaneous delivery.⁸⁷ Dialysis has also been instituted prophylactically during pregnancy to increase the chances of a successful outcome.⁸⁸ Nevertheless, we believe that these women should not take additional health risks. The aim should be to preserve what little renal function remains and to achieve renal rehabilitation by dialysis and transplantation, after which the question of pregnancy can be considered if appropriate.

The literature that forms the basis of our views is primarily *retrospective*. Most patients described had only mild dysfunction, and women with greater dysfunctional disease were limited in number. Confirmation of any preconception guidelines requires definitive observational trials that must be prospective.

Antenatal Strategy and Decision Making

Patients should be seen at least at 2-week intervals or less until 32 weeks' gestation, after which assessment should be weekly. Routine serial antenatal observations should be supplemented with the following:

1. Assessment of renal function using serum creatinine levels and protein excretion using the protein to creatinine ratio on a spot urine sample on approximately a monthly basis

- Careful monitoring of blood pressure for early detection of hypertension and treatment to keep blood pressure at 140/90 mm Hg or less
- Early detection of superimposed preeclampsia, with checks of blood urea nitrogen, full blood cell count, liver function tests, blood pressure, and proteinuria
- Biophysical assessment of fetal size, development, and well-being
- Early detection of asymptomatic bacteriuria or confirmation of UTI every month

Renal Function

If renal function deteriorates, reversible causes should be sought, such as a UTI, subtle dehydration, or electrolyte imbalance, which is occasionally precipitated by inadvertent diuretic therapy. Near term, a 15% to 20% decrement in function, which affects serum creatinine levels minimally, is permissible. Failure to detect a reversible cause of a significant decrement is reason to end the pregnancy by elective delivery. When proteinuria occurs and persists but blood pressure is normal and renal function is preserved, the pregnancy can be allowed to continue.

Blood Pressure

Most of the specific risks of hypertension appear to be mediated through superimposed preeclampsia. There is still controversy about the incidence of preeclampsia in women with preexisting renal disease. The diagnosis cannot be made with certainty on clinical grounds alone because hypertension and proteinuria may be manifestations of the underlying renal disease. Treatment of hypertension in pregnancy is considered in Chapter 35.

High blood pressure in the presence of an underlying kidney disorder is treated more aggressively than are other hypertensive complications of pregnancy. This is done because such actions preserve function longer. Although diastolic levels of 100 mm Hg or less may be permissible in many pregnant women with underlying essential hypertension, a diastolic goal of 90 mm Hg or less should be set for patients with renal disease.

Fetal Surveillance and Timing of Delivery

Serial assessment of fetal well-being is essential because renal disease can be associated with intrauterine growth restriction, and when complications do arise, the judicious moment for intervention is influenced by fetal status. Current technology should minimize the risk of intrauterine fetal death and neonatal morbidity and mortality. Regardless of gestational age, most infants weighing 1500 g or more are better off in a special care nursery than in a hostile intrauterine environment. Deliberate preterm delivery may be necessary if renal function deteriorates substantially or for the usual maternal and fetal causes, such as uncontrollable hypertension, and signs adduced by monitoring of fetal jeopardy.

Renal Biopsy

Percutaneous renal biopsy is usually avoided in pregnancy because the plethoric kidney appears to be more prone to bleeding, especially in hypertensive pregnant women.⁸⁹ Renal biopsy, although not usually required for the diagnosis and management of preeclampsia, may be indicated if there is reason to suspect a renal lesion that could be successfully treated, especially in early pregnancy and up to 32 weeks' gestation, whilst permitting the pregnancy to continue.

Postpartum Care

It can take up to 3 months (occasionally longer) for the physiologic changes of pregnancy to disappear. During that time, close monitoring

of fluid balance, renal function, and blood pressure and a further review of drug therapy are necessary. Breastfeeding should be encouraged in women with CKD, but is sometimes not possible for those with severe CKD. Information is still lacking on whether some immunosuppressive drugs appear in breast milk, but prednisolone, azathioprine, and ACE inhibitors are barely detectable in breast milk. Women who have heavy proteinuria associated with preeclampsia should be followed until the proteinuria disappears or a diagnosis of renal disease is made.

Problems Associated with Specific Kidney Diseases

In 1991, Imbasciati and Ponticelli⁹⁰ reviewed outcomes for more than 1000 patients with a variety of specific disorders, which were usually documented by kidney biopsy. In this review and in other editorials,³ therapeutic abortions were excluded from calculation of pregnancy success rates and the discussion of the underlying factors.

Acute and Chronic Glomerulonephritis

The acute form of glomerulonephritis is a rare complication of pregnancy, and it can be mistaken for preeclampsia. For patients with chronic glomerulonephritis, one view warns of aggravation because of the hypercoagulable state accompanying pregnancy, with patients more prone to superimposed preeclampsia or hypertensive crises earlier in pregnancy. The consensus, however, is that if renal function is stable and hypertension is absent, most pregnancies are successful.⁷⁶ In a review of 906 pregnancies in 557 women, these generalizations were endorsed⁹⁰ and several specific issues were highlighted:

- Complications developed more frequently in women who already had some dysfunction or hypertension in early pregnancy.
- De novo hypertension or worsening of preexisting hypertension occurred in 25% of pregnancies but usually reverted after delivery, suggesting superimposed preeclampsia, a diagnosis that is not easy to confirm in this group of patients.
- In 10% of pregnancies, hypertension persisted after delivery, especially in patients with focal and segmental glomerulosclerosis, membranoproliferative glomerulonephritis, and IgA nephropathy.
- Higher rates of fetal loss observed in these women can be accounted for by the greater prevalence of severe hypertension and renal insufficiency.

Other, smaller series have endorsed these points. For example, pregnancy is well tolerated without effect on the course of the disease if blood pressure is normal and the GFR is higher than 70 mL/minute before conception.^{76,91} With hypertension, the rate of live births is reduced if hypertension exists before pregnancy or is not well controlled during gestation.

Hereditary nephritis, an uncommon disorder, may first manifest or become exacerbated during pregnancy, but most gestations succeed. One variant of hereditary nephritis involves disordered platelet morphology and function. In these cases, pregnancy has been successful but was sometimes complicated by bleeding problems, especially at delivery.

Chronic Pyelonephritis

Chronic pyelonephritis (i.e., tubulointerstitial disease) in pregnancy may be infectious or noninfectious. The prognosis in pregnancy is similar to that for patients with glomerular disease; the outcome is best for patients with adequate renal function and normal blood pressure. Compared with nonpregnant women, pregnant women have a higher frequency of symptomatic infections, but these patients may have a more benign antenatal course than do women with glomerular disease.

Reflux Nephropathy

The term *reflux nephropathy* is used to describe renal morphologic and functional changes that relate to past (and usually present) vesicoureteric reflux, which often is complicated by recurrent infection. Opinions were once controversial, but with preserved renal function and no hypertension, fetal and maternal outcomes appear to be excellent.⁷⁷ For these patients, vigilance is still necessary to detect and treat UTIs (28% to 65%), with many physicians advocating prophylactic antibiotics. Unfortunately, reflux nephropathy is often associated with hypertension and moderate or severe renal dysfunction by the time these patients reach childbearing age, and such a scenario adversely affects pregnancy outcome. Specific obstetric concerns about affected patients include severe intrauterine growth restriction and the risk of sudden, rapid worsening of hypertension and renal function with accelerated progression to renal failure.⁹²

Urolithiasis

The prevalence of urolithiasis in pregnancy is 0.03% to 0.35%.⁹³ Renal and ureteric calculi cause nonuterine abdominal pain severe enough to necessitate hospital admission during pregnancy. Most calculi are calcium oxalate (the more benign type), but occasionally, the more malicious struvite stones (e.g., staghorn) are seen. Uric acid and cystine are much less common.

Management should be conservative initially, with adequate hydration, appropriate antibiotic therapy, and pain relief with systemic analgesics. Most women pass their stones spontaneously. The use of continuous segmental (T11 to L2) epidural block has been advocated, as in nonpregnant patients with ureteric colic, and it may favorably influence spontaneous passage of the stones. With good pain relief, patients micturate without difficulty, move without assistance, and are less at risk for thromboembolic problems than if they are drowsy, nauseated, and bedridden with pain.

When there are complications that may require surgical intervention, pregnancy should not be a deterrent to limited IVU, even though the clinician may be reluctant to consider radiologic investigation. Specific clinical criteria should be met before a limited IVU is undertaken: microscopic hematuria, recurrent urinary tract symptoms, and sterile urine culture when pyelonephritis is suspected. The presence of two of these criteria indicates a diagnosis of calculi in 60% of women.⁹⁴

Magnetic resonance urography can be used to avoid radiation exposure.⁹⁵ Another approach involves the cystoscopic placement of an intraureteral tube, or stent, between the bladder and kidney under local anesthesia.⁹⁶ The stent retains its position because it has a pigtail or J-like curve at each end (double-J), and it can be changed every 8 weeks to prevent encrustation. Early empiric use for presumed stone obstruction in pregnant women with flank pain is recommended by some, especially when hydration, analgesia, and antibiotics do not resolve

pain or fever, and when the pregnancy is over, the usual x-ray evaluation is obtained and standard management resumed.⁹⁷

Sonographically guided percutaneous nephrostomy is another effective and safe method of treating gravidas with ureteric colic or symptomatic obstructive hydronephrosis. The procedure is rapid, requires minimal anesthesia, and is preferable to retrograde stenting or more invasive surgery.

In patients with cystinuria, assiduous maintenance of high fluid intake is the mainstay of management. Although D-penicillamine appears relatively safe, it should be used only for severe cases, such as when urinary cystine excretion is known to be very high.⁹⁸

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common genetic renal disorder, but it may remain undetected during pregnancy. Careful questioning for a history of familial problems and the use of ultrasonography may lead to earlier detection. Patients do well when functional impairment is minimal and hypertension is absent, as is often the case in childbearing years.⁹⁹ They do, however, have an increased incidence of hypertension late in pregnancy and a higher rate of perinatal mortality compared with that in pregnancies of sisters unaffected by this autosomal dominant disease.

Women with advanced renal failure are best advised against pregnancy, although use of prophylactic dialysis has been advocated, despite lack of controlled studies, for this type of patient.¹⁰⁰ If one or the other prospective parent has evidence of polycystic renal disease, the couple may seek genetic counseling. There is a 50% chance of transmitting the disease to the offspring, which is caused by two identified genes: *PKD1* (85%) and *PKD2* (15%). DNA probe techniques can make the diagnosis of ADPKD, but a significant number of ADPKD mutations are caused by multiple amino acid substitutions, which need to be interpreted with caution.¹⁰¹

Diabetic Nephropathy

Because many patients have had diabetes since childhood, they probably already have microscopic changes in the kidneys.¹⁰² During pregnancy, diabetic women have an increased prevalence of covert bacteriuria (and may be more susceptible to symptomatic UTI), peripheral edema, and preeclampsia.⁸⁴

Most women with diabetic nephropathy who become pregnant still have good renal function and demonstrate normal GFR increments (with perhaps significant proteinuria), and pregnancy does not accelerate renal deterioration.¹⁰³ There is, however, a report of diabetic women with moderate renal dysfunction (serum creatinine level above 125 $\mu\text{mol/L}$ or ≤ 1.4 mg/dL) whose renal function permanently deteriorated in pregnancy compared with the changes before and afterward.¹⁰⁴ Such changes occurred despite good metabolic control and might have been related to hypertension, which often accelerates in the third trimester regardless of intensified treatment.¹⁰⁵ However, there were no controls for this study. The condition of diabetic patients with creatinine levels above 1.4 mg/dL who do not become pregnant often progresses rapidly to further renal failure.

Hypertension should be treated more intensively in diabetics. As with other renal disorders during pregnancy, we believe that more aggressive antihypertensive therapy is a reasonable objective. These patients often are treated with “renoprotecting” ACE inhibitors or angiotensin receptor blockers prescribed before conception, but

these drugs should be stopped as soon as possible after conception to avoid teratogenic effects that become evident after 6 weeks' gestation.⁸⁵

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a relatively common disease and has a predilection for women of childbearing age. Its coincidence with pregnancy poses complex clinical problems because of the profound disturbance of the immunologic system, multiorgan involvement, and complicated immunology of pregnancy itself.⁸⁴ The outcome of pregnancy for women with SLE is variable and to some extent unpredictable, so careful monitoring, especially for those women with lupus nephritis, is required (see Chapter 51).

Decisions regarding the status of the disease and the importance of having a child to the patient and her partner should be made on an individual basis. Most pregnancies succeed, especially when the maternal disease has been in complete clinical remission for 6 months before conception, even if there were marked pathologic changes in the original renal biopsy and heavy proteinuria in the early stages of the disease.¹⁰⁶ Continued signs of disease activity or increasing renal dysfunction reduces the likelihood of an uncomplicated pregnancy and the clinical course thereafter.

The effects of gestation on SLE activity and on the course of lupus nephritis have long been debated. Taking into account extrarenal manifestations and renal changes, at least 50% of women show some change in clinical status, often called a *lupus flare*.¹⁰⁷ Some increments in proteinuria or blood pressure may result from preeclampsia. Women with lupus nephritis and renal insufficiency (serum creatinine level higher than 125 $\mu\text{mol/L}$ or 1.4 mg/dL) that antedates pregnancy have worse outcomes.

Lupus nephritis may sometimes become manifest during pregnancy, and when accompanied by hypertension and renal dysfunction, it may be mistaken for preeclampsia. Some patients experience relapse, occasionally severely in the puerperium; therefore, some clinicians prescribe or increase immunosuppression at this time.¹⁰⁸ It is our practice to increase immunosuppression only if there are signs of increased disease activity.

SLE serum contains an array of autoantibodies (i.e., lupus serum factor) against nucleic acids, nucleoproteins, cell-surface antigens, and phospholipids. Antiphospholipid antibodies exert a complicated effect on the coagulation system.¹⁰⁹ This led to the definition of a lupus anticoagulant, which is found in 5% to 10% of patients with SLE (see Chapter 40). Because treatment with low-molecular-weight heparin and aspirin may lead to successful pregnancies, it is important to screen for lupus anticoagulant in women with SLE and especially in those with a history of recurrent intrauterine death or thrombotic episodes to identify this particular cohort.

Periarteritis Nodosa

In contrast to lupus nephritis, the outcome of pregnancy in women with renal involvement as a result of periarteritis nodosa is very poor, largely because of the associated hypertension, which frequently is malignant. Many cases in the literature have involved maternal demise. However, this dismal prognosis is based primarily on selected anecdotal studies, and a few successful pregnancies have been reported. Still, until more data are available (perhaps through a registry), consideration of early therapeutic termination must be made in the best interests of maternal health.

Systemic Sclerosis

Scleroderma is a term that includes a heterogeneous group of limited and systemic conditions causing hardening of the skin. Systemic sclerosis implies involvement of skin and other sites, particularly certain internal organs. Renal involvement is thought to occur in about 60% of these patients, usually within 3 to 4 years of diagnosis. Manifestation may take one of three forms: sudden onset of malignant hypertension, rapidly progressive renal failure, or slowly increasing azotemia.¹¹⁰

The combination of systemic sclerosis and pregnancy is unusual because the disease occurs most often in the fourth and fifth decades, and affected patients are usually infertile. When it has its onset in pregnancy, there is a greater tendency for deterioration. Patients with scleroderma and no evidence of renal involvement before conception have developed severe kidney disease during gestation. There are also instances in which pregnancy has been uneventful and successful, but marked reactivation occurred unexpectedly in the puerperium. Most maternal deaths involve rapidly progressive scleroderma with severe pulmonary complications, infections, hypertension, and renal failure.

The extent of systemic involvement is probably more important than the duration of the disease, and limited, mild disease carries a better prognosis. Sclerosis usually spares the abdominal wall skin, but there is one report of hydronephrosis, presumed to have been caused by thickened skin and decreased abdominal wall compliance, in a twin pregnancy complicated by polyhydramnios.¹¹¹

Wegener Granulomatosis

Information on the outcome of pregnancy in women with Wegener granulomatosis is scarce. Proteinuria (with or without hypertension) is common, and reports have described complicated and uneventful pregnancies.¹¹² Experience with cyclophosphamide (Cytoxan) in pregnancy is limited, and the risks to the embryo and fetus must be weighed in relation to the course of the disease if such therapy were to be withheld from the mother.

Previous Urinary Tract Surgery

Permanent urinary diversion is still used in the management of patients with congenital lower urinary tract defects, but its use for neurogenic bladder has declined since the introduction of self-catheterization. The most common complication of pregnancy is urinary infection. Premature labor occurs in 20%, and the use of prophylactic antibiotics throughout pregnancy may reduce its incidence. Decline in renal function may occur, invariably related to infection or intermittent obstruction, or both. With an ileal conduit, elevation and compression by the expanding uterus can cause outflow obstruction, whereas with a ureterosigmoid anastomosis, actual ureteral obstruction may occur. The changes usually reverse after delivery.

The mode of delivery is dictated by obstetric factors. Abnormal presentation accounts for a cesarean section rate of 25%. Vaginal delivery is safe, but because the continence of a ureterosigmoid anastomosis depends on an intact anal sphincter, this area must be protected with a mediolateral episiotomy.

During the past decade, urinary tract reconstruction by means of augmentation cystoplasty, with or without artificial genitourinary sphincter, has become more common. Deterioration of renal function and urinary tract obstruction or infection can occur at any time in pregnancy. Delivery by cesarean section is recommended for these

gravidas because of the potential for disruption of the continence mechanism.

Solitary Kidney

Some patients have a congenital absence of one kidney or marked unilateral renal hypoplasia. Most, however, have had a previous nephrectomy because of pyelonephritis (with abscess or hydronephrosis), unilateral tuberculosis, congenital abnormalities, or a tumor. It is important to know the indication for and the time elapsed since the nephrectomy. In patients with an infectious or a structural renal problem, sequential pre-pregnancy investigation is needed to detect any persistent infection.

It makes no difference whether the right or left kidney remains, as long as it is located in the normal anatomic position. If function is normal and stable, women with this problem seem to tolerate pregnancy well despite the superimposition of GFR increments on already hyperfiltering nephrons. Single kidneys are most often associated with the rare instances of acute renal failure as a result of obstruction during pregnancy.

Ectopic kidneys (usually pelvic) are more vulnerable to infection and are associated with decreased fetal salvage, probably because of associated malformations of the urogenital tract. If infection occurs in a solitary kidney during pregnancy and does not quickly respond to antibiotics, termination may have to be considered for preservation of renal function.

Nephrotic Syndrome

The most common cause of nephrotic syndrome in late pregnancy is preeclampsia. Other causes include proliferative or membranoproliferative glomerulonephritis, lipid nephrosis, lupus nephritis, hereditary nephritis, diabetic nephropathy, renal vein thrombosis, and amyloidosis. Some of these conditions do not respond to steroids and may even be aggravated by them; this emphasizes the importance of a tissue diagnosis before steroid therapy is begun.¹¹³

If renal function is adequate and hypertension is absent, there should be few complications during pregnancy and good fetal outcome. However, physiologic changes occurring during gestation may mimic aggravation or exacerbation of disease. Increments in renal hemodynamics and increases in renal vein pressure may enhance protein excretion during pregnancy. Serum albumin levels usually decrease by 0.5 to 1.0 g/dL during normal pregnancy, and further decreases due to nephrotic syndrome may enhance the tendency toward fluid retention. Care must be taken with the use of diuretics to treat edema because reduced intravascular volume may reduce uteroplacental perfusion or aggravate the increased tendency to thrombotic episodes.

Human Immunodeficiency Virus—Associated Nephropathy

During the past 25 years, there have been increasing numbers of reports about a nephrotic syndrome and severe renal impairment in patients infected with the human immunodeficiency virus (HIV).¹¹⁴ The condition is characterized by severe proteinuria, by bright echogenic kidneys, and often by rapid progression to end-stage renal disease. The distinctive features seen on histologic evaluation of renal biopsy are a collapsing glomerulosclerosis, visceral epithelial cell hypertrophy, and cystic tubular degenerative changes.¹¹⁴ The

incidence of this HIV-associated nephropathy appears to be increasing, particularly in the African-American population and in cases of intravenous drug abuse. Although few cases of this nephropathy have been reported in pregnant women, with the rising incidence of acquired immunodeficiency syndrome (AIDS), especially among black African women, this form of renal disease should be considered in HIV-infected patients presenting with severe proteinuria.

Factors Affecting Prognosis

Effects of Specific Disorders on Fetal Outcome

The problems associated with the specific disorders discussed in this section are summarized in Table 44-4. In general, we suggest that preserved renal function and the absence of hypertension before conception predict successful fetal outcome and few maternal complications, regardless of the nature of the disorder. These conclusions often are based on poorly controlled, retrospective data, underscoring the need for registries and for prospectively acquired data; there is only one such study.⁷⁰

Effect of Pregnancy on Renal Disease/Remote Prognosis

Pregnancy does not adversely affect the natural history of the renal lesion if kidney dysfunction is minimal and hypertension is absent at conception, with the exception of certain collagen disorders. An important factor in remote prognosis is the sclerotic effect that hyperfiltration might already have had in the residual (intact) glomeruli of kidneys of patients with renal insufficiency. Further progressive loss of renal function can ensue in pregnancy, but this is not the case in animals when pregnancy is superimposed on experimental glomerulonephritis.¹¹⁵

The superimposition of pregnancy hyperfiltration on the compensatory changes already present in a single kidney may lessen the lifespan of the kidney. The crux of this hypothesis is the implication that increases in glomerular pressure or glomerular plasma flow cause sclerosis within the glomerulus and that in pregnancy further physiologic hyperfiltration augments the damage. In health, it seems unlikely that there are long-term renal sequelae.¹¹⁵ More human and animal research is needed because patients with renal disease can have unpredicted, accelerated, and irreversible renal decline in pregnancy or immediately afterward, and the mechanisms are unknown.

Hemodialysis Patients and Pregnancy

It has been several decades since the first description of conception and successful delivery in a patient on chronic hemodialysis, and additional case reports and registry data have been published since then.¹¹⁶⁻¹¹⁹ Any optimism must be tempered by the thought that clinicians are reluctant to publish failures or disasters, and consequently, the true incidence of unsuccessful pregnancies in women on dialysis cannot be determined. The high surgical abortion rate in these patients, although decreased from 40% in 1989 to 18% today, still indicates that those who become pregnant do so accidentally, probably because they are unaware that pregnancy is a possibility.

TABLE 44-4 CHRONIC RENAL DISEASE AND PREGNANCY

Renal Disease	Effects
Chronic glomerulonephritis and focal glomerular sclerosis (FGS)	Incidence of high blood pressure late in gestation is increased, but there usually is no adverse effect if renal function is preserved and hypertension is absent before gestation. Some disagree, believing coagulation changes in pregnancy exacerbate disease, especially immunoglobulin A (IgA) nephropathy, membranoproliferative glomerulonephritis, and FGS.
IgA nephropathy	Some cite risks of sudden escalating or uncontrolled hypertension and renal deterioration. Most find good outcomes when renal function is preserved.
Chronic pyelonephritis (infectious tubulointerstitial disease)	Bacteriuria occurs in pregnancy and may lead to exacerbation.
Reflux nephropathy	In the past, some emphasized risks of sudden escalating hypertension and worsening of renal function. Consensus now is that results are satisfactory when preconception function is only mildly affected and hypertension is absent. Vigilant screening for urinary tract infections is necessary.
Urolithiasis	Ureteral dilatation and stasis do not seem to affect natural history, but infections can become more frequent. Stents have been successfully placed, and sonographically controlled ureterostomy has been performed during gestation.
Polycystic kidney disease	Functional impairment and hypertension are usually minimal in childbearing years.
Diabetic nephropathy	There are no adverse effects of the renal lesion. Frequencies of infections, edema, and preeclampsia increase.
Systemic lupus erythematosus	Prognosis is most favorable if disease is in remission 6 or more months before conception. Some authorities increase steroid dosage in the immediate postpartum period.
Periarthritis nodosa	Fetal prognosis is poor. Disease is associated with maternal death. Therapeutic abortion should be considered.
Scleroderma	For onset during pregnancy, there can be rapid overall deterioration. Reactivation of quiescent scleroderma can occur during pregnancy and after delivery.
Previous urologic surgery	Depending on the original reason for surgery, there may be other malformations of the urogenital tract. Urinary tract infection is common during pregnancy, and renal function may undergo reversible decrease. No significant obstructive problem, but cesarean section may be necessary in case of abnormal presentation or to avoid disruption of the continence mechanism if artificial sphincters or neourethras are present.
After nephrectomy, solitary and pelvic kidney	Pregnancy is well tolerated. Condition may be associated with other malformations of the urogenital tract. Dystocia rarely occurs with a pelvic kidney.

Counseling and Early Pregnancy Assessment

Despite irregular or absent menstruation and impaired infertility, women on dialysis should use contraception if they wish to avoid pregnancy.¹²⁰ The introduction of recombinant human erythropoietin (rHuEPO) for the treatment of women with renal failure appears to be associated in some cases with return of normal menses (and ovulation), probably because of improved overall health.¹²¹

There are substantial arguments against pregnancy, not least of which are the risks to the patient (e.g., severe hypertension, cardiac failure, maternal death) and the fact that even when therapeutic termination of pregnancy is excluded, there is at the very best only a 40% to 50% likelihood of a successful outcome.¹²² If only data since the late 1990s are considered, fetal survival seems to be improving, although maternal risk remains formidable (Table 44-5).¹¹⁶

Early diagnosis of pregnancy is difficult. A missed period is usually ignored. The mistake the clinician may make is failure to consider the possibility of pregnancy, and many of these patients have not been given contraception counseling. Resistance to rHuEPO or progression of anemia (i.e., hematocrit decrease by 8% of pre-pregnancy levels) can be a useful clue to early diagnosis of pregnancy. Urine pregnancy tests are unreliable, and definitive diagnosis and estimation of gestational age are best accomplished by sonar technology.

TABLE 44-5 ESTIMATES FOR PREGNANCY COMPLICATIONS AND OUTCOMES IN DIALYSIS PATIENTS

Complication or Outcome	Incidence or Timing*
Polyhydramnios	40%
Intrauterine growth restriction	90%
Preterm delivery	85%
Average gestational age at delivery	33 wk
Hypertension/preeclampsia (Severe)	70%
	15%
Surviving infant	
Conceived on dialysis	50%
Conceived before dialysis	75%

*Estimates are based on literature from 1992 to 2007, with all pregnancies attaining at least 24 weeks' gestation. Data from references 2, 88, 121, 123-127, 163, 164.

Antenatal Strategy and Decision Making

For a successful outcome, scrupulous attention must be paid to blood pressure control, fluid balance, increased hours of dialysis, and provision of good nutrition. Excellent publications should be consulted for more details.^{116,123-127}

Dialysis Policy

Some patients show apparent increments in GFR even though the level of renal function is too poor to sustain life without hemodialysis, whereas other women remain completely anuric.¹²⁸ Women with some residual renal function and satisfactory daily urine volumes, in whom dialysis control is easier, are more likely to become pregnant and to sustain pregnancy.

Management of dialysis during pregnancy should mimic the physiologic changes of healthy pregnancy as closely as possible. This aim can be capsulated in seven points:

1. Maintain serum urea at less than 20 mmol/L (60 mg/dL), although some would argue lower (e.g., 15 mmol/L [<45 mg/dL]). This is likely to necessitate almost daily dialysis from the end of the first trimester
2. Avoid hypotension during dialysis, which could be damaging to the fetus. In late pregnancy, the gravid uterus and the supine posture may aggravate this by decreasing venous return.
3. Ensure good control of blood pressure, but consider excess fluid as a cause of hypertension.
4. Ensure minimal fluctuations in fluid balance, and limit volume changes.
5. Scrutinize carefully for preterm labor, because dialysis or uterine contractions with or without significant changes in fetal hemodynamics are associated.¹²⁷
6. Watch calcium levels closely, and avoid hypercalcemia.
7. Limit interdialysis weight gain to about 1 kg until late pregnancy. After midpregnancy, the physician should take the classic 0.5 kg/wk weight gain into account when considering dry weight. This means at least a 50% increase in hours and frequency of dialysis. Frequent dialysis renders dietary management and control of weight gain much easier.

In one report from Saudi Arabia of 27 pregnancies in 22 women, only 10 went beyond 28 weeks' gestation, and 8 of these were successful.¹²⁴ Comparing the pregnancies that ended before 28 weeks with those that went beyond, the researchers found no significant differences in blood pressure, hemoglobin, creatinine levels, type of dialysate, obstetric history, or duration on hemodialysis, but the dialysis hours were significantly longer for the successful group.

Intensified Anemia Management

Patients with severe renal insufficiency are usually anemic. This anemia is aggravated further in pregnancy, and increased erythropoietin therapy and even blood transfusion may be needed, especially before delivery. Caution is necessary because erythropoietin therapy or transfusion may exacerbate hypertension and impair the ability to control circulatory overload, even with extra dialysis. Fluctuations in blood volume can be minimized if packed red cells are transfused during dialysis.

It appears that genetically engineered erythropoietin (rHuEPO) is well tolerated in pregnancy.^{121,130} The theoretical risks of hypertension alluded to previously and thrombotic complications have not been cited. Invariably, rHuEPO requirements to maintain a target hematocrit of 30% increase until delivery¹³¹ may attain 300 IU/kg/wk.¹²⁶ No adverse effects have been identified in neonates in whom normal hematologic indices and erythropoietin concentrations for gestational age suggest that rHuEPO does not have significant transplacental effects.

Unnecessary blood sampling should be avoided when there is anemia or a lack of venipuncture sites. The protocol for various tests

usually performed in a particular unit should be followed strictly, with no more blood removed per venipuncture than is absolutely necessary.

Hypertension

Because patients with hypertension may have abnormal lipid profiles and possibly accelerated atherogenesis, it is difficult to predict the cardiovascular capacity to tolerate pregnancy. Diabetic women receiving dialysis who have become pregnant are those in whom cardiovascular problems are most evident. In these and other women with renal disease, a normotensive state at conception is reassuring. Unfortunately, blood pressure tends to be labile, and hypertension is a common problem, although it may be possible to help control it by dialysis.

Ensuring Good Maternal Nutrition

Despite more frequent dialysis, relatively free dietary intake should be discouraged. A daily oral intake of 70 g of protein, 1500 mg of calcium, 50 mM of potassium, and 80 mM of sodium is advised, with supplements of dialyzable vitamins, particularly folic acid. Vitamin D supplementation can be difficult to judge in patients who have had parathyroidectomy. In addition, the placenta produces hydroxyvitamin D, which is one reason why oral supplementation may have to be curtailed. All of this poses risks for fetal nutrition in addition to the fact that the exact impact of the uremic environment is difficult to assess. The use of parenteral nutrition supplementation in pregnancy in these gravidas has been advocated.¹³²

Fetal Surveillance and Timing of Delivery

What has been said with regard to chronic renal disease applies here as well. Cesarean section should be necessary only for purely obstetric reasons. It could be argued that elective cesarean section in all cases may minimize potential problems during labor. Preterm labor is generally the rule and may commence during hemodialysis.¹³³ The role of cesarean section in this situation needs to be carefully considered.

Peritoneal Dialysis Patients and Pregnancy

Since 1976, continuous ambulatory peritoneal dialysis (CAPD) and continuous cycling peritoneal dialysis have been used more frequently in the management of patients with all forms of renal insufficiency. Several features of peritoneal dialysis make it an attractive approach for the management of renal failure in pregnancy:

- Maintenance of a more stable environment for the fetus in terms of fluid and electrolyte concentrations
- Avoidance of episodes of abrupt hypotension, a frequent occurrence during hemodialysis, which can cause fetal distress
- Continuous allowance for extracellular fluid volume control so that blood pressure control is augmented
- Better blood sugar control in patients with diabetes mellitus with the use of intraperitoneal insulin

Nevertheless, there appears to be no differences in outcome because of mode of renal replacement therapy (i.e., hemodialysis versus peritoneal dialysis), and there may even be greater infertility in patients receiving CAPD.^{88,116} Peritoneal dialysis may not be able to keep up with the physiologic changes of pregnancy to the same extent as daily hemodialysis.

Peritonitis, which can be a severe complication of CAPD, accounts for most therapy failures in nonpregnant populations. Peritonitis superimposed on a pregnancy can present a confusing diagnostic picture and a whole series of treatment problems.

Renal Transplant Patients and Pregnancy

After transplantation, renal and endocrine functions return rapidly, and normal sexual activity can ensue.¹³⁴ About 1 in 50 women of childbearing age with a functioning renal transplant becomes pregnant. Of the conceptions, 40% do not go beyond the initial trimester because of spontaneous or therapeutic abortion. More than 90% of pregnancies that continue past the first trimester end successfully (Table 44-6).⁷⁵

Allografting has been performed when the surgeons were unaware that the recipient was in early pregnancy.¹³⁵ Obstetric success in such cases does not negate the importance of contraception counseling for all patients with renal failure and the exclusion of pregnancy before transplantation.

Counseling and Early Pregnancy Assessment

A woman should be counseled from the time the various treatments for renal failure and the potential for optimal rehabilitation are discussed. Information regarding potential reproductive capacity must be included. Even after transplantation, stress will still be a major factor in everyday life, which will always have a baseline of uncertainty. Couples who want a child should be encouraged to discuss all the implications, including the harsh realities of maternal prospects of survival.¹³⁶

Preconception Guidelines

Individual centers have their own guidelines.^{137,138} For most, a wait of 12 to 18 months after transplantation is advised. This has turned out to be good advice, because by then, the patient will have recovered from the major surgery and any sequelae, graft function will have stabilized, and immunosuppression is likely to be at maintenance levels. If function is well maintained at 24 months, there also is a high probability of allograft survival at 5 years.

A suitable set of guidelines is given here, but the criteria are only relative:

1. Good general health for 12 to 18 months after transplantation, with comorbid factors under control
2. Stature compatible with good obstetric outcome
3. No or minimal proteinuria.
4. Absence of or well-controlled hypertension
5. No evidence of graft rejection
6. Absence of pelvicalyceal distention on a recent IVU or renal ultrasound
7. Stable renal function with a serum creatinine level of 180 $\mu\text{mol/L}$ (2 mg/dL) or less and preferably less than 125 $\mu\text{mol/L}$ (1.4 mg/dL)^{139,140}
8. Drug therapy reduced to maintenance levels for prednisone (≤ 15 mg/day), azathioprine (≤ 2 mg/kg/day), cyclosporine (≤ 5 mg/kg/day), and tacrolimus (≤ 0.1 to 0.2 mg/kg/day)

Experience with newer immunosuppressive drugs (e.g., mycophenolate mofetil, sirolimus) is minimal, and current advice is to avoid their use in pregnancy unless stopping them would seriously endanger maternal health. Further information is keenly awaited about outcomes with the use of newer agents.

Pregnancy in the female transplant population and its ethical dilemmas have been comprehensively discussed in several publications, particularly those from a Consensus Conference on Reproductive Issues and Transplantation.^{138,141,142} These issues do apply to all women with potentially serious medical conditions and their partners who want to become parents.

Ectopic Pregnancy

Ectopic pregnancy occurs in at least 0.5% of all conceptions. The diagnosis can be difficult because irregular bleeding and amenorrhea accompany deteriorating renal function or even an intrauterine pregnancy. Patients who have had previous urologic surgery, peritoneal dialysis, and pelvic inflammatory disease are at higher risk for ectopic pregnancy because of pelvic adhesions. Intrauterine contraceptive devices have a higher failure rate in immunosuppressed women. The main clinical problem is that symptoms of genuine pelvic pathology are erroneously attributed to the transplant.

Antenatal Strategy and Decision Making

Patients must be monitored as high-risk cases by an obstetrician and an experienced transplantation nephrologist. Management requires attention to serial assessment of renal function, diagnosis and treat-

TABLE 44-6 PRE-PREGNANCY RENAL FUNCTION IN RENAL TRANSPLANT RECIPIENTS WITH ESTIMATES FOR PREGNANCY OUTCOME (>24 WEEKS) AND IMPACT ON MATERNAL RENAL FUNCTION

Serum Creatinine Level $\mu\text{mol/L}$ (mg/dL)	Loss of Renal Function*						
	IUGR (%)	Preterm Delivery (%)	Preeclampsia (%)	Perinatal Deaths (%)	Pregnancy (%)	Persists after Delivery (%)	ESRF in 1 year (%)
<125 (<1.4)	30	35	24	3	15	4	—
125-160 (1.4-1.85)	50	70	45	7	20	7	10
>160 (>1.85)	60	90	60	12	45	35	70

*Estimates are based on literature from 1991 to 2007, with all pregnancies attaining at least 24 weeks' gestation.

ESRF, end-stage renal function; IUGR, intrauterine growth restriction.

Data from references 139, 140, 145, 148, 158, 166, 170-177.

ment of rejection, blood pressure control, early diagnosis or prevention of anemia, treatment of any infection, and meticulous assessment of fetal well-being.

Antenatal visits should be at least at every 2 weeks up to 32 weeks and weekly thereafter. The following tests should be undertaken monthly:

- Complete blood cell count, including platelets
- Blood urea nitrogen
- Creatinine level
- Electrolyte levels
- Urate levels
- Twenty-four-hour creatinine clearance and protein excretion
- Midstream urine specimens for microscopy and culture

Liver function tests, plasma protein, and calcium and phosphate levels should be checked at 6-week intervals. Tests for cytomegalovirus and herpesvirus should be performed during each trimester if the initial findings are negative (see Chapter 38). Although immunosuppressive therapy is usually maintained at pre-pregnancy levels, adjustments may be needed if there are decreases in the maternal white blood cell and platelet counts. Hematinic agents should be prescribed if the various hematologic indices show deficiency.

Allograft Function

Serial data on renal function are needed to supplement routine antenatal observations (discussed earlier). The anatomic changes and the increased and then sustained GFR characteristic of early pregnancy are evident, even though the allograft is ectopic, denervated, potentially damaged by previous ischemia, and immunologically different from both recipient and fetus. The better the pre-pregnancy GFR, the greater the increment in pregnancy, and graft gender has no significant effect on the hyperfiltration response.¹⁴³ Transient reductions in GFR can occur during the third trimester and usually do not represent a deteriorating situation with permanent impairment. In 15% of patients, significant renal functional impairment develops during pregnancy and may persist after delivery. Because a gradual decline in function is common in nonpregnant patients, it is difficult to delineate a specific effect of pregnancy.

Subclinical chronic rejection with declining renal function may occur after an episode of acute rejection or if immunosuppression becomes suboptimal. Whether cyclosporine is more nephrotoxic in pregnancy compared with the blunting of augmentation in GFR in the nonpregnant patient is unknown. We recommend keeping cyclosporine and tacrolimus levels at the lower end of the therapeutic range during pregnancy, which usually necessitates a small rise in drug dose. Increases in proteinuria, often to abnormal levels, occur near term in 40% of patients; this regresses after delivery and, in the absence of hypertension, is not significant.

Allograft Rejection

Serious rejection episodes occur in 6% of pregnant allograft recipients. Although this incidence of rejection is no greater than that expected for nonpregnant transplant patients, it is unusual because it has been assumed that the privileged immunologic state of pregnancy could be beneficial. Rejection can occur in the puerperium and may be caused by return to a normal immune state (despite immunosuppression) or possibly by a rebound effect from the altered immunoresponsiveness of pregnancy.

Chronic rejection may be a problem in all recipients, having a progressive subclinical course. Whether a pregnancy influences the course

of subclinical chronic rejection is unknown. No factors consistently predict which patients will experience allograft rejection during pregnancy. Some have hypothesized a nonimmune contribution to chronic graft failure because of the damaging effect of hyperfiltration through remnant nephrons, which is perhaps even exacerbated during pregnancy. From the clinical viewpoint, several points are important. Because rejection is difficult to diagnose, when any of the clinical hallmarks are present (e.g., fever, oliguria, deteriorating renal function, renal enlargement, tenderness), the diagnosis should be considered. Although ultrasonography may prove helpful in the nonpregnant setting, in the pregnant state, without renal biopsy, rejection cannot be distinguished from acute pyelonephritis, recurrent glomerulopathy, possibly severe preeclampsia, and even cyclosporine nephrotoxicity. Renal biopsy is indicated before aggressive anti-rejection therapy is instigated.

Immunosuppression

Immunosuppressive therapy is usually maintained at pre-pregnancy levels, but adjustments may be needed if the maternal leukocyte or platelet count decreases.^{144,145} When white blood cell counts are maintained within physiologic limits for pregnancy, the neonate usually is born with a normal blood count. Azathioprine liver toxicity has been seen occasionally during pregnancy, and it responds to dose reduction. The National Transplantation Pregnancy Registry (NTPR), maintained by Vincent T. Armenti at Thomas Jefferson University in Philadelphia, is accruing data.^{146,147}

Numerous adverse effects are attributed to cyclosporine in non-pregnant transplant recipients, including renal toxicity, hepatic dysfunction, chronic hypertension, tremor, convulsions, diabetogenic effects, hemolytic uremic syndrome, and neoplasia. In pregnancy, some of the maternal adaptations that normally occur may theoretically be blunted or abolished by cyclosporine, especially plasma volume expansion and renal hemodynamic augmentation. Data suggest that patients treated with cyclosporine have more hypertension ($\approx 70\%$) and smaller infants (20% to 50%), but it is still too early for definitive conclusions.^{140,148}

Newer agents such as mycophenolate mofetil (MMF/CellCept) and lymphocyte immune globulin (Atgam) are being prescribed more frequently for transplant recipients,¹⁴⁹ but there is little information about these agents in pregnancy. Orthodione (OKT3) is an IgG that crosses the placenta, but data are limited.¹⁵⁰ Some of the agents were originally considered to have a rescue role only for kidney and kidney-pancreas transplantations, but they are being used as primary immunosuppressants.¹⁴⁹

Hypertension and Preeclampsia

At least 50% of patients have significant hypertension requiring medication before pregnancy (see Chapter 35). All medications should be reviewed. The appearance of hypertension or worsening of chronic hypertension in the third trimester, its relationship to deteriorating renal function, and the possibility of chronic underlying pathology and preeclampsia are diagnostic problems. Escalating hypertension, particularly before 28 weeks' gestation, is associated with adverse perinatal outcome,¹⁵¹ which may be linked to covert cardiovascular changes that accompany or are aggravated by chronic hypertension. Preeclampsia is diagnosed clinically in about 30% of pregnancies with transplants.

Infections

Patients should be carefully monitored for all types of infection throughout pregnancy. Prophylactic antibiotics must be given before

any surgical procedure, however trivial. The various viral infections that may be involved in these patients are discussed in Chapter 38.

Diabetes Mellitus

Pregnancies are increasingly reported in women whose renal failure was caused by juvenile onset type 1 diabetes mellitus. Pregnancy complications occur with at least twice the frequency seen in the nondiabetic patient, and this may result from the presence of generalized cardiovascular pathology, which is part of the metabolic risk factor syndrome.¹⁵² Successful pregnancies are increasingly reported after confirmed pancreas-kidney allografting.

Fetal Surveillance and Timing of Delivery

The points given for chronic renal disease are equally applicable to transplantation patients. Preterm delivery is common (45% to 60%) because of intervention for obstetric reasons and the common occurrence of preterm labor or preterm rupture of membranes. Preterm labor frequently is associated with poor renal function.¹⁴⁴ However, gestational age is the crucial confounding variable associated with renal dysfunction and hypertension, and it needs adjusting when assessing influence on birth weight.

Vaginal delivery should be the aim, and there usually is no mechanical injury to the transplant. Unless there are specific obstetric problems, spontaneous onset of labor can be awaited.¹⁵³

Management during Labor

Careful monitoring of maternal fluid balance, cardiovascular status, and temperature is essential, and aseptic technique is important for every procedure. Surgical induction of labor (i.e., amniotomy) and episiotomy warrant antibiotic coverage. Pain relief is conducted as for healthy women. Augmentation of steroids is necessary to cover delivery.

Role of Cesarean Section

The kidney does not usually obstruct the birth canal. Cesarean section is necessary for the usual obstetric reasons. Several factors are important when choosing the delivery route. Transplant recipients may have pelvic osteodystrophy related to previous renal failure (and dialysis) or prolonged steroid therapy, particularly before puberty. Antenatal diagnosis of these problems is important and permits the planning of elective cesarean delivery.

If there is a question of disproportion or kidney compression, simultaneous IVU and x-ray pelvimetry can be performed (with limitation of the IVU to one to three films) at 36 weeks' gestation. When a cesarean section is performed, a lower segment approach is usually feasible, although previous urologic surgery or peritonitis may make this difficult.

Pediatric Management

Immediate Problems

More than 50% of liveborn infants have no neonatal problems. Preterm delivery is common (45% to 60%), small-for-gestational-age (SGA) infants are delivered in 30% to 50% of cases, and the two factors occasionally coexist. Although management is the same as in neonates of other mothers, some specific problems exist. Adrenocortical insufficiency due to the maternal steroid therapy potentially increases the risk of overwhelming neonatal infection. There are anecdotal data associating tacrolimus with oligoanuria and hypokalemia in the neonate.¹³³

Breastfeeding

There are substantial benefits to breastfeeding. It could be argued that because the infant has been exposed to immunosuppressive agents and their metabolites in pregnancy, breastfeeding should not be allowed. Little is known, however, about the quantities of these agents and their metabolites in breast milk and whether the levels are biologically trivial or substantial. Cyclosporine levels in breast milk are usually greater than those in a simultaneously taken blood sample. Until the many uncertainties are resolved, breastfeeding should not be encouraged or perhaps limited to 1 month in the first instance and the neonate monitored for healthy growth and well-being after that time. Azathioprine does not appear in breast milk,¹⁵⁴ but cyclosporine and tacrolimus do.¹⁵⁵

Long-Term Assessment

Azathioprine can cause abnormalities in the chromosomes of leukocytes, which may take almost 2 years to disappear spontaneously. The sequelae could be eventual development of malignant tumors in affected offspring, autoimmune complications, or abnormalities in the reproductive performance in the next generation.¹⁴⁵ There are some worrisome animal data. For instance, fertility problems affect the female offspring of mice that have received low doses of 6-mercaptopurine, the major metabolite of azathioprine (equivalent to 3 mg/kg). These offspring subsequently proved to be sterile; if they conceived, they had smaller litters and more dead fetuses than did unexposed dams, with the inference that exposure in utero may not affect otherwise normal females until they attempt childbearing.¹⁵⁶ The long-term sequelae of in utero exposure to the newer immunosuppressants are unknown. However, to date, information about general progress in early childhood has been good.¹⁵⁷

Maternal Follow-up after Pregnancy

The ultimate measure of transplant success is the long-term survival of the patient and the graft. Because it is only 30 years since this procedure became widely employed in the management of end-stage renal failure, few long-term data from sufficiently large series exist from which to draw conclusions. The long-term results for renal transplantation come from a period when many aspects of management would be unacceptable by current standards. Average survival figures for large numbers of patients worldwide indicate that about 90% of recipients of kidneys from related living donors are alive 5 years after transplantation. With cadaver kidneys, the figure is approximately 60%. If renal function was normal 2 years after transplantation, the survival rate increased to about 80%. This is why women are counseled to wait 1 to 2 years before considering a pregnancy, although the emerging view is that 1 year is sufficient.^{138,141}

A major concern is that the mother may not survive or remain well enough to rear the child she bears. Pregnancy occasionally and sometimes unpredictably causes irreversible declines in renal function. However, the consensus is that pregnancy has no effect on graft function or survival provided graft function before pregnancy is satisfactory (ideally, a serum creatinine level less than 125 $\mu\text{mol/L}$ or 1.4 mg/dL).^{140,158} Repeated pregnancies do not adversely affect graft function or fetal development, provided that renal function is well preserved at the time of conception.^{159,160} If the pre-pregnancy serum creatinine level is higher than 150 $\mu\text{mol/L}$ (1.8 mg/dL) and there is drug-treated hypertension during pregnancy, there is poorer graft survival after pregnancy.¹⁴⁰

Many women choose parenthood in an effort to reestablish a normal life and possibly in defiance of the sometimes negative atti-

tudes of the medical establishment. More long-term studies are needed to assess this area, especially with the advent of newer immunosuppressive drugs, so that counseling can be based on recorded experience rather than clinical anecdote.

Contraception

It is unwise to offer the option of sterilization at the time of transplantation; this decision should not take place at that time. Oral contraceptives may cause or aggravate hypertension or thromboembolism and can produce subtle changes in the immune system, but this does not necessarily contraindicate their use.

An intrauterine contraceptive device (IUD) may aggravate menstrual problems, which may obscure signs and symptoms of abnormalities of early pregnancy, such as threatened abortion and ectopic pregnancy. The increased risk of pelvic infection associated with the IUD in an immunosuppressed patient makes this method worrisome. Because insertion or replacement of an IUD can be associated with bacteremia of vaginal origin, antibiotic coverage is essential at this time. The efficacy of the IUD may be reduced by immunosuppressive and anti-inflammatory agents, possibly because of modification of the leukocyte response. Careful counseling and follow-up are essential.

Gynecologic Problems

There is a danger that symptoms resulting from genuine pelvic pathology may be erroneously attributed to the transplant because of its location near the pelvis. Patients may be at slightly higher risk for ectopic pregnancy because of pelvic adhesions resulting from previous urologic surgery, pelvic inflammatory disease, or the overzealous use of IUDs. Diagnosis can be overlooked because irregular bleeding and amenorrhea may be associated with deteriorating renal function and intrauterine pregnancy.

Transplant recipients receiving immunosuppressive therapy have a malignancy rate estimated to be 100 times greater than normal, and the female genital tract is no exception.¹⁶¹ This association is probably related to factors such as loss of immune surveillance, chronic immunosuppression allowing tumor proliferation, and prolonged antigenic stimulation of the reticuloendothelial system. Regular gynecologic assessment is essential. Management should be on conventional lines, with the outcome unlikely to be influenced by stopping or reducing immunosuppression.

Summary

Changes in the urinary tract during normal pregnancy are so marked that norms in the nonpregnant state cannot be used for obstetric management. Awareness of all gestational alterations is essential if kidney problems in pregnancy are to be suspected or detected and then handled correctly.

Lower urinary infections are no more common in pregnancy compared with sexually active nonpregnant women, but lower UTIs are more likely to ascend to cause pyelonephritis. Asymptomatic bacteriuria should be screened for every 4 to 6 weeks in women who have renal disease and treated. If there is more than one UTI, low-dose antibiotic prophylaxis should be given for the remainder of the pregnancy and until 6 weeks after delivery.

Most women with mild and moderate renal disease tolerate pregnancy well and have a successful obstetric outcome without adverse effect on the natural history of the underlying renal lesion. Crucial determinants are renal functional status at conception, the presence or

absence of hypertension, and the type of renal disease. There have been disagreements regarding pregnancy outcome in the presence of focal glomerular sclerosis, IgA nephropathy, mesangioproliferative glomerulonephritis, and reflux disease, although the evidence seems to favor the importance of renal function before pregnancy. Patients with certain collagen disorders (especially periarteritis nodosa and scleroderma) do poorly. In general, prognosis is good if renal dysfunction is minimal and hypertension is absent.

Pregnancy in women receiving dialysis treatment can be excessively complicated. Increased frequency and duration of dialysis are needed to increase the likelihood of a successful pregnancy outcome. There is high fetal wastage at all stages of pregnancy, but especially in the first trimester. In the absence of severe maternal problems, the hazards of pregnancy in renal transplant recipients are minimal, and successful obstetric outcome is the rule.

The key to management of acute renal failure in pregnancy is to identify the cause of renal impairment and treat it. This often necessitates premature delivery in favor of maternal health.

Chapter 45

Respiratory Diseases in Pregnancy

Janice E. Whitty, MD, and Mitchell P. Dombrowski, MD

Proper functioning of the cardiorespiratory system is imperative to achieve adequate oxygenation of maternal and fetal tissues. The maternal cardiorespiratory system undergoes significant changes during gestation to optimize oxygen delivery to the fetus and maternal tissues. Pulmonary disease is one of the most frequent maternal complications during pregnancy, and it may result in significant morbidity or mortality for the mother and her fetus. Depending on the specific diagnosis, other maternal complications of pregnancy may have an adverse or positive impact on the pulmonary function of the gravida.

In this chapter, we briefly review the physiologic adaptations of the respiratory system that occur during gestation. Specific respiratory diseases that occur in pregnancy and the effects of the disease on pregnancy and pregnancy on the disease are discussed. The obstetrician should realize that most diagnostic tests useful in evaluating pulmonary function during gestation are not harmful to the fetus and, if indicated, should be performed. Most medications used to treat respiratory disease in pregnancy are also well tolerated by the fetus. With few exceptions, the diagnostic and treatment algorithms for respiratory disease closely resemble those used for a nonpregnant woman.

Physiologic Changes of the Respiratory System

Because there is no increase in respiratory rate, the increase in maternal minute ventilation results from an increase in tidal volume.¹ The almost 50% increase in tidal volume occurs at the expense of an 18% decrease in the functional residual capacity. The resulting hyperventilation of pregnancy results in a compensated respiratory alkalosis (i.e., arterial partial pressure of carbon dioxide $[PaCO_2] \leq 30$ mm Hg) and a modest increase in arterial oxygenation tension (i.e., 101 to 104 mm Hg).² The $PaCO_2$ decreases early in pregnancy in parallel with the change in ventilation; however, a further progressive decrease in $PaCO_2$ may occur.³ The decrease in $PaCO_2$ is even greater at altitudes where the mother exhibits compensatory hyperventilation in an attempt to maintain the arterial partial pressure of oxygen as high as possible. The decrease in $PaCO_2$ is matched by an equivalent increase in renal excretion of and decrease in plasma bicarbonate concentration; therefore, arterial pH is not altered from the normal nonpregnant level of about 7.4.

It has been suggested that the hyperventilation of pregnancy results primarily from progesterone acting as a respiratory stimulant.⁴ Because hyperventilation has been observed during the luteal phase of the menstrual cycle and progesterone can produce similar changes in

nonpregnant women, it is likely that this phenomenon results from progestational influences.^{5,6} The $PaCO_2$ is linearly and inversely related to the log of the progesterone concentration.⁷ Wilbrand and colleagues⁸ reported that progesterone lowers the carbon dioxide threshold of the respiratory center. During pregnancy, the sensitivity of the respiratory center increases⁹ so that an increase in $PaCO_2$ of 1 mm Hg increases ventilation by 6 L/min in pregnancy, compared with 1.5 L/min in the nonpregnant state.^{1,10,11} It is possible that progesterone acts as a primary stimulant to the respiratory center independently of any change in carbon dioxide sensitivity or threshold.⁴ In addition to stimulating ventilation, progesterone may also increase levels of carbonic anhydrase B in the red blood cell.¹² Schenker and associates¹³ reported that carbonic anhydrase levels increase in pregnant patients and in women taking oral contraceptives. An increase in the carbonic anhydrase level facilitates carbon dioxide transfer and tends to decrease $PaCO_2$ independently of any change in ventilation. This respiratory stimulant effect of progesterone has been used in the treatment of respiratory failure and emphysema.^{6,14,15}

During gestation, ventilation is increased by the rise in tidal volume from approximately 500 to 700 mL in each breath.^{1,16-18} Because there is no change in respiratory rate, minute ventilation rises from about 7.5 to 10.5 L/min.^{11,17,19} Minute ventilation increases in the first trimester and remains at that level throughout pregnancy. The physiologic dead space is increased by about 60 mL in pregnancy. This may result from dilation of the small airways.¹¹ Residual volume is reduced by about 20%,¹⁶ from 1200 to 1000 mL.²⁰⁻²² The vital capacity, which is the maximum volume of gas that can be expired after a maximum inspiration, does not change in pregnancy.^{16,21-25}

Anatomic Changes of the Respiratory System

Observed changes in the configuration of the chest during pregnancy are in keeping with the findings of no change in vital capacity and a reduction in residual volume. The effect of pregnancy on pulmonary mechanics has been compared with the effect of a pneumoperitoneum. In both situations, the residual lung volume is decreased, but ventilation remains unimpaired. Radiologic studies performed early in pregnancy have shown that the subcostal angle increases from 68 to 103 degrees before there is any mechanical pressure from the enlarging uterus.²⁶ The level of the diaphragm rises by about 4 cm, and the transverse diameter of the chest increases by 2 cm.²⁷⁻²⁹ These changes account for the decrease in residual volume because the lungs are

relatively compressed during forced expiration; however, the excursion of the diaphragm in respiration increases by about 1.5 cm in pregnancy compared with the nonpregnant state.^{29,30}

Oxygen Delivery and Consumption

Oxygen Delivery

All tissues require oxygen for the combustion of organic compounds to fuel cellular metabolism. The cardiopulmonary system delivers a continuous supply of oxygen and other essential substrates to tissues. Oxygen delivery depends on oxygenation of blood in the lungs, oxygen-carrying capacity of the blood, and cardiac output.³¹ Under normal conditions, oxygen delivery exceeds oxygen consumption by about 75%.³² The amount of oxygen delivered is determined by the cardiac output (CO, L/min) times the arterial oxygen content (CaO_2 , mL/O₂/min):

$$\text{Oxygen delivery} = \text{CO} \times \text{CaO}_2 \times 10 \text{ (700 to 1400 mL/min)}$$

The arterial oxygen content is determined by the amount of oxygen that is bound to hemoglobin (i.e., arterial blood saturation with oxygen [SaO_2]) and by the amount of oxygen that is dissolved in plasma (i.e., arterial partial pressure of oxygen [$\text{PaO}_2 \times 0.0031$]):

$$\text{CaO}_2 = (\text{hemoglobin} \times 1.34 \times \text{SaO}_2) + (\text{PaO}_2 \times 0.0031) \\ \text{(16 to 22 mL O}_2\text{/dL)}$$

As can be seen in this formula, the amount of oxygen dissolved in plasma is negligible, and the arterial oxygen content therefore depends

largely on hemoglobin concentration and arterial oxygen saturation. Oxygen delivery can be impaired by conditions that affect arterial oxygen content or cardiac output (flow), or both. Anemia leads to low arterial oxygen content because of a lack of hemoglobin binding sites for oxygen. Carbon monoxide poisoning likewise decreases oxyhemoglobin because of blockage of binding sites for oxygen. The patient with hypoxemic respiratory failure does not have sufficient oxygen available to saturate the hemoglobin molecule. Desaturated hemoglobin is altered structurally such that it has a diminished affinity for oxygen.³³

The amount of oxygen available to tissues also is affected by the affinity of the hemoglobin molecule for oxygen. The oxyhemoglobin dissociation curve (Fig. 45-1) and the conditions that influence the binding of oxygen negatively or positively must be considered when attempts are made to maximize oxygen delivery.³⁴ An increase in the plasma pH level or a decrease in temperature or the concentration of 2,3-diphosphoglycerate can increase hemoglobin affinity for oxygen, shifting the curve to the left and resulting in diminished tissue oxygenation. If the plasma pH level, temperature, or 2,3-diphosphoglycerate level increases, hemoglobin affinity for oxygen decreases, and more oxygen is available to tissues (see Fig. 45-1).³⁴

In certain clinical conditions, such as septic shock and adult respiratory distress syndrome, there is maldistribution of flow relative to oxygen demand, leading to diminished delivery and consumption of oxygen. The release of vasoactive substances is hypothesized to result in the loss of normal mechanisms of vascular autoregulation, producing regional and microcirculatory imbalances in blood flow.³⁵ This mismatching of blood flow with metabolic demand causes excessive blood flow to some areas and relative hypoperfusion of other areas, limiting optimal systemic use of oxygen.³⁵ The patient with diminished cardiac output resulting from hypovolemia or pump failure is unable to distribute oxygenated blood to tissues. Therapy directed at increasing the volume with normal saline or with blood if the hemoglobin

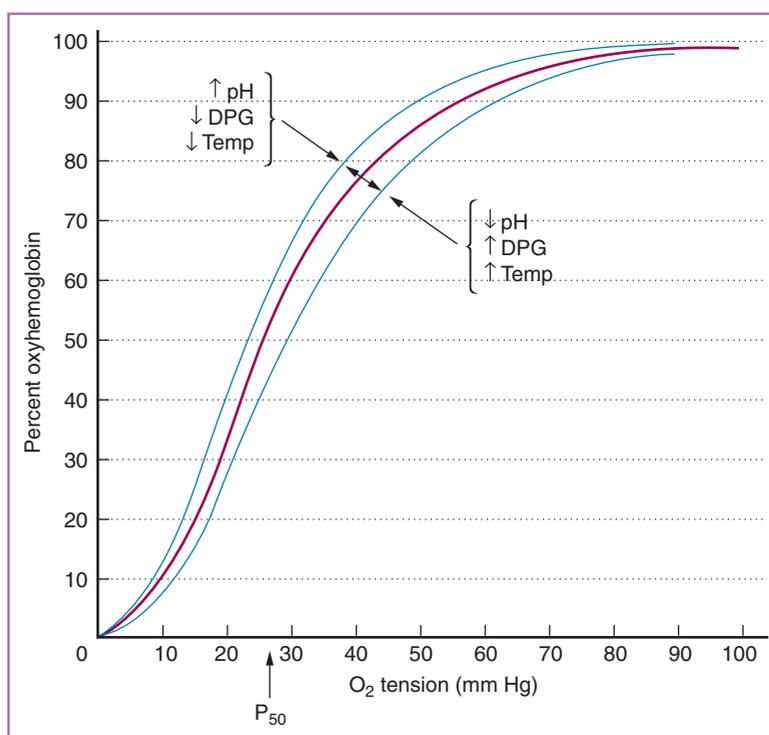

FIGURE 45-1 The oxygen-binding curve for human hemoglobin A under physiologic conditions (*red curve*). The affinity is shifted by changes in pH, diphosphoglycerate (DPG) concentration, and temperature. P_{50} is the oxygen tension at one-half saturation.

level is less than 10 g/dL increases delivery of oxygen in the hypovolemic patient. The patient with cardiac failure may benefit from inotropic support and afterload reduction in addition to supplementation of intravascular volume.

Relationship of Oxygen Delivery to Consumption

Oxygen consumption is the product of the arteriovenous oxygen content difference ($C_{(a-v)}O_2$) and cardiac output (CO). Under normal conditions, oxygen consumption is a direct function of the metabolic rate³⁶:

$$\text{Oxygen consumption} = C_{(a-v)}O_2 \times CO \times 10 \\ (180 \text{ to } 280 \text{ mL/min})$$

The oxygen extraction ratio is the fraction of delivered oxygen that actually is consumed:

$$\text{Oxygen extraction ratio} = O_2 \text{ consumption}/O_2 \text{ delivery} (0.25)$$

The normal oxygen extraction ratio is about 25%. A rise in the oxygen extraction ratio is a compensatory mechanism used when oxygen delivery is inadequate for the level of metabolic activity. A subnormal value suggests flow maldistribution, peripheral diffusion defects, or functional shunting.³⁶ As the supply of oxygen is reduced, the fraction extracted from blood increases and oxygen consumption is maintained. If a severe reduction in oxygen delivery occurs, the limits of oxygen extraction are reached, tissues are unable to sustain aerobic energy production, and consumption decreases. The level of oxygen delivery at which oxygen consumption begins to decrease is called *critical oxygen delivery* (Fig. 45-2).³⁷ At the critical oxygen delivery level, tissues begin to use anaerobic glycolysis, with resultant lactate production and metabolic acidosis.³⁷ If oxygen deprivation continues, irreversible tissue damage and death ensue.

Mixed Venous Oxygenation

The mixed venous oxygen tension and mixed venous oxygen saturation ($S\bar{V}O_2$) are parameters of tissue oxygenation.³⁷ The normal mixed

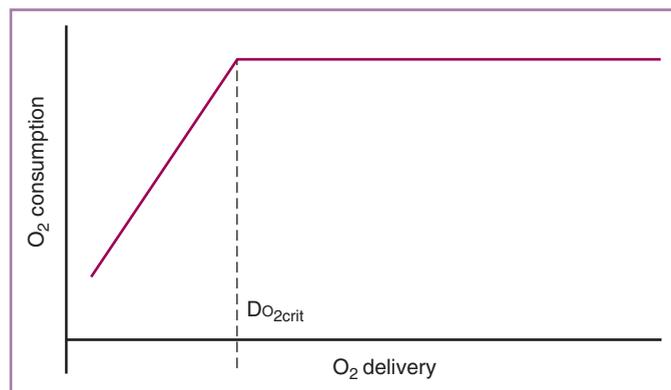

FIGURE 45-2 Relationship of oxygen consumption (VO_2) and oxygen delivery (DO_2). At the point of critical oxygen delivery, tissues begin to use anaerobic glycolysis, with resultant lactate production and metabolic acidosis. If the oxygen deprivation continues, irreversible tissue damage and death ensue.

venous oxygen tension is 40 mm Hg with a saturation of 73%. Saturations less than 60% are abnormally low. These parameters can be measured directly by obtaining a blood sample from the distal port of the pulmonary artery catheter. The $S\bar{V}O_2$ also can be measured continuously with special pulmonary artery catheters equipped with fiberoptics. Mixed venous oxygenation is a reliable parameter in the patient with hypoxemia or low cardiac output, but findings must be interpreted with caution. When the $S\bar{V}O_2$ is low, oxygen delivery can be assumed to be low. However, normal or high $S\bar{V}O_2$ values do not guarantee that tissues are well oxygenated. In conditions such as septic shock and adult respiratory distress syndrome, the maldistribution of systemic flow may lead to an abnormally high $S\bar{V}O_2$ value in the face of severe tissue hypoxia.³⁵ The oxygen dissociation curve must be considered when interpreting the $S\bar{V}O_2$ as an indicator of tissue oxygenation.³³ Conditions that result in a left shift of the curve cause the venous oxygen saturation to be normal or high, even when the mixed venous oxygen content is low. $S\bar{V}O_2$ is useful for monitoring trends in a particular patient, because a significant decrease occurs when oxygen delivery has decreased because of hypoxemia or a decrease in cardiac output.

Oxygen Delivery and Consumption in Pregnancy

The physiologic anemia of pregnancy results in a reduction in the hemoglobin concentration and arterial oxygen content. Oxygen delivery is maintained at or above normal despite this because of the 50% increase in cardiac output. The pregnant woman therefore depends on cardiac output for maintenance of oxygen delivery more than the nonpregnant patient.³⁸ Oxygen consumption increases steadily throughout pregnancy and is greatest at term, reaching an average of 331 mL/min at rest and 1167 mL/min with exercise.¹¹ During labor, oxygen consumption increases by 40% to 60%, and cardiac output increases by about 22%.^{39,40} Because oxygen delivery normally far exceeds consumption, the normal pregnant patient usually is able to maintain adequate delivery of oxygen to herself and her fetus, even during labor. When a pregnant patient has low oxygen delivery, she very quickly can reach the critical oxygen delivery level during labor, compromising herself and her fetus. The obstetrician therefore must make every effort to optimize oxygen delivery before allowing labor to begin in the compromised patient.

Pneumonia in Pregnancy

Pneumonia is fortunately a rare complication of pregnancy, occurring in 1 of 118 to 2288 deliveries.^{41,42} However, pneumonia contributes to considerable maternal mortality and is reportedly the most common non-obstetric infection to cause maternal mortality in the peripartum period.⁴³ Maternal mortality was as high as 24% before the introduction of antibiotic therapy.⁴⁴ Research reports have documented a dramatic decrease in maternal mortality from 0% to 4% with modern management and antibiotic therapy.^{42,45,46} Preterm delivery is a significant complication of pneumonia complicating pregnancy. Even with antibiotic therapy and modern management, preterm delivery continues to occur for 4% to 43% of gravidas who have pneumonia.^{42,45,46}

The increasing incidence of pneumonia in pregnancy may reflect the declining general health status of certain segments of the childbearing population (e.g., morbid obesity).⁴⁶ The epidemic of human immunodeficiency virus (HIV) infection has increased the number of potential mothers who are at risk for opportunistic lung infections.

HIV infection is also associated with increased risks of invasive pneumococcal disease (odds ratio [OR] = 41.8) and Legionnaire disease (OR = 41.8).⁴⁷ HIV infection further predisposes the pregnant woman to the infectious complications of acquired immunodeficiency syndrome (AIDS).^{47,48} Reported incidence rates range from 97 to 290 cases per 1000 HIV-infected persons per year. HIV-infected persons are 7.8 times more likely to develop pneumonia than non-HIV-infected individuals with similar risk factors. Women with medical conditions that increase the risk for pulmonary infection, such as cystic fibrosis (CF), are living to childbearing age more frequently than in the past. This disorder contributes to the increased incidence of pneumonia in pregnancy.

Pneumonia can complicate pregnancy at any time during gestation and may be associated with preterm birth, poor fetal growth, and perinatal loss. In an early report, 17 of 23 patients developed pneumonia between 25 and 36 weeks' gestation.⁴⁹ In that series, seven gravidas delivered during the course of their acute illness, and there were two maternal deaths. Another report described 39 cases of pneumonia in pregnancy.⁴⁵ Sixteen gravidas presented before 24 weeks' gestation, 15 between 25 and 36 weeks' gestation, and 8 after 36 weeks' gestation. Twenty-seven patients in this series were followed to completion of pregnancy; only two required delivery during the acute phase of pneumonia. Of these 27 patients, 3 suffered a fetal loss, and 24 delivered live fetuses, although there was one neonatal death resulting from prematurity.

Madinger and associates⁴² reported 25 cases of pneumonia occurring among 32,179 deliveries and observed that fetal and obstetric complications were much more common than in earlier studies. Preterm labor complicated 11 of 21 gestations. Eleven patients had pneumonia at the time of delivery. Preterm delivery was more likely for women who had bacteremia, needed mechanical ventilation, and had a serious underlying maternal disease. In addition to the complication of preterm labor, there were three perinatal deaths in this series. Berkowitz and LaSala⁴⁶ reported 25 patients with pneumonia complicating pregnancy; 14 women had term deliveries, 1 delivered preterm, 3 had a voluntary termination of pregnancy, 3 had term deliveries of growth-restricted infants, and 4 were lost to follow-up. Birth weight was significantly lower in the study group in this series (2770 ± 224 g versus 3173 ± 99 g in the control group; $P < .01$). In this series, pneumonia complicated 1 of 367 deliveries. The investigators attributed the increase in the incidence of pneumonia in this population to a decline in general health status, including anemia, a significant incidence of cocaine use (52% versus 10% of the general population), and HIV positivity (24% versus 2% of the general population) in the study group.

Bacteriology

Most series describing pneumonia complicating pregnancy have used incomplete methodologies to diagnose the etiologic pathogens for pneumonia, relying primarily on cultures of blood and sputum. In most cases, no pathogen was identified; however, pneumococcus and *Haemophilus influenzae* remain the most common identifiable causes of pneumonia in pregnancy.^{42,45,46} Because comprehensive serologic testing has rarely been done, the true incidence of viral, *Legionella*, and *Mycoplasma* pneumonia in pregnancy is difficult to estimate. The data presented by Benedetti, Madinger, Berkowitz, and their respective colleagues all support pneumococcus as the predominant pathogen causing pneumonia in pregnancy and *H. influenzae* as the second most common organism.^{42,45,46} In the series of Berkowitz and LaSala,⁴⁶ one patient was infected with *Legionella* species.

Pneumonia in pregnancy has several causes, including mumps, infectious mononucleosis, swine influenza, influenza A, varicella, coccidioidomycosis, and other fungi.⁵⁰ Varicella pneumonia can complicate primary varicella infections in 5.2% to 9%⁵¹ of infections in pregnancy, compared with 0.3% to 1.8% in the nonpregnant population.⁵² Influenza A has a higher mortality rate among pregnant women than among nonpregnant patients.⁵³ The increase in virulence of viral infections reported in pregnancy may result from the alterations in maternal immune status that characterize pregnancy, including reduced lymphocyte proliferative response, reduced cell-mediated cytotoxicity by lymphocytes, and a decrease in the number of helper T lymphocytes.^{53,54} Viral pneumonias can also be complicated by superimposed bacterial infection, particularly pneumococcus.

Aspiration Pneumonia

Mendelson syndrome describes chemical pneumonitis resulting from the aspiration of gastric contents in pregnancy. Chemical pneumonitis can be superinfected with pathogens present in the oropharynx and gastric juices, primarily anaerobes and gram-negative bacteria.⁴⁵ Mendelson's original report of aspiration⁵⁵ consisted of 44,016 nonfasted obstetric patients between 1932 and 1945, and more than one half had received "operative intervention" with ether by mask without endotracheal intubation. He described aspiration in 66 cases (rate of 1 case per 667 patients). Although several of the patients were critically ill from their aspirations, most recovered within 24 to 36 hours, and only two died from this complication (rate of 1 death per 22,008 patients). A review described 37,282 vaginal deliveries; 85% were performed with general anesthesia by mask and without intubation, and 65% to 75% had ingested liquids or solid food within 4 hours of onset of labor.⁵⁶ The investigators found five mild cases of aspiration (1 per 7456 patients) with no sequelae.⁵⁶ Another report described one occurrence of "mild aspiration" without adverse outcome among 1870 women undergoing nonintubated peripartum surgery with intravenous ketamine, benzodiazepines, barbiturates, fentanyl, or some combination of these drugs.⁵⁷ Soreide and colleagues⁵⁸ observed four episodes of aspiration each during 36,800 deliveries and 3600 cesarean sections with no mortality. Based on these data, most hospitals permit free intake of clear liquids during labor. The risk of aspiration, pneumonia, and death from general anesthesia appears to be very low. This may reflect the use of modern techniques and therapy to reduce gastric pH.

Bacterial Pneumonia

Streptococcus pneumoniae (pneumococcus) is the most common bacterial pathogen that causes pneumonia in pregnancy; *H. influenzae* is the next most common. These pneumonias typically manifest as an acute illness accompanied by fever, chills, and a purulent, productive cough and are seen as a lobar pattern on the chest radiograph (Fig. 45-3). Streptococcal pneumonia produces a "rusty" sputum, with gram-positive diplococci on Gram stain, and it demonstrates asymmetrical consolidation with air bronchograms on the chest radiograph.⁵⁴ *H. influenzae* is a gram-negative coccobacillus that produces consolidation with air bronchograms, often in the upper lobes.⁵⁴ Less common bacterial pathogens include *Klebsiella pneumoniae*, which is a gram-negative rod that causes extensive tissue destruction with air bronchograms, pleural effusion, and cavitation seen on the chest radiograph. Patients with *Staphylococcus aureus* pneumonia present with pleuritis, chest pain, purulent sputum, and consolidation without air bronchograms identified on the chest radiograph.⁵⁴

FIGURE 45-3 Right lower lobe pneumonia. Lobar consolidation in the right lower lobe is consistent with pneumococcal pneumonia.

Patients infected with atypical pneumonia pathogens, such as *Mycoplasma pneumoniae*, *Legionella pneumophila*, and *Chlamydia pneumoniae* (TWAR agent), present with gradual onset of symptoms. They have a lower fever, appear less ill, have mucoid sputum, and have a patchy or interstitial infiltrate seen on the chest radiograph. The severity of the findings on the chest radiograph usually is out of proportion to the mild clinical symptoms. *M. pneumoniae* is the most common organism responsible for atypical pneumonia and is best detected by the presence of cold agglutinins in about 70% of cases.

The normal physiologic changes in the respiratory system associated with pregnancy result in a loss of ventilatory reserve. Coupled with the immunosuppression that accompanies pregnancy, this puts the mother and fetus at great risk from respiratory infection. Any gravida suspected of having pneumonia should be managed aggressively. The pregnant patient should be admitted to the hospital and a thorough investigation undertaken to determine the cause. One study examined 133 women admitted with pneumonia during pregnancy using protocols based on the British Thoracic Society and American Thoracic Society admission guidelines for management of nonpregnant individuals. The investigators reported that if the American Thoracic Society guidelines were used, 25% of the pregnant women with pneumonia could have avoided admission. Using the American criteria, none of the gravidas who would have been managed as an outpatient had any complications. If the British Thoracic Society guidelines had been used, 66% of the pregnant women in this group would have been assigned to outpatient therapy. However, 14% would have required readmission for complications. Most of the 133 women who were hospitalized with pneumonia in this study did not receive a chest radiograph for confirmation of the diagnosis. This limits the value of the study for guiding admission criteria for pneumonia in pregnancy. Until additional information is available, admission for all pregnant women with pneumonia is still recommended.

The workup should include a physical examination, arterial blood gas determinations, a chest radiograph, sputum Gram stain and culture, and blood cultures. Several studies have called into question the use of cultures to identify the microbes of community-acquired pneumonia. Success rates for identification of the bacterial cause with cultures range from 2.1% to approximately 50%. Review of available clinical data reflects an overall reliance on clinical judgment and the patient's response to treatment to guide therapy. Other tests are available to identify the cause of pneumonia that do not require culture and are more sensitive and specific. An assay approved by the U.S. Food and Drug Administration (FDA) for pneumococcal urinary antigen has been assessed in several studies. The sensitivity for identifying pneumococcal disease in adults is reportedly 60% to 90%, with a specificity close to 100%. In one study, the pneumococcal antigen was detected in 26% of patients in whom no pathogens had been identified. This finding suggests that cases that are undiagnosed by standard test can be identified with the assay. In this study, 10% of samples from patients with pneumonia caused by other agents were positive on the pneumococcal assay, indicating a potential problem with specificity. If the response to therapy directed at pneumococcus is inadequate, coverage for other potential pathogens should be added.

The test for *Legionella* urinary antigen has a sensitivity of 70% and specificity of 90% for serogroup 1. This is especially useful in the United States and Europe, because about 85% of *Legionella* isolates are serogroup 1. *Legionella* is a common cause of severe community-acquired pneumonia. The urinary antigen for serogroup 1 should be considered for any patient requiring admission into an intensive care unit for pneumonia.

Percutaneous-transthoracic needle aspiration has been advocated as a valuable and safe method to increase the chance of establishing the causative agent for pneumonia. This test should be reserved for use in compromised individuals, suspected tuberculosis in the absence of a productive cough, selected cases of chronic pneumonia, pneumonia associated with neoplasm or a foreign body, suspected *Pneumocystis jiroveci* pneumonia, and suspected conditions that necessitate lung biopsy. Cold agglutinins and *Legionella* titers may also be useful. Empiric antibiotic coverage should be started, usually with a third-generation cephalosporin such as ceftriaxone or cefotaxime. *Legionella* pneumonia has a high mortality rate and sometimes manifests with consolidation, mimicking pneumococcal pneumonia. It is recommended that a macrolide, such as azithromycin, be added to the empiric therapy. Dual coverage has been demonstrated to improve response to therapy even for abbreviated macrolide regimens. This may reflect the added anti-inflammatory effect of the macrolides. Azithromycin administration is an independent predictor of a positive outcome and reduced length of hospital stay for patients with mild to moderate community-acquired pneumonia. The use of macrolides to treat community-acquired pneumonia should be limited when possible, because their use has also been associated with increased penicillin resistance by *S. pneumoniae*.

When admission for pneumonia is required, there is evidence that inpatient and 30-day mortality rates have been reduced when antibiotics are administered in less than 8 hours. Current U.S. federal standards require that the first dose of antibiotics be administered within 4 hours of arrival to the hospital. After the results of the sputum culture, blood cultures, Gram stain, and serum studies are obtained and a pathogen has been identified, antibiotic therapy can be directed toward the identified cause. The third-generation cephalosporins are effective agents for most pathogens causing a community-acquired pneumonia. They are also effective against penicillin-resistant *S. pneumoniae*. The quinolones as a class should be avoided in pregnancy because they may

damage developing fetal cartilage. However, with the emergence of highly resistant bacterial pneumonia, their use may be lifesaving and therefore justified in specific circumstances. The respiratory quinolones are effective against highly penicillin-resistant *S. pneumoniae* strains, and their use does not increase resistance. The respiratory quinolones include levofloxacin, gatifloxacin, and moxifloxacin. These are ideal agents for community-acquired pneumonia because they are highly active against penicillin-resistant strains of *S. pneumoniae*. They are also active against *Legionella* and the other atypical pulmonary pathogens. Another advantage is a favorable pharmacokinetic profile, such that blood or lung levels are the same whether the drug is administered orally or intravenously. Arguments against more extensive respiratory quinolone use are based on concerns about the potential for developing resistance, the variable incidence of *Legionella*, and cost. An additional caveat is that the respiratory quinolones are only partially effective against *Mycobacterium tuberculosis*. Evaluation for this infection should be done when considering the use of quinolones for pneumonia.

In addition to antibiotic therapy, oxygen supplementation should be given. Frequent arterial blood gas measurements should be obtained to maintain partial pressure of oxygen at 70 mm Hg, a level necessary to ensure adequate fetal oxygenation. Arterial saturation also can be monitored with pulse oximetry. When the gravida is afebrile for 48 hours and has signs of clinical improvement, an oral cephalosporin can be started and intravenous therapy discontinued. A total of 10 to 14 days of treatment should be completed.

Pneumonia in pregnancy can be complicated by respiratory failure requiring mechanical ventilation. If this occurs, team management should include the obstetrician, maternal-fetal medicine specialist, and intensivist. In addition to meticulous management of the gravida's respiratory status, the patient should be maintained in the left lateral recumbent position to improve uteroplacental perfusion. The viable fetus should be monitored with continuous fetal monitoring. If positive end-expiratory pressure greater than 10 cm H₂O is required to maintain oxygenation, central monitoring with a pulmonary artery catheter should be instituted to adequately monitor volume status and maintain maternal and uteroplacental perfusion. There is no evidence documenting that elective delivery results in overall improvement in respiratory function,⁵⁹ and elective delivery should be reserved for the usual obstetric indications. However, if there is evidence of fetal compromise or profound maternal compromise and impending demise, delivery should be accomplished.

Pneumococcal polysaccharide vaccination prevents pneumococcal pneumonia in otherwise healthy populations with an efficacy of 65% to 84%. The vaccine is safe in pregnancy and should be administered to high-risk gravidas. Those at high risk include individuals with sickle cell disease with autosplenectomy, patients who have a surgical splenectomy, and individuals who are immunosuppressed. An additional advantage to maternal immunization with the pneumococcal vaccine is that several studies have demonstrated there is significant transplacental transmission of vaccine-specific antibodies in infants at birth and at 2 months. Colostrum and breast milk antibodies are also significantly increased in women who have received the pneumococcal vaccine.

Viral Pneumonias

Influenza

An estimated 4 million cases of pneumonia and influenza occur annually in the United States, and it is the sixth leading cause of death.⁶⁰ In

contrast to the general population, pregnant women seem to be at higher risk for influenza pneumonia.^{61,62} Epidemiologic data from the 1918 to 1919 influenza A pandemic revealed a maternal mortality rate that approached 50% for pregnant women with influenza pneumonia.^{63,64} Three types of influenza virus can cause human disease—A, B, and C—but most epidemic infections are caused by influenza A.⁵⁰ Influenza A typically has an acute onset after a 1- to 4-day incubation period and first manifests as high fever, coryza, headache, malaise, and cough. In uncomplicated cases, results of the chest examination and chest radiograph are normal.⁵⁰ If symptoms persist longer than 5 days, especially in a pregnant woman, complications should be suspected. Pneumonia may complicate influenza as the result of secondary bacterial infection or viral infection of the lung parenchyma.⁵⁰ In the epidemic of 1957, autopsies demonstrated that pregnant women died most commonly of fulminant viral pneumonia, whereas nonpregnant patients died most often of secondary bacterial infection.⁶⁵

A large, nested, case-control study evaluated the rate of influenza-related complications over 17 influenza seasons among women enrolled in the Tennessee Medicaid system. This study demonstrated a high risk for hospitalization for influenza-related reasons in low-risk pregnant women during the last trimester of pregnancy. The study authors estimated that 25 of 10,000 women in the third trimester during the influenza season are hospitalized with influenza-related complications. A later, matched-cohort study using the administrative database of pregnant women enrolled in the Tennessee Medicaid system examined pregnant women between the ages of 25 and 44 years with respiratory hospitalization during the 1985 to 1993 influenza seasons. In this population of pregnant women, those with asthma accounted for one half of all respiratory-related hospitalizations during the influenza season. Among pregnant women with diagnosis of asthma, 6% required respiratory hospitalization during the influenza season (OR = 10.63; 95% confidence interval [CI], 8.61 to 13.83) compared with women without a medical comorbidity. This study detected no significant increases in adverse perinatal outcome associated with respiratory hospitalization during flu season.

Primary influenza pneumonia is characterized by rapid progression from a unilateral infiltrate to diffuse bilateral disease. The gravida may develop fulminant respiratory failure requiring mechanical ventilation and positive end-expiratory pressure. Aggressive therapy is indicated when pneumonia complicates influenza in pregnancy. Antibiotics should be started and directed at the likely pathogens that can cause secondary infection, including *S. aureus*, pneumococcus, *H. influenzae*, and certain enteric gram-negative bacteria. Antiviral agents, such as oseltamivir and zanamivir, should also be considered.⁶⁶ It has been recommended that the influenza vaccine be given routinely to gravidas in the second and third trimester of pregnancy to prevent the occurrence of influenza and the development of pneumonia. Women at high risk for pulmonary complications, such as those with asthma, chronic obstructive pulmonary disease, cystic fibrosis, and splenectomy, should be vaccinated regardless of the trimester to prevent the occurrence of influenza and the development of secondary pneumonia. In addition to maternal protection, prospective studies have demonstrated higher cord blood antibody levels to influenza in infants born to mothers immunized during pregnancy. There is a delay in the onset and decrease in severity of influenza in infants born with higher antibody levels.

Varicella

Varicella-zoster virus is a DNA virus that usually causes a benign, self-limited illness in children, but it may infect up to 2% of all adults.⁶⁷ Varicella infection occurs in 0.7 of every 1000 pregnancies.⁶⁸ Pregnancy may increase the likelihood of varicella pneumonia, complicating the

primary infection.⁵² Treatment with acyclovir is safe in pregnancy. In one report,⁵² there was one intrauterine fetal death. Another report⁵¹ documented a 5.2% incidence of varicella pneumonia among gravidas with varicella-zoster infection. The investigators also reported that gravidas who smoke or manifest more than 100 skin lesions are more likely to develop pneumonia.⁵¹ Varicella pneumonia occurs most often in the third trimester, and the infection is likely to be severe.^{52,68,69} The maternal mortality rate for varicella pneumonia may be as high as 35% to 40%, compared with 11% to 17% for nonpregnant individuals.^{52,69} Although one review reported a decreased mortality rate, with only three deaths among 28 women with varicella pneumonia,⁶⁸ another study documented a maternal mortality rate of 35%.⁵² However, a later report documented 100% survival among 18 gravidas with varicella pneumonia who were treated with acyclovir.⁵¹ In this report, there was one intrauterine fetal death at 25 weeks' gestation in a woman with varicella. In one report of 312 pregnancies, there was no increase in the number of birth defects and no consistent pattern of congenital abnormalities. In another report, 17 other infants were delivered beyond 36 weeks, and there was no evidence of neonatal varicella.⁵¹

Varicella pneumonia usually manifests 2 to 5 days after the onset of fever, rash, and malaise and is heralded by the onset of pulmonary symptoms, including cough, dyspnea, pruritic chest pain, and hemoptysis.⁵² The severity of the illness may vary from asymptomatic radiographic abnormalities to fulminant pneumonitis and respiratory failure (Fig. 45-4).^{52,70}

All gravidas with varicella pneumonia should be aggressively treated with antiviral therapy and admitted to the intensive care unit for close observation or intubation if indicated. Acyclovir, a DNA polymerase inhibitor, should be started. The early use of acyclovir was associated with an improved hospital course after the 5th day and a lower mean temperature, lower respiratory rate, and improved oxygenation.⁵² Treatment with acyclovir is safe in pregnancy. Among 312 pregnancies, there was no increase in the number of birth defects and no consistent

pattern of congenital abnormalities.⁷¹ A dose of 7.5 mg/kg given intravenously every 8 hours has been recommended.⁷²

Varicella vaccine is an attenuated live virus vaccine that was added to the universal childhood immunization schedule in the United States in 1995. The program of universal childhood vaccination against varicella in the United States has resulted in a sharp decline in the rate of death from varicella. However, varicella vaccine is not recommended for use in pregnancy. The overall decline in incidence of adult varicella infection because of childhood vaccination will likely result in a decreased incidence of varicella infection and varicella pneumonia during pregnancy.

A study⁷³ assessed the risk of congenital varicella syndrome and other birth defects in offspring of women who inadvertently received varicella vaccine during pregnancy or within 3 months of conception. Fifty-eight women received their first dose of varicella vaccine during the first or second trimester. No cases (0%) of congenital varicella syndrome were identified among 56 live births (CI, 0 to 15.6). Among the prospective reports of live births, five congenital anomalies were identified in the susceptible cohort or the sample population as a whole. The investigator suggested that although the numbers in the study were small, the results should provide some reassurance to health care providers and women with inadvertent exposure before or during pregnancy.

Pneumocystis jiroveci

Infection with the HIV virus significantly increases the risk for pulmonary infection. *S. pneumoniae* and *H. influenzae* are the most commonly isolated organisms.⁷³ One report⁷⁴ also identified *Pseudomonas aeruginosa* as a significant cause of bacterial pneumonia in HIV-infected individuals. *Pneumocystis* pneumonia, an AIDS-defining illness, occurs more frequently when the helper T-cell count (CD4⁺) is less than 200 cells/mm³. *Pneumocystis jiroveci* pneumonia (PJP), formerly designated *Pneumocystis carinii* pneumonia (PCP), is the most common of the serious opportunistic infections in pregnant women infected with HIV.^{75,76} *P. jiroveci* is the number one cause of pregnancy-associated AIDS deaths in the United States.⁷⁷ Initial reports of PJP in pregnancy described a 100% maternal mortality rate.^{47,75,78-80} However, in a 2001 review of 22 cases of PJP in pregnancy, the mortality rate was 50% (11 of 22 patients).⁸¹ However, the mortality rate is still higher than that reported for HIV-infected nonpregnant individuals.⁸¹ In that series, respiratory failure developed in 13 patients, and 59% required mechanical ventilation. The survival rate of gravidas requiring mechanical ventilation was 31%. In this series, maternal and fetal outcomes were better in cases of PJP that occurred during the third trimester of pregnancy.

A high index of suspicion is necessary when gravidas at risk for HIV infection present with symptoms such as weight loss, fatigue, fever, tachypnea, dyspnea, and nonproductive cough.⁷⁵ The onset of disease can be insidious, including normal radiographic findings, and it can then proceed to rapid deterioration.⁷⁵ When the chest radiograph is positive, it typically exhibits bilateral alveolar disease in the perihilar regions and lower lung fields (Fig. 45-5), which can progress to include the entire parenchyma.⁷⁵ Diagnosis can be accomplished by means of sputum silver stains, bronchial aspiration, or bronchoscope-directed biopsy.⁸² Lung biopsy is recommended for definitive diagnosis.⁷⁸

Therapy for PJP in pregnancy includes trimethoprim-sulfamethoxazole (TMP-SMX), which is a category C drug. Gravidas with a history of PJP, a CD4⁺ lymphocyte count of less than 200/mm³, or oral pharyngeal candidiasis should receive prophylaxis.⁸³ TMP-SMX is the drug of choice and may provide cross protection against toxoplasmosis and other bacterial infections.⁸⁴ The usual dose is one double-strength

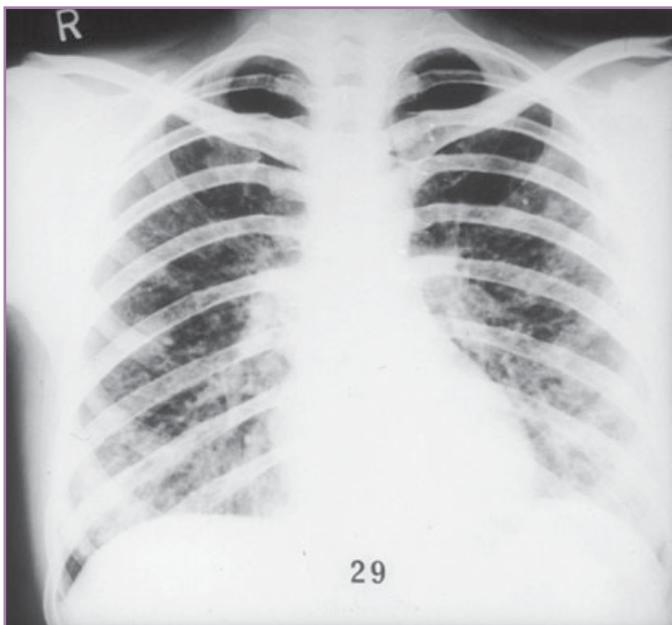

FIGURE 45-4 Varicella pneumonia. The chest radiograph demonstrates bilateral nodular and interstitial pneumonia of varicella pneumonia.

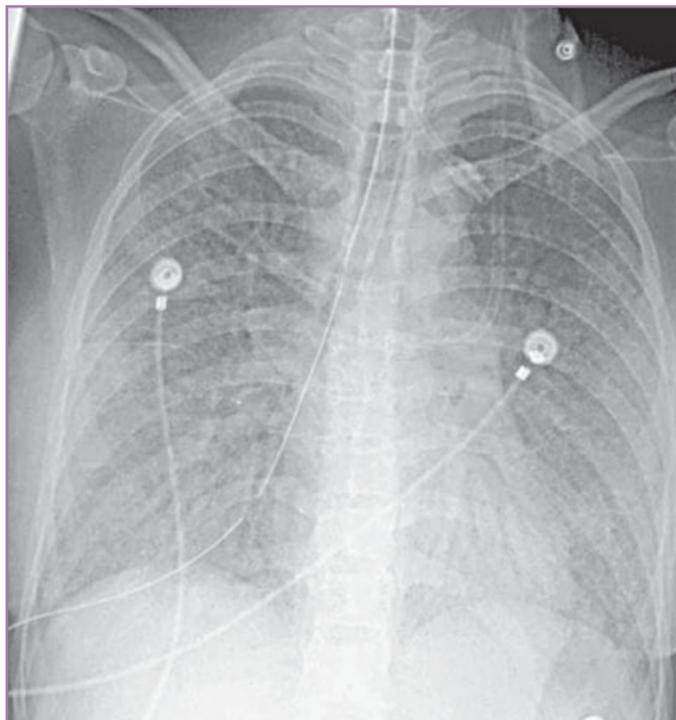

FIGURE 45-5 *Pneumocystis jirovecii* pneumonia (PJP). Bilateral alveolar disease is consistent with PJP pneumonia.

tablet (150 mg/m² of TMP and 750 mg/m² of SMX given three times each week). Adverse reactions such as drug allergy, nausea, fever, neutropenia, anemia, thrombocytopenia, and elevated transaminase levels have been reported in 20% to 30% of nonpregnant individuals receiving TMP-SMX therapy.⁸⁴ Complete blood cell count with a differential cell count and liver function tests should be obtained every 6 to 8 weeks to monitor for toxicity. Other regimens used for prophylaxis for individuals with intolerance to TMP-SMX include aerosolized pentamidine (300 mg every month by Respigard II nebulizer) or dapsone (100 mg once daily). Hussain and colleagues⁸⁵ found that the survival rate for patients treated with SMX alone was 71% (5 of 7 patients) and that the rate with SMX and steroids was 60% (3 of 5 patients); the overall survival rate for both groups was 66.6% (8 of 12 patients). The investigators concluded that PJP has a more aggressive course during pregnancy, with increased morbidity and mortality.⁸⁵ However, treatment with SMX compared with other therapies may result in improved outcome. They also caution that withholding appropriate PJP prophylaxis may adversely affect maternal and fetal outcomes.⁸⁵

PJP is a devastating opportunistic infection in pregnant women who are infected with HIV. The maternal mortality rate is extremely high, and prophylaxis with TMP-SMX is indicated during the antepartum period for individuals with a CD4⁺ cell count less than 200/mm³ or a history of oropharyngeal candidiasis and for individuals with a prior history of PJP infection. Initiation of therapy during the antepartum period can also prevent the rare occurrence of perinatally transmitted PJP.⁸⁴ When a gravida is demonstrating symptoms consistent with a possible infection, a diligent search should be conducted to quickly identify PJP as the cause of pneumonia. When PJP is untreated, the maternal mortality rate can approach 100%. In summary, PJP pneumonia remains a dreaded complication of HIV infection and an AIDS-defining illness. There is a very high maternal and fetal mortality rate when PJP complicates pregnancy. Primary prophylaxis against

Pneumocystis pneumonia with TMP-SMX in HIV-infected adults, including pregnant women and patients receiving highly active anti-retroviral therapy, should begin when the CD4⁺ cell count is less than 200 cells/mm³ or there is a history of oropharyngeal candidiasis. Prophylaxis should be discontinued when the CD4⁺ cell count increases to more than 200 cells/mm³ for a period of 3 months.

Tuberculosis in Pregnancy

Tuberculosis kills more than 1 million women per year worldwide, and it is estimated that 646 million women and girls are already infected with tuberculosis. In women between 15 and 44 years old in developing countries, tuberculosis is the third most common cause of morbidity and mortality combined, and tuberculosis kills more women than any other infectious disease, including malaria and AIDS.

Case-notification rates from countries with a high prevalence of tuberculosis suggest that tuberculosis may be less common among females.⁸⁶ Epidemiologic information shows differences between men and women in prevalence of infection, rate of progression from infection to disease, incidence of clinical disease, and mortality resulting from tuberculosis. Seventy percent more smear-positive male than female tuberculosis patients are diagnosed every year and reported to the World Health Organization.⁸⁶ Differences between males and females have also been shown in the development and outcome of active disease, with female cases having a higher progression from infection to disease and a higher case-fatality rate.⁸⁷ The conclusion of a research workshop on gender and tuberculosis was that a combination of biologic and social factors is responsible for these differences.⁸⁶

The incidence of tuberculosis in the United States began to decline in the early part of the 20th century and fell steadily until 1953, when the introduction of isoniazid led to a dramatic decrease in the number of cases, from 84,000 cases in 1953 to 22,255 cases in 1984.⁸⁸ However, since 1984, there have been significant changes in tuberculosis morbidity trends. From 1985 through 1991, reported cases of tuberculosis increased by 18%, representing approximately 39,000 more cases than expected had the previous downward trend continued. This increase results from many factors, including the HIV epidemic, deterioration in the health care infrastructure, and more cases among immigrants.^{88,89} Between 1985 and 1992, the number of tuberculosis cases among women of childbearing age increased by 40%.⁹⁰ One report described tuberculosis-complicated pregnancies in 94.8 cases per 100,000 deliveries between 1991 and 1992.⁹¹

The emergence of drug-resistant tuberculosis has become a serious concern. In New York City in 1991, 33% of tuberculosis cases were resistant to at least one drug, and 19% were resistant to isoniazid and rifampin. Multidrug resistance is an additional problem. Many centers advocate directly observed therapy in the treatment of multidrug-resistant disease. Pregnancy complicates treatment of multidrug-resistant tuberculosis for the following reasons:

- Several antimycobacterial drugs are contraindicated during gestation.
- Patients and physicians may fear the effects of chest radiography on the fetus.
- Untreated, infectious, multidrug-resistant tuberculosis may be vertically and laterally transmitted.⁹²

In one report,⁹² three patients had disease resulting from multidrug-resistant *M. tuberculosis*, and one had disease resulting from

multidrug-resistant *Mycobacterium bovis*. Only one patient began retreatment during pregnancy because her organism was susceptible to three antituberculosis drugs that were considered nontoxic to the fetus. Despite concern about teratogenicity of the second-line antituberculosis medications, careful timing of treatment initiation resulted in clinical cure for the mothers, regardless of some complications because of chronic tuberculosis or therapy. In this series, all infants were born healthy and remained free of tuberculosis.⁹²

Diagnosis

Most gravidas with tuberculosis in pregnancy are asymptomatic. All gravidas at high risk for tuberculosis (Table 45-1) should be screened with subcutaneous administration of intermediate-strength purified protein derivative (PPD). If anergy is suspected, control antigens such as candidal, mumps, or tetanus toxoids should be used.⁹³ The sensitivity of the PPD is 90% to 99% for exposure to tuberculosis. The tine test should not be used for screening because of its low sensitivity.

The onset of the recent tuberculosis epidemic stimulated the need for rapid diagnostic tests using molecular biology methods to detect *M. tuberculosis* in clinical specimens. Two direct amplification tests have been approved by the FDA, the *Mycobacterium tuberculosis* Direct (MTD) Test (Gen-Probe, San Diego, CA) and the Amplicor *Mycobacterium tuberculosis* (MTB) Test (Roche Diagnostic Systems, Branchburg, NJ). Both tests amplify and detect *M. tuberculosis* 16S ribosomal DNA.⁹⁴ When testing acid-fast stained smear–positive respiratory specimens, each test has a sensitivity of greater than 95% and a specificity of essentially 100% for detecting the *M. tuberculosis* complex.^{95,96} When testing acid-fast stained smear–negative respiratory specimens, the specificity remains greater than 95%, but the sensitivity ranges from 40% to 77%.^{95,96} These tests are FDA approved only for testing acid-fast stained smear–positive respiratory specimens obtained from untreated patients or those who have received no more than 7 days of antituberculosis therapy. The PPD remains the most commonly used screening test for tuberculosis.

Immigrants from areas where tuberculosis is endemic may have received the bacillus Calmette-Guérin (BCG) vaccine, and they are likely to have a positive response to the PPD. However, this reactivity should wane over time. The PPD should be used to screen these patients for tuberculosis unless their skin tests are known to be positive.⁹³ If BCG vaccine was given 10 years earlier and the PPD is positive with a skin test reaction of 10 mm or more, the individual should be considered infected with tuberculosis and managed accordingly.⁹³

TABLE 45-1 HIGH-RISK FACTORS FOR TUBERCULOSIS

Human immunodeficiency virus infection
Close contact with persons known or suspected to have tuberculosis
Medical risk factors known to increase risk for disease if infected
Birth in a country with high tuberculosis prevalence
Medically underserved status
Low income
Alcohol addiction
Intravenous drug use
Residency in a long-term care facility (e.g., correctional institutions, mental institutions, nursing homes and facilities)
Health professionals working in high-risk health care facilities

Women with a positive PPD skin test result must be evaluated for active tuberculosis with a thorough physical examination for extrapulmonary disease and a chest radiograph after they are beyond the first trimester.⁵⁴ Symptoms of active tuberculosis include cough (74%), weight loss (41%), fever (30%), malaise and fatigue (30%), and hemoptysis (19%).⁹⁷ Individuals with active pulmonary tuberculosis may have radiographic findings, including adenopathy, multinodular infiltrates, cavitation, loss of volume in the upper lobes, and upper medial retraction of hilar markings (Fig. 45-6). The finding of acid-fast bacilli in early morning sputum specimens confirms the diagnosis of pulmonary tuberculosis. At least three first-morning sputum samples should be examined for the presence of acid-fast bacilli. If sputum cannot be produced, sputum induction, gastric washings, or diagnostic bronchoscopy may be indicated.

Extrapulmonary tuberculosis occurs in up to 16% of cases in the United States; however, the pattern may occur in 60% to 70% of all patients with AIDS.⁹⁸ Extrapulmonary sites include lymph nodes, bone, kidneys, intestine, meninges, breasts, and endometrium. Extrapulmonary tuberculosis appears to be rare in pregnancy.⁹⁹ Extrapulmonary tuberculosis that is confined to the lymph nodes has no effect on obstetric outcomes, but tuberculosis at other extrapulmonary sites does adversely affect the outcome of pregnancy.¹⁰⁰ Jana and colleagues¹⁰⁰ documented that tuberculosis lymphadenitis did not affect the course of pregnancy, labor, or perinatal outcome. However, compared with control women, the 21 women with tubercular involvement of other extrapulmonary sites had higher rates of antenatal hospitalization (24% versus 2%; $P < .0001$), infants with low Apgar scores (≤ 6) soon after birth (19% versus 3%; $P = .01$), and low-birth-weight (<2500 g) infants (33% versus 11%; $P = .01$). Rarely, mycobacteria

FIGURE 45-6 Chest radiograph of pulmonary tuberculosis. Radiographic findings may include adenopathy, multinodular infiltrates, cavitation, loss of volume in the upper lobes, and upper medial retraction of hilar markings.

invade the uteroplacental circulation, and congenital tuberculosis results.^{49,90,101} The diagnosis of congenital tuberculosis is based on one of the following factors⁹⁰:

- Demonstration of primary hepatic complex or cavitating hepatic granuloma by percutaneous liver biopsy at birth
- Infection of the maternal genital tract or placenta
- Lesions seen in the first week of life
- Exclusion of the possibility of postnatal transmission by a thorough investigation of all contacts, including attendants

Prevention

Most gravidas with a positive PPD result in pregnancy are asymptomatic and have no evidence of active disease; they are classified as infected without active disease. The risk of progression to active disease is highest in the first 2 years of conversion. It is important to prevent the onset of active disease while minimizing maternal and fetal risk. An algorithm for management of the positive PPD is presented in Figure 45-7.^{102,103} In women with a known recent conversion (2 years) to a positive PPD result and no evidence of active disease, the recommended prophylaxis is isoniazid (300 mg/day), starting after the first trimester and continuing for 6 to 9 months.⁵⁴ Under base-case assumptions in a Markov decision-analysis model, the fewest cases of tuberculosis within the cohort occurred with antepartum treatment (1400 per 100,000), compared with no treatment (3300 per 100,000) or postpartum treatment (1800 per 100,000).¹⁰⁴ Antepartum treatment

resulted in a marginal increase in life expectancy because of the prevented isoniazid-related hepatitis and deaths, compared with no treatment or postpartum treatment. Antepartum treatment was the least expensive.¹⁰⁴ Isoniazid should be accompanied by pyridoxine (vitamin B₆) supplementation (50 mg/day) to prevent the peripheral neuropathy that is associated with isoniazid treatment. Women with an unknown or prolonged duration of PPD positivity (>2 years) should receive isoniazid (300 mg/day) for 6 to 9 months after delivery. Isoniazid prophylaxis is not recommended for women older than 35 years who have an unknown or prolonged PPD positivity in the absence of active disease. The use of isoniazid is discouraged in this group because of an increased risk for hepatotoxicity. Isoniazid is associated with hepatitis in pregnant and nonpregnant adults. However, monthly monitoring of liver function tests may prevent this adverse outcome. Among individuals receiving isoniazid, 10% to 20% will develop mildly elevated values detected on liver function tests. These changes resolve after the drug is discontinued.¹⁰⁵

Treatment

The gravida with active tuberculosis should be treated initially with isoniazid (300 mg/day) combined with rifampin (600 mg/day) (Table 45-2).¹⁰⁶ Resistant disease results from initial infection with resistant strains (33%) or can develop during therapy.¹⁰⁷ The development of resistance is more likely in individuals who are noncompliant with therapy. If resistance to isoniazid is identified or anticipated, 2.5 g of ethambutol per day should be added, and the treatment period should

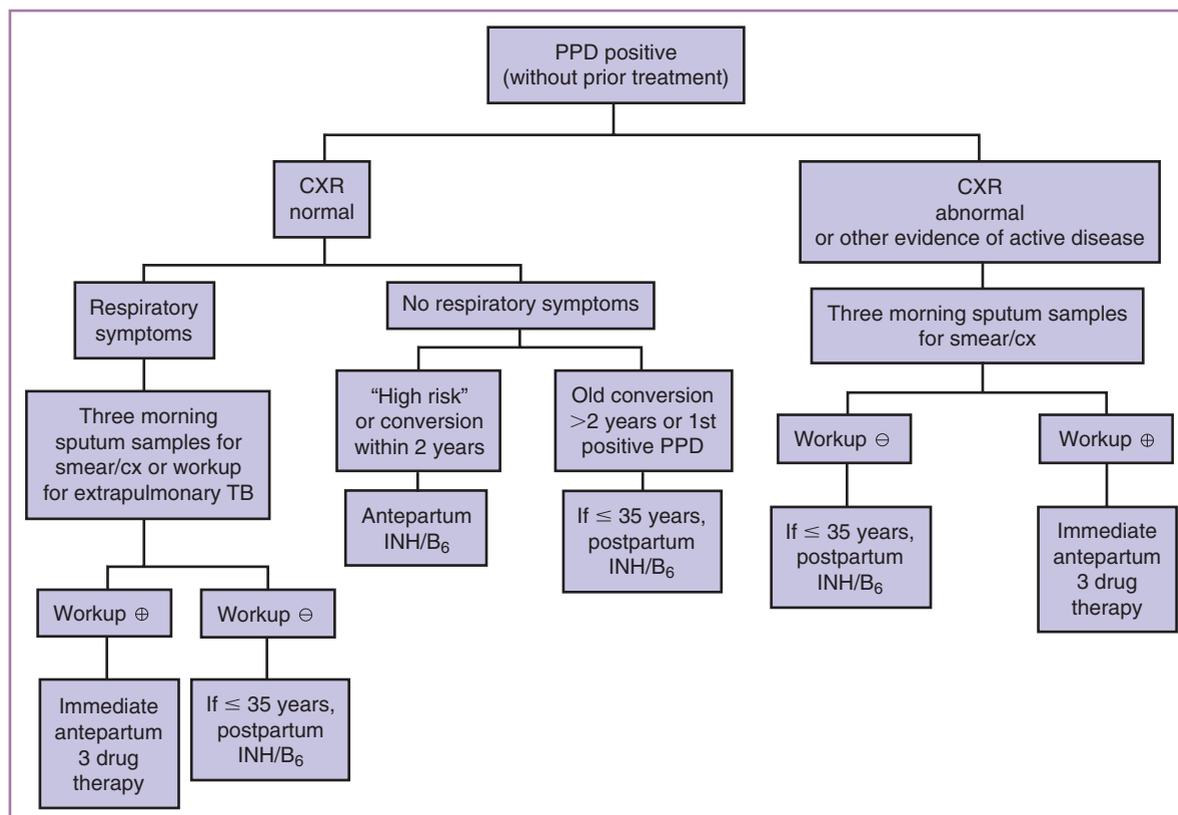

FIGURE 45-7 Algorithm for the management of a patient with a positive purified protein derivative (PPD) result. In women with known conversion within the past 2 years to a positive PPD result and no evidence of active disease, the recommended prophylaxis is 300 mg of isoniazid per day, starting after the first trimester and continuing for 6 to 9 months. B₆, pyridoxine; cx, culture; CXR, chest radiograph; INH, isoniazid; TB, tuberculosis.

TABLE 45-2 ANTITUBERCULOSIS DRUGS

Drug	Dosage Route	Daily Dose	Weekly Dose	Major Adverse Reactions
First-Line Drugs (for Initial Treatment)				
Isoniazid	PO, IM	10 mg/kg, up to 300 mg	15 mg/kg, up to 900 mg	Hepatic enzyme elevation, peripheral neuropathy hepatitis, hypersensitivity
Rifampin	PO	10 mg/kg, up to 600 mg	10 mg/kg, up to 600 mg	Orange discoloration of secretions and urine; nausea, vomiting, hepatitis, febrile reaction, purpura (rare)
Pyrazinamide	PO	15-30 mg/kg, up to 2 g	50-70 mg/kg, twice	Hepatotoxicity, hyperuricemia, arthralgias, rash, gastrointestinal upset
Ethambutol	PO	15 mg/kg, up to 2.5 g	50 mg/kg	Optic neuritis (decreased red-green color discrimination, decreased visual acuity), rash
Streptomycin	IM	15 mg/kg, up to 1 g	25-30 mg/kg, up to 1 g	Ototoxicity, nephrotoxicity
Second-Line Drugs (Daily Therapy)				
Capreomycin	IM	15-30 mg/kg, up to 1 g		Auditory, vestibular, and renal toxicity
Kanamycin	IM	15-30 mg/kg, up to 1 g		Auditory and renal toxicity, rare vestibular toxicity
Ethionamide	PO	15-20 mg/kg, up to 1 g		Gastrointestinal disturbance, hepatotoxicity, hypersensitivity
<i>p</i> -Amino-salicylic acid	PO	150 mg/kg, up to 1 g		Gastrointestinal disturbance, hypersensitivity, hepatotoxicity, sodium load
Cycloserine	PO	15-20 mg/kg, up to 1 g		Psychosis, convulsions, rash

IM, intramuscularly; PO, orally.

be extended to 18 months.¹⁰⁸ Ethambutol is teratogenic in animals; however, this effect has not been seen in humans.

The most common side effect of ethambutol therapy is optic neuritis. Streptomycin should be avoided during pregnancy because it is associated with cranial nerve VIII damage in neonates.¹⁰⁹ Antituberculous agents not recommended for use in pregnancy include ethionamide, streptomycin, capreomycin, kanamycin, cycloserine, and pyrazinamide.⁵⁴ However, case reports documenting the use of these antituberculous agents in pregnancy revealed no adverse fetal or neonatal effects. There were no congenital abnormalities, and pregnancy outcomes for the individuals treated were good. Untreated tuberculosis has been associated with higher morbidity and mortality rates among pregnant women. The management of the gravida with multidrug-resistant tuberculosis should be individualized. The patient should be counseled about the small risk of teratogenicity and understand that the risk of postpartum transmission of tuberculosis to the infant may be higher among those born to patients with drug-resistant tuberculosis. In patients with active disease at the time of delivery, separation of the mother and newborn should be accomplished to prevent infection of the newborn.

Women who are being treated with antituberculous drugs may breastfeed. Only 0.75% to 2.3% of isoniazid and 0.05% of rifampin are excreted into breast milk. Ethambutol excretion into breast milk is also minimal. However, if the infant is concurrently taking oral antituberculous therapy, excessive drug levels may be reached in the neonate, and breastfeeding should be avoided. Breastfed infants of women taking isoniazid should receive a multivitamin supplement that includes pyridoxine.⁵⁴ Neonates of women taking antituberculous therapy should have a PPD skin test at birth and again when 3 months old. Infants born to women with active tuberculosis at the time of delivery should receive isoniazid prophylaxis (10 mg/kg/day) until maternal disease has been inactive for 3 months as evidenced by nega-

tive maternal sputum cultures.⁵⁴ Infants of women with multidrug-resistant tuberculosis should probably be placed with an alternative caregiver until there is no evidence of active disease in the mother. The newborn should also receive BCG vaccine and isoniazid prophylaxis.⁹² Active tuberculosis in the neonate should be treated appropriately with isoniazid and rifampin immediately on diagnosis or with multiagent therapy if drug-resistant organisms are identified. Infants and children who are at high risk for intimate and prolonged exposure to untreated or ineffectively treated persons should receive the BCG vaccine.¹¹⁰

In summary, high-risk gravida should be screened for tuberculosis and treated appropriately with isoniazid prophylaxis for infection without overt disease and with dual antituberculous therapy for active disease. The newborn also should be screened for evidence of tuberculosis. Proper screening and therapy will lead to a good outcome for the mother and infant in most cases.

Asthma in Pregnancy

Asthma may be the most common potentially serious medical condition to complicate pregnancy.¹¹¹ Asthma is characterized by chronic airway inflammation with increased airway responsiveness to a variety of stimuli and airway obstruction that is partially or completely reversible.¹¹¹ Approximately 4% to 8% of pregnancies are complicated by asthma.^{112,113} The prevalence and morbidity rates for asthma are increasing, although the mortality rate has decreased in recent years.

Insight into the pathogenesis of asthma has changed with the recognition that airway inflammation occurs in almost all cases. The medical management for asthma emphasizes treatment of airway inflammation to decrease airway responsiveness and prevent asthma symptoms.

Diagnosis

The enlarging uterus elevates the diaphragm about 4 cm, reducing the functional residual capacity. However, there are no significant alterations in forced vital capacity, peak expiratory flow rate (PEFR), or forced expiratory volume in 1 second (FEV₁) in normal pregnancies. Shortness of breath at rest or with mild exertion is common and is often referred to as physiologic dyspnea of pregnancy. Asthma is characterized by paroxysmal or persistent symptoms, including breathlessness, chest tightness, cough, and sputum production. The diagnosis of asthma is based on a history of symptoms and results of spirometry. Patients with asthma have improved FEV₁ after administration of a short-acting, inhaled β_2 -agonist and increased sensitivity to inhaled methacholine, although this test is not usually performed during pregnancy.

In 2004, the National Asthma Education and Prevention Program (NAEPP) Working Group on Asthma and Pregnancy¹¹⁴ defined mild intermittent, mild persistent, moderate persistent, and severe persistent asthma according to daytime and nighttime symptoms (e.g., wheezing, cough, dyspnea) and objective tests of pulmonary function. The most commonly used pulmonary function parameters are the PEFR and FEV₁. The NAEPP guidelines suggest classifying asthma *severity* in patients not on symptom-controlling drugs and asthma *control* in patients on symptom-controlling medications (Table 45-3).¹¹⁵ Pregnant patients with mild asthma according to symptoms and pulmonary function who nonetheless required regular medications to control their asthma are similar to those with moderate asthma with respect to asthma exacerbations; those requiring regular systemic corticosteroids to control asthma symptoms were similar to severe asthmatics with respect to exacerbations.¹¹⁶

Effects of Pregnancy on Asthma

Asthma has been associated with considerable maternal morbidity. In a large, prospective study of pregnant women, those with mild asthma had an exacerbation rate of 12.6% and hospitalization rate of 2.3%; those with moderate asthma had an exacerbation rate of 25.7% and hospitalization rate of 6.8%; and severe asthmatics had an exacerbation rate of 51.9% and hospitalization rate of 26.9%.¹¹⁶ The effects of pregnancy on asthma vary. In a large, prospective study, 23% improved and 30% became worse during pregnancy.¹¹⁶ One of the most important conclusions of this study is that pregnant women with mild or even well-controlled asthma should be monitored by PEFR and FEV₁ testing during pregnancy.

Effects of Asthma on Pregnancy

Existing studies on the effects of asthma on pregnancy have had inconsistent results in regard to maternal and perinatal outcomes. For example, asthma has been associated with increased perinatal mortality,¹¹⁷ hyperemesis gravidarum,¹¹⁸ hemorrhage,^{112,118,119} hypertension or preeclampsia,¹¹⁸⁻¹²⁵ preterm birth,^{118,122,123,126-128} hypoxia at birth,¹¹⁸ low birth weight,^{118,129} increased cesarean section,^{119,121,122,126,129} small-for-gestational-age status or intrauterine growth restriction,^{122,123,130} gestational diabetes,^{119,126} and anomalies.¹²²

In contrast, asthma has *not* been associated with prematurity,^{112,117,129-132} malformations,^{112,118,121,123,131} birth injury,¹¹⁸ increased perinatal mortality,¹¹⁸ reduced gestational age,^{120,121,133-135} reduced mean birth weight,^{120,121,129,134-136} perinatal death,^{119,121,131,135,137} low Apgar score,¹²¹ neonatal respiratory difficulty,¹²¹ antepartum or postpartum hemorrhage,^{123,129,133} perinatal complications,^{124,129} gestational hypertension or preeclampsia,^{126,130,131,138} intrauterine growth restriction,^{126,131} increased cesarean section,^{112,132,137} low birth weight,^{121,132,133,136,137} gestational diabetes,^{112,124} or respiratory distress syndrome.¹¹²

Many of these studies have methodologic inadequacies, including low power, variable inclusion criteria, little or no information regarding asthma management or control, and time frames that do not reflect current management. Some positive findings may result from non-existent or inadequate control for confounders such as oral corticosteroid treatment, ethnicity, smoking status, obesity, socioeconomic status, and hypertension. Another potential explanation for inconsistencies is that most of these studies did not classify asthma severity. Classification of asthma severity has important clinical implications in regard to asthma morbidity and tailoring optimal treatment regimens.^{139,140} Asthma medications and poor asthma control leading to hypoxia may explain some of these observations.¹⁴¹ Some data support a relationship between poor asthma control, as indicated by hospitalization for exacerbations or decreased FEV₁ values, and low birth weight and low ponderal index.^{137,141,142} Studies have shown that women with more severe asthma may have the greatest risk for complications during pregnancy,^{122,126,127,143} whereas better-controlled asthma is associated with decreased risks.^{131,144,145} Poor control of asthma during pregnancy may be caused by the physician's reluctance to prescribe medications during pregnancy. Women with asthma significantly reduce their medications, especially inhaled and rescue corticosteroids, during the first trimester.¹⁴⁶

There is considerable consistency among prospective studies of the effects of asthma during pregnancy. Eight prospective studies reporting maternal and neonatal outcomes with at least 100 subjects

TABLE 45-3 CLASSIFICATION OF ASTHMA SEVERITY AND CONTROL IN PREGNANT PATIENTS

Signs and Symptoms	Well Controlled*	Not Well Controlled*		Very Poorly Controlled*
	Intermittent [†]	Mild Persistent [†]	Moderate Persistent [†]	Severe Persistent [†]
Symptom frequency/short-acting β -agonist use	≤2 days per week	>2 days per week, but not daily	Daily symptoms	Throughout the day
Nighttime awakening	≤2 times per month	>2 times per month	>1 time per week	≥4 times per week
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
FEV ₁ or peak flow (percent predicted/personal best)	>80%	>80%	60-80%	<60%

*Asthma control: assess in patients on long-term-control medications to determine whether step-up, step-down, or no change in therapy is indicated.

[†]Asthma severity: assess severity for patients who are not on long-term-control medications, see Table 45-7 to determine starting controller therapy based on severity.

FEV₁, forced expiratory volume in 1 second.

in locations at or near sea level have been published in the English literature.^{121,124,131-133,137,144,145,147} These studies show that a gravida with mild or moderate asthma can have excellent maternal and perinatal outcomes (Table 45-4). These findings do not contradict the possibility that suboptimal control of asthma during pregnancy is associated with increased risk to the mother or infant.¹⁴⁵ Lower FEV₁ values during pregnancy are significantly associated with increased risks for low birth weight and prematurity.¹⁴⁸ The two largest studies indicate that classification of asthma severity with therapy tailored according to asthma severity can result in excellent perinatal and maternal outcomes.^{144,145} This generally confirms the findings of two earlier and smaller prospective cohort studies^{131,133} in which asthma was managed by asthma specialists.

There are important caveats when interpreting this literature. Prospective studies have tended to find fewer significant adverse associations, possibly because of better asthma surveillance and treatment. The excellent maternal and perinatal outcomes were achieved at centers that tended to actively manage asthma during pregnancy. Women who enroll in research studies tend to be more compliant and better motivated than the general public. The lack of finding more adverse outcomes among women with severe asthma may also be a function of the relatively small numbers of this cohort and the resulting lack of power to find adverse outcomes that were statistically significant. Nonetheless, these prospective studies are reassuring in their consensus of good pregnancy outcomes among women with asthma. However, they do not suggest that asthma should be considered to be a benign condition, because active asthma management was a part of these studies and might have positively influenced outcomes.

Management Approaches

The ultimate goal of asthma therapy during pregnancy is to maintain adequate oxygenation of the fetus by prevention of hypoxic episodes in the mother. Other goals include achievement of minimal or no maternal symptoms day or night, minimal or no exacerbations, no limitations of activities, maintenance of normal or near-normal pulmonary function, minimal use of short-acting β₂-agonists, and minimal or no adverse effects from medications. Consultation or comanagement with an asthma specialist is appropriate for evaluation of the role of allergy and irritants, complete pulmonary function studies, or evaluation of the medication plan if there are complications in achieving the goals of therapy or the patient has severe asthma. A team approach is helpful if more than one clinician is managing the asthma and the pregnancy. The effective management of asthma during pregnancy relies on four integral components: objective assessment, trigger avoidance, patient education, and pharmacologic therapy.

Objective Measures for Assessment and Monitoring

Subjective measures of lung function by the patient or physician provide an insensitive and inaccurate assessment of airway hyperresponsiveness, airway inflammation, and asthma severity. The FEV₁ value after a maximal inspiration is the single best measure of pulmonary function. When adjusted for confounders, a mean FEV₁ less than 80% of the predicted value has been significantly associated with increased preterm delivery at less than 32 weeks and less than 37 weeks and with a birth weight less than 2500 g.¹⁴⁸ However, measurement of

FEV₁ requires a spirometer. The PEFR correlates well with the FEV₁, and it can be measured reliably with inexpensive, disposable, portable peak flow meters.

PEFR monitoring by the patient provides valuable insight to the course of asthma throughout the day, assesses circadian variation in pulmonary function, and helps detect early signs of deterioration so that timely therapy can be instituted. Patients with persistent asthma should be evaluated at least monthly, and those with moderate to severe asthma should have daily PEFR monitoring.¹¹⁴ The typical PEFR in pregnancy should be 380 to 550 L/min. She should establish her “personal best” PEFR and then calculate her individualized PEFR zones. The green zone is more than 80% of the personal best PEFR, yellow zone is between 50% and 80% of the personal best value, and red zone is less than 50% of the personal best PEFR.

Avoiding or Controlling Asthma Triggers

Limiting adverse environmental exposures during pregnancy is important for controlling asthma. Irritants and allergens that provoke acute symptoms also increase airway inflammation and hyperresponsiveness. Avoiding or controlling such triggers can reduce asthma symptoms, airway hyperresponsiveness, and the need for medical therapy. Association of asthma with allergies is common; 75% to 85% of patients with asthma have positive skin test results for common allergens, including animal dander, house dust mites, cockroach antigens, pollens, and molds. Other common nonimmunologic triggers include tobacco smoke, strong odors, air pollutants, food additives such as sulfites, and certain drugs, including aspirin and β -blockers. Another trigger can be strenuous physical activity. For some patients, exercise-induced asthma can be avoided with inhalation of albuterol 5 to 60 minutes before exercise.

Specific measures for avoiding asthma triggers include removing carpeting, using an allergen-impermeable mattress and pillow covers, weekly washing of bedding in hot water, avoiding tobacco smoke, inhibiting mite and mold growth by reducing humidity, and leaving the house when it is vacuumed. Animal dander control includes weekly bathing of the pet, keeping furry pets out of the bedroom, or removing the pet from the home. Cockroaches can be controlled by poison or bait traps and eliminating exposed food or garbage.

Patient Education

Patients should be made aware that controlling asthma during pregnancy is especially important for the well-being of the fetus. The pregnant woman should understand that she can reduce symptoms by limiting asthma triggers. She should have a basic understanding of the medical management during pregnancy, including self-monitoring of PEFRs and the correct use of inhalers. The patient should be instructed on proper PEFR technique. She should make the measurement while standing, take a maximum inspiration, and observe the reading on the peak flow meter.

Pharmacologic Therapy

The goals of asthma therapy include relieving bronchospasm, protecting the airways from irritant stimuli, mitigating pulmonary and inflammatory responses to an allergen exposure, and resolving the inflammatory process in the airways, leading to improved pulmonary function with reduced airway hyperresponsiveness. The step-care approach uses the least amount of drug intervention necessary to control a patient's severity of asthma.

It is safer for pregnant women with asthma to be treated with asthma medications than it is for them to have asthma symptoms and exacerbations.¹¹⁴ Current pharmacologic therapy emphasizes treat-

TABLE 45-5 TYPICAL DOSAGES OF ASTHMA MEDICATIONS

Drug	Dosage
Albuterol MDI	2-6 puffs as needed
Salmeterol DPI	1 puff bid
Fluticasone and salmeterol (Advair) DPI	1 inhalation bid, dose depends on severity of asthma
Montelukast	10-mg tablet at night
Zafirlukast	20 mg twice daily
Prednisone	20-60 mg/day for active symptoms
Theophylline	Start at 200 mg PO bid, target serum levels of 5-12 μ g/mL (decrease dosage by one half if treated with erythromycin or cimetidine)
Ipratropium MDI	2-3 puffs q6h
Ipratropium nebulizer	1 mL (0.25 mg) q6h
Cromolyn MDI	2 puffs qid

DPI, dry powder inhaler; MDI, metered-dose inhaler; PO, orally.

ment of airway inflammation to decrease airway hyperresponsiveness and prevent asthma symptoms. Typical dosages of commonly used asthma medications are listed in Table 45-5. Low, medium, and high doses of inhaled corticosteroids are provided in Table 45-6.

Although it is assumed that asthma medications are equally effective during pregnancy, differences in maternal physiology and pharmacokinetics may affect the absorption, distribution, metabolism, and clearance of medications during pregnancy. Endocrinologic and immunologic changes during pregnancy include elevations in free plasma cortisol, possible tissue refractoriness to cortisol,¹⁴⁹ and changes in cellular immunity.¹⁵⁰

STEP THERAPY

The step-care approach to therapy increases the number and frequency of medications with increasing asthma severity (Table 45-7). Based on the severity of asthma, medications are considered to be *preferred* or *alternative*. Patients not optimally responding to treatment should be stepped up to more intensive medical therapy. After control is achieved and sustained for several months, a step-down approach can be considered, but it should be undertaken cautiously and gradually to avoid compromising the stability of the asthma control. For some patients, it may be prudent to postpone until after birth attempts to reduce therapy that is effectively controlling the patient's asthma.¹¹⁴ For a patient who had a favorable response to an alternative drug before becoming pregnant, it is preferable to maintain the therapy that successfully controlled the asthma before pregnancy. However, when initiating new treatment for asthma during pregnancy, preferred medications should be considered rather than alternative treatment options.¹¹⁴

A burst of oral corticosteroids is indicated for exacerbations not responding to initial β_2 -agonist therapy, regardless of asthma severity. Patients who require increasing inhaled albuterol therapy to control their symptoms may benefit from oral corticosteroids. In such cases, a short course of oral prednisone (40 to 60 mg/day) for 1 week followed by 7 to 14 days of tapering may be effective.

INHALED CORTICOSTEROIDS

Inhaled corticosteroids are the preferred treatment for the management of all levels of persistent asthma during pregnancy.¹¹⁴ Because almost all patients have airway inflammation, inhaled corticosteroids

TABLE 45-6 COMPARATIVE DAILY DOSES FOR INHALED CORTICOSTEROIDS

Drug	Dose Conversion*	Low Dose	Medium Dose	High Dose
Beclomethasone HFA	40 µg/puff	2-6 puffs	>6-12 puffs	>12 puffs
	80 µg/puff	1-3 puffs	>3-6 puffs	>6 puffs
Budesonide	200 µg/inhalation	1-3 puffs	>3-6 puffs	>6 puffs
Flunisolide	250 µg/puff	2-4 puffs	4-8 puffs	>8 puffs

TABLE 45-7 STEP-CARE THERAPY FOR ASTHMA DURING PREGNANCY

Type of Asthma	Preferred Management	Alternative Management
Mild intermittent	No daily medications, albuterol as needed	—
Mild persistent	Low-dose inhaled corticosteroid	Cromolyn, leukotriene receptor antagonist, or theophylline (serum level of 5-12 µg/mL)
Moderate persistent	Low-dose inhaled corticosteroid and salmeterol, medium-dose inhaled corticosteroid, or (if needed) medium-dose inhaled corticosteroid and salmeterol	Low-dose or (if needed) medium-dose inhaled corticosteroid and a leukotriene receptor antagonist or theophylline (serum level of 5-12 µg/mL)
Severe persistent	High-dose inhaled corticosteroid and salmeterol and (if needed) oral corticosteroid	High-dose inhaled corticosteroid and theophylline (serum level of 5-12 µg/mL) and (if needed) oral corticosteroid

have been advocated as first-line therapy for those with mild asthma.¹⁵¹ The use of inhaled corticosteroids among nonpregnant asthmatics has been associated with a marked reduction in fatal and near-fatal episodes of asthma.¹⁵² Inhaled corticosteroids produce clinically important improvements in bronchial hyperresponsiveness that appear dose related¹⁵³ and include prevention of increased bronchial hyperresponsiveness after seasonal exposure to allergen.^{154,155} Continued administration is effective in reducing the immediate pulmonary response to an allergen challenge. In a prospective, observational study of 504 pregnant women with asthma, 177 patients were not initially treated with inhaled budesonide or inhaled beclomethasone.¹³³ This cohort had a 17% rate of acute exacerbation rate compared with only a 4% rate among those treated with inhaled corticosteroids from the start of pregnancy.

The NAEPP Working Group reviewed 10 studies that included 6113 patients who took inhaled corticosteroids during pregnancy for asthma.¹¹⁴ There is no evidence linking inhaled corticosteroid use with increases in congenital malformations or adverse perinatal outcomes. Included among these studies was the Swedish Medical Birth Registry that had 2014 infants whose mothers had used inhaled budesonide in early pregnancy.¹⁵⁶ Because there are more data on using budesonide during pregnancy than on using other inhaled corticosteroids, the NAEPP considered budesonide to be a preferred medication. However, if a woman's asthma is well controlled by a different inhaled cortico-

steroid before pregnancy, it seems reasonable to continue that medication during pregnancy. All inhaled corticosteroids are labeled by the FDA as pregnancy class C, except budesonide, which is class B.

INHALED β_2 -AGONISTS

Inhaled β_2 -agonists are recommended for all degrees of asthma during pregnancy.^{114,157} Albuterol has the advantage of a rapid onset of effect in the relief of acute bronchospasm by means of smooth muscle relaxation, and it is an excellent bronchoprotective agent for pretreatment before exercise. Salmeterol and formoterol are long-acting preparations.

The β_2 -agonists are associated with tremor, tachycardia, and palpitations. They do not block the development of airway hyperresponsiveness.¹⁵⁸ Comparison of an inhaled glucocorticoid, budesonide, with the inhaled terbutaline raised the question about whether routine use of terbutaline may result in increased airway hyperresponsiveness.¹⁵¹ Increased frequency of bronchodilator use may indicate the need for additional anti-inflammatory therapy; chronic use of short-acting β_2 -agonists has been associated with an increased risk of death.^{157,159} The β_2 -agonists appear to be safe based on a NAEPP review of six published studies of a total of 1599 women with asthma who took β_2 -agonists during pregnancy.¹¹⁴ In a large, prospective study, no significant relationship was found between the use of inhaled β_2 -agonists ($n = 1828$) and adverse pregnancy outcomes.¹⁶⁰

CROMOLYN

Cromolyn sodium is virtually devoid of significant side effects. It blocks the early and late phases of pulmonary response to an allergen challenge, and it prevents the development of airway hyperresponsiveness.¹⁵⁸ Cromolyn does not have any intrinsic bronchodilator or antihistaminic activity. Compared with inhaled corticosteroids, the time to maximal clinical benefit is longer for cromolyn. Cromolyn appears to be less effective than inhaled corticosteroids in reducing objective and subjective manifestations of asthma. Cromolyn appears to be safe during pregnancy¹⁶⁰ and is an alternative treatment for mild persistent asthma.¹¹⁴

THEOPHYLLINE

Theophylline is an alternative treatment for mild persistent asthma and an adjunctive treatment for the management of moderate and severe persistent asthma during pregnancy.¹¹⁴ Subjective symptoms of adverse theophylline effects, including insomnia, heartburn, palpitations, and nausea, may be difficult to differentiate from typical pregnancy symptoms. High doses have caused jitteriness, tachycardia, and vomiting in mothers and neonates.^{161,162} Dosing guidelines have recommended that serum theophylline concentrations be maintained at 5 to 12 µg/mL during pregnancy.¹¹⁴ Theophylline can have significant interactions with other drugs, which can cause decreased clearance with resultant toxicity. For instance, cimetidine can cause a 70% increase in serum levels, and erythromycin use can increase theophylline serum levels by 35%.¹⁶³

The main advantage of theophylline is the long duration of action, 10 to 12 hours with the use of sustained-release preparations, which is especially useful in the management of nocturnal asthma.¹⁶⁴ Theophylline is indicated only for chronic therapy and is not effective for the treatment of acute exacerbations during pregnancy.¹⁶⁵ Theophylline has anti-inflammatory actions¹⁶⁶ that may be mediated by inhibition of leukotriene production and its capacity to stimulate prostaglandin E₂ production.¹⁶⁷ Theophylline may potentiate the efficacy of inhaled corticosteroids.¹⁶⁸

The NAEPP reviewed eight human studies that had a total of 660 women with asthma who took theophylline during pregnancy.¹¹⁴ These studies and clinical experience confirm the safety of theophylline at a serum concentration of 5 to 12 µg/mL during pregnancy. In a randomized, controlled trial, there were no differences in asthma exacerbations or perinatal outcomes in a cohort receiving theophylline compared with the cohort receiving inhaled beclomethasone.¹⁶⁹ However, the theophylline cohort had significantly more reported side effects, discontinuation of the study medication, and an increased proportion of those with an FEV₁ less than 80% of the predicted value.

LEUKOTRIENE MEDIATORS

Leukotrienes are arachidonic acid metabolites that have been implicated in transducing bronchospasm, mucous secretion, and increased vascular permeability.¹⁷⁰ Bronchoconstriction associated with aspirin ingestion can be blocked by leukotriene receptor antagonists.¹⁷¹ Treatment with the leukotriene receptor antagonist montelukast (Singulair) has significantly improved pulmonary function as measured by FEV₁.¹⁷⁰ The leukotriene receptor antagonists zafirlukast (Accolate) and montelukast are pregnancy category B drugs. There are minimal data regarding the efficacy or safety of these agents during human pregnancy. Leukotriene receptor antagonists provide an alternative treatment for mild persistent asthma and an adjunctive treatment for the management of moderate and severe persistent asthma during pregnancy.¹¹⁴

ORAL CORTICOSTEROIDS

The NAEPP Working Group reviewed eight human studies, including one report of two meta-analyses.¹¹⁴ Most subjects in these studies did not take oral corticosteroids for asthma, and the length, timing, and dose of exposure to the drug were not well described. The panel concluded that findings from the evidence are conflicting. Oral corticosteroid use during the first trimester of pregnancy is associated with a threefold increased risk for isolated cleft lip with or without cleft palate. Because the background incidence is about 0.1%, the excess risk attributable to oral steroids is 0.2% to 0.3%.¹⁷² Oral corticosteroid use during pregnancy by patients who have asthma has been associated with an increased incidence of preeclampsia, preterm delivery, and low birth weight.^{126,131,144,160,172} A prospective study found that use of systemic corticosteroids resulted in a deficit of about 200 g in birth weight compared with controls and those exclusively treated with β₂-agonists.¹⁷³ However, it is difficult to separate the effects of the oral corticosteroids on these outcomes from the effects of severe or uncontrolled asthma.

Because of the uncertainties in these data and the definite risks of severe, uncontrolled asthma to the mother and fetus, the NAEPP Working Group recommends the use of oral corticosteroids when indicated for the long-term management of severe asthma or exacerbations during pregnancy.¹¹⁴ For the treatment of acute exacerbations, methylprednisolone or other corticosteroids may be given at a dose of 120 to 180 mg per day in three or four divided doses; after the PEFR reaches 70% of the personal best value, the daily dosage of parenteral or oral corticosteroid, such as prednisone, can be dropped to 60 to 80 mg per day.¹¹⁴

Management of Allergic Rhinitis Exacerbating Asthma

Rhinitis, sinusitis, and gastroesophageal reflux may exacerbate asthma symptoms, and their management should be considered an integral aspect of asthma care. Intranasal corticosteroids are the most effective medications for control of allergic rhinitis. Loratadine (Claritin) or cetirizine (Zyrtec) are recommended second-generation antihistamines. Because oral decongestant ingestion during the first trimester has been associated with gastroschisis, inhaled decongestants or inhaled corticosteroids should be considered before use of oral decongestants.¹¹⁴ Immunotherapy is considered safe during pregnancy, but because of the risk of anaphylaxis, initiation of immunotherapy is not recommended during pregnancy.

Antenatal Management

Patients with moderate or severe asthma should be considered to be at risk for pregnancy complications. Adverse outcomes can be increased by underestimation of asthma severity and undertreatment of asthma. The first prenatal visit should include a detailed medical history with attention to medical conditions that can complicate the management of asthma, including active pulmonary disease. The patient should be questioned about her smoking history and the presence and severity of symptoms, episodes of nocturnal asthma, the number of days of work missed, and emergency care visits due to asthma. Asthma severity should be determined (see Table 45-3). The type and amount of asthma medications, including the number of puffs of β₂-agonists used each day, should be determined.

Gravidas with moderate or severe asthma should have scheduling of prenatal visits based on clinical judgment. In addition to routine care, monthly or more frequent evaluations of asthma history (i.e., emergency visits, hospital admissions, symptom frequency, severity,

nocturnal symptoms, and medication dosages and compliance) and pulmonary function (i.e., FEV₁ or PEFr) are recommended. Patients should be instructed on proper dosing and administration of their asthma medications.

Daily peak flow monitoring should be considered for patients with moderate to severe asthma and especially for patients who have difficulty perceiving signs of worsening asthma.¹¹⁴ It may be helpful to maintain an asthma diary containing a daily record of symptoms, peak flow measurements, activity limitations, medical contacts initiated, and regular and as-needed medications taken. Identifying and avoiding asthma triggers can lead to improved maternal well-being and less need for medications. Specific recommendations can be made for appropriate environmental controls based on the patient's history of exposure and, when available, skin test reactivity to asthma triggers.

Women who have moderate or severe asthma during pregnancy may benefit from additional fetal surveillance in the form of ultrasound examinations and antenatal fetal testing. Because asthma has been associated with intrauterine growth restriction and preterm birth, it is useful to establish pregnancy dating accurately by first-trimester ultrasound when possible. In the opinion of the NAEPP Working Group,¹¹⁴ the evaluation of fetal activity and growth by serial ultrasound examinations may be considered for women who have suboptimally controlled asthma, for those with moderate to severe asthma (starting at 32 weeks), and after recovery from a severe asthma exacerbation. The intensity of antenatal surveillance of fetal well-being should be considered on the basis of the severity of the asthma and any other high-risk features of the pregnancy. All patients should be instructed to be attentive to fetal activity.

Home Management of Asthma Exacerbations

An asthma exacerbation that causes minimal problems for the mother may have severe sequelae for the fetus. An abnormal fetal heart rate tracing may be the initial manifestation of an asthmatic exacerbation. A maternal PO₂ value of less than 60 mm Hg or hemoglobin saturation of less than 90% may be associated with profound fetal hypoxia. Asthma exacerbations in pregnancy should be aggressively managed. Patients should be given an individualized guide for decision making and rescue management, and they should be educated to recognize signs and symptoms of early asthma exacerbations, such as coughing, chest tightness, dyspnea, or wheezing, or by a 20% decrease in the PEFr. Early recognition enables prompt institution of home rescue treatment to avoid maternal and fetal hypoxia.

Patients should use inhaled albuterol (two to four puffs) every 20 minutes for up to 1 hour (Table 45-8). The response is considered to be good if symptoms are resolved or become subjectively mild, normal activities can be resumed, and the PEFr is more than 70% of the personal best value. The patient should seek further medical attention if the response is incomplete or if fetal activity is decreased.

Hospital and Clinic Management

The principal goal of hospital and clinic management should be the prevention of hypoxia. Measurement of oxygenation by pulse oximetry is essential, and arterial blood gas determinations should be obtained if oxygen saturation remains less than 95%. Chest radiographs usually are not needed. Continuous electronic fetal monitoring should be initiated if gestation has advanced to point of potential fetal viability. Albuterol (2.5 to 5 mg every 20 minutes for three doses and then 2.5 to 10 mg every 1 to 4 hours as needed or 10 to 15 mg/hr administered continuously) should be delivered by nebulizer driven with oxygen.¹¹⁴ Occasionally, nebulized treatment is not effective because the patient is moving air poorly; in such cases, terbutaline (0.25 mg) can be

TABLE 45-8 HOME MANAGEMENT OF ACUTE ASTHMA EXACERBATIONS

Initial Approach

Use albuterol MDI at a dose of 2-4 puffs (or single nebulizer treatment), and measure PEFr.

Poor Response

If PEFr < 50% of predicted, severe wheezing and shortness of breath occur, or fetal movement is decreased, repeat albuterol at a dose of 2-4 puffs by MDI and obtain emergency care.

Incomplete Response

If PEFr is 50-80% of predicted or if wheezing and shortness of breath persist, repeat albuterol treatment at a dose of 2-4 puffs by MDI at 20-minute intervals up to two more times.

If repeat PEFr is 50-80% of predicted or if fetal movement is decreased, contact caregiver or go for emergency care.

Good Response

If PEFr > 80% of predicted, there is no wheezing or shortness of breath, and the fetus is moving normally, patient may continue inhaled albuterol at a dose of 2-4 puffs by MDI every 3-4 hours as needed.

MDI, metered-dose inhaler; PEFr, peak expiratory flow rate.
Modified from National Asthma Education and Prevention Program (NAEPP) expert panel report (NAEPP 04): Managing asthma during pregnancy: Recommendations for pharmacologic treatment—2004 update. NHLBI, NIH publication no. 05-3279. Available at http://www.nhlbi.nih.gov/health/prof/lung/asthma/astpreg/astpreg_qr.pdf (accessed January 2008).

administered subcutaneously every 15 minutes for three doses. The patient should be assessed for general level of activity, color, pulse rate, use of accessory muscles, and airflow obstruction determined by auscultation and FEV₁ or PEFr before and after each bronchodilator treatment. Guidelines for the management of asthma exacerbations are given in Table 45-9.

Labor and Delivery Management

Asthma medications should not be discontinued during labor and delivery. Although asthma is usually quiescent during labor, consideration should be given to assessing PEFrs on admission and at 12-hour intervals. The patient should be kept hydrated and should receive adequate analgesia to decrease the risk of bronchospasm. If systemic corticosteroids have been used in the previous 4 weeks, intravenous corticosteroids (e.g., 100 mg of hydrocortisone every 8 hours) should be administered during labor and for the 24-hour period after delivery to prevent an adrenal crisis.¹¹⁴ An elective delivery should be postponed if the patient is having an exacerbation.

It is rarely necessary to perform a cesarean section for an acute asthma exacerbation. Maternal compromise and fetal compromise usually respond to aggressive medical management. Occasionally, delivery may improve the respiratory status of a patient with unstable asthma who has a mature fetus. Prostaglandin E₂ or E₁ can be used for cervical ripening, the management of spontaneous or induced abortions, or postpartum hemorrhage, although the patient's respiratory status should be monitored.¹⁷⁴ Carboprost (15-methyl PGF_{2α}) and ergonovine and methylergonovine (Methergine) can cause bronchospasm.¹⁷⁵ Magnesium sulfate is a bronchodilator, but indomethacin can induce bronchospasm in the aspirin-sensitive patient. There are no reports of the use of calcium channel blockers for tocolysis among

TABLE 45-9 EMERGENCY DEPARTMENT AND HOSPITAL-BASED MANAGEMENT OF ASTHMA EXACERBATION**Initial Assessment and Treatment**

Obtain a history, perform an examination (e.g., auscultation, use of accessory muscles, heart rate, respiratory rate), assess PEF_R or FEV₁ and oxygen saturation, and obtain other tests as indicated.

Initiate fetal assessment; consider fetal monitoring or BPP, or both, if the fetus is potentially viable.

For severe exacerbations (i.e., FEV₁ or PEF_R < 50% with severe symptoms at rest), administer high-dose albuterol by nebulizer every 20 minutes or continuously for 1 hour and provide inhaled ipratropium bromide and a systemic corticosteroid.

Give albuterol by MDI or nebulizer, providing up to three doses in the first hour.

Administer an oral corticosteroid if there was no immediate response or the patient recently was treated with a systemic corticosteroid.

Administer oxygen to maintain a saturation level greater than 95%.

Repeat assessment of symptoms, the physical examination, and assessment of PEF_R and oxygen saturation.

Continue albuterol every 60 minutes for 1 to 3 hours, provided there is improvement.

Repeat Assessment

Evaluate the symptoms, perform a physical examination, assess PEF_R and oxygen saturation, and obtain other tests as needed.

Continue fetal assessment.

Good Response

Values for FEV₁ or PEF_R are 70% of normal or greater.

Response is sustained for 60 minutes after the last treatment.

Patient is not in distress.

Results of the physical examination are normal.

Fetal status is reassuring.

Patient is discharged to her home.

Incomplete Response

Values for FEV₁ or PEF_R are between 50% and 70% of normal.

Symptoms are mild or moderate.

Continue fetal assessment until the patient is stabilized.

Monitor the FEV₁ or PEF_R, oxygen saturation, and pulse.

Continue inhaled albuterol and oxygen.

Administer inhaled ipratropium bromide.

Administer a systemic (oral or intravenous) corticosteroid.

The decision for hospitalization is individualized.

Poor Response

Values for FEV₁ or PEF_R are less than 50%.

Values for PCO₂ are greater than 42 mm Hg.

Results of the physical examination include severe symptoms, drowsiness, and confusion.

Continue fetal assessment.

Admit the patient to the intensive care unit.

Impending or Actual Respiratory Arrest

Admit the patient to the intensive care unit.

Perform intubation and mechanical ventilation with 100% oxygen.

Administer nebulized albuterol plus inhaled ipratropium bromide.

Administer an intravenous corticosteroid.

Intensive Care Unit

Administer inhaled albuterol hourly or continuously plus inhaled ipratropium bromide.

Administer an intravenous corticosteroid.

Administer oxygen.

Intubation and mechanical ventilation may be necessary.

Continue fetal assessment until the patient is stabilized.

Discharge to Home

Continue treatment with albuterol.

Administer an oral systemic corticosteroid if indicated.

Initiate or continue inhaled corticosteroid until review at medical follow-up.

Provide patient education.

Review the patient's medicine use.

Review or initiate an action plan.

Recommend close medical follow-up.

BPP, biophysical profile; FEV₁, forced expiratory volume in 1 second; MDI, metered-dose inhaler; PCO₂, carbon dioxide partial pressure; PEF_R, peak expiratory flow rate.

Modified from National Asthma Education and Prevention Program (NAEPP) expert panel report (NAEPP 04): Managing asthma during pregnancy: Recommendations for pharmacologic treatment—2004 update. NHILBI, NIH publication no. 05-3279. Available at http://www.nhlbi.nih.gov/health/prof/lung/asthma/astpreg/astpreg_qr.pdf (accessed January 2008).

patients with asthma, although an association with bronchospasm has not been observed with wide clinical use.

Lumbar anesthesia has the benefit of reducing oxygen consumption and minute ventilation during labor.¹⁷⁶ Fentanyl may be a better analgesic than meperidine, which causes histamine release, but meperidine is rarely associated with the onset of bronchospasm during labor. A 2% incidence of bronchospasm has been reported with regional anesthesia.¹⁷⁷ Ketamine is useful for induction of general anesthesia because it can prevent bronchospasm.¹⁷⁸ Communication between the obstetric, anesthetic, and pediatric caregivers is important for optimal care.

Breastfeeding

Only small amounts of asthma medications enter breast milk. Prednisone, theophylline, antihistamines, beclomethasone, β_2 -agonists, and cromolyn are not considered to be contraindications for breastfeeding.^{114,179} However, among sensitive individuals, theophylline may cause toxic effects in the neonate, including vomiting, feeding difficulties, jitteriness, and cardiac arrhythmias.

Overview of Asthma during Pregnancy

Asthma is an increasingly common problem during pregnancy. Mild and moderate asthma can be associated with excellent maternal and perinatal pregnancy outcomes, especially if patients are managed according to contemporary NAEPP recommendations. Severe and poorly controlled asthma may be associated with increased prematurity, the need for cesarean delivery, preeclampsia, and growth restriction. Severe asthma exacerbations can result in maternal morbidity and mortality and can have commensurate adverse pregnancy outcomes. The management of asthma during pregnancy should be based on objective assessment, trigger avoidance, patient education, and step therapy. Asthma medications should be continued during pregnancy and while breastfeeding.

Restrictive Lung Disease in Pregnancy

Clinical Manifestations

Restrictive ventilatory defects occur when lung expansion is limited because of alterations in the lung parenchyma or because of abnormalities in the pleura, chest wall, or the neuromuscular apparatus.¹⁸⁰ These conditions are characterized by a reduction in lung volumes and an increase in the ratio of FEV₁ to forced vital capacity.¹⁸¹ The interstitial lung diseases include idiopathic pulmonary fibrosis, sarcoidosis, hypersensitivity pneumonitis, pneumomycosis, drug-induced lung disease, and connective tissue disease. Additional conditions that cause a restrictive ventilatory defect include pleural and chest wall diseases and extrathoracic conditions such as obesity, peritonitis, and ascites.¹⁸¹

Restrictive lung disease in pregnancy has not been well studied. Consequently, little is known about the effects of restrictive lung disease on the outcome of pregnancy or the effects of pregnancy on the disease process. One study presented data on nine pregnant women with interstitial and restrictive lung disease who were prospectively managed.¹⁸² Diagnoses included idiopathic pulmonary fibrosis, hypersensitivity pneumonitis, sarcoidosis, kyphoscoliosis, and multiple pulmonary emboli. Three of the gravidas had severe disease characterized by a vital capacity of no more than 1.5 L (50% of predicted) or a dif-

fusing capacity of no more than 50% of predicted. Five of the patients had exercise-induced oxygen desaturation, and four patients required supplemental oxygen. In this group, one patient had an adverse outcome and was delivered at 31 weeks. She subsequently required mechanical ventilation for 72 hours. All other patients were delivered at or beyond 36 weeks with no adverse intrapartum or postpartum complications. All infants were at or above the 30th percentile for growth.¹⁸² The investigators concluded that restrictive lung disease was well tolerated in pregnancy. However, exercise intolerance is common, and these patients may require early oxygen supplementations.¹⁸²

Sarcoidosis

Sarcoidosis is a systemic granulomatosis disease of undetermined origin that often affects young adults. Pregnancy outcome for most patients with sarcoidosis is good.^{183,184} In one study, 35 pregnancies in 18 patients with sarcoidosis were evaluated retrospectively.¹⁸³ There was no effect of the disease process during pregnancy in nine patients, improvement was demonstrated in six patients, and there was a worsening of the disease in three patients. During the postpartum period, no relapse occurred in 15 patients; however, progression of the disease continued in 3 women. Another retrospective study assessed 15 pregnancies complicated by maternal sarcoidosis over a 10-year period.¹⁸⁴ Eleven of these patients remained stable, two experienced disease progression, and two died because of complications of severe sarcoidosis. In this group, factors indicating a poor prognosis included parenchymal lesions identified on the chest radiograph, advanced radiographic staging, advanced maternal age, low inflammatory activity, requirement for drugs other than steroids, and the presence of extrapulmonary sarcoidosis.¹⁸⁴ Both patients who succumbed during gestation had severe disease at the onset of pregnancy. The overall cesarean section rate was 40%, and 4 (27%) of 15 infants weighed less than 2500 g. None of the patients developed preeclampsia. One explanation for the commonly observed improvement in sarcoidosis may be the increased concentration of circulating corticosteroids during pregnancy. However, because sarcoidosis improves spontaneously in many nonpregnant patients, the improvement may be coincident with pregnancy.

Maycock and associates¹⁸⁵ reported 16 pregnancies in 10 patients with sarcoidosis. Eight of these patients showed improvement in at least some of the manifestations of sarcoidosis during the antepartum period. In two patients, no effect was seen. A recurrence of the abnormal findings was observed in the postpartum period within several months after delivery in approximately one half of the patients. Some had new manifestations of sarcoidosis not previously observed. Another study examined 17 pregnancies in 10 patients and concluded that pregnancy had no consistent effect on the course of the disease.¹⁸⁶ Scadding¹⁸⁷ separated patients into three categories based on characteristic patterns of their chest radiographs. When the lesions on the chest radiograph had resolved before pregnancy, radiographs remained normal throughout gestation. In women with radiographic changes before pregnancy, resolution continued throughout the prenatal period. Patients with inactive fibrotic residual disease had stable chest radiographs, and those with active disease tended to have partial or complete resolution of those changes during pregnancy. However, most patients in the latter group experienced exacerbation of the disease within 3 to 6 months after delivery.

Patients with pulmonary hypertension complicating restrictive lung disease may have a mortality rate as high as 50% during gestation. These patients need close monitoring during the labor, delivery, and postpartum periods. Invasive monitoring with a pulmonary artery

catheter may be indicated to optimize cardiorespiratory function. Gravidas with restrictive lung disease, including pulmonary sarcoidosis, may benefit from early institution of steroid therapy for evidence of worsening pulmonary status. Individuals with evidence of severe disease need close monitoring and may require supplemental oxygen therapy during gestation.

During labor, consideration should be given to the early use of epidural anesthesia if it is not contraindicated. The early institution of pain management in this population can minimize pain, decrease the sympathetic response, and decrease oxygen consumption during labor and delivery. The use of general anesthesia should be avoided, if possible, because these patients may develop pulmonary complications after general anesthesia, including pneumonia and difficulty weaning from the ventilator. Close fetal surveillance throughout gestation is indicated because impaired oxygenation may lead to impaired fetal growth and the development of fetal heart rate abnormalities during labor and delivery.

An additional consideration is the need to counsel all women with restrictive lung disease about the potential for continued impairment of their respiratory status during pregnancy, particularly if their respiratory status is deteriorating when they conceive. The individual with clinical signs consistent with pulmonary hypertension or severe restrictive disease should be cautioned about the possibility of maternal mortality resulting from worsening pulmonary function during gestation.

In summary, although the literature on restrictive lung disease in pregnancy is limited, it supports the conclusion that most patients with restrictive lung disease complicating pregnancy, including those with pulmonary sarcoidosis, can have a favorable pregnancy outcome. However, the clinician should keep in mind that patients with restrictive lung disease can have worsening of their clinical condition and may succumb during gestation.

Cystic Fibrosis in Pregnancy

CF involves the exocrine glands and epithelial tissues of the pancreas, sweat glands, and mucous glands in the respiratory, digestive, and reproductive tracts. Chronic obstructive pulmonary disease, pancreatic exocrine insufficiency, and elevated levels of sweat electrolytes are present in most patients with CF.¹⁸⁸ The disease is genetically transmitted with an autosomal recessive pattern of inheritance. The CF gene was identified and cloned in 1989. The gene is localized to chromosome 7, and the molecular defect accounting for most cases has been identified.^{189,190,191} In the United States, approximately 4% of the white population are heterozygous carriers of the CF gene. The disease occurs in 1 of 3200 white live births.¹⁹²

Morbidity and mortality in patients with CF usually result from progressive chronic bronchial pulmonary disease. Pregnancy and the attendant physiologic changes can stress the pulmonary, cardiovascular, and nutritional status of women with CF. The purpose of this section is to familiarize the obstetrician and gynecologist with the physiologic effects of this complex disease, the impact of the disease on pregnancy, and the effect of pregnancy on the disease.

Survival for patients with CF has increased dramatically since 1940. According to the Cystic Fibrosis Foundation's Patient Registry (www.cff.org), survival in 2006 had increased to 37 years. More than 40% of all people with CF in the United States are 18 years or older.¹⁸⁸ This increase in survival of patients with CF likely reflects earlier diagnosis and intervention and the advances in antibiotic therapy and nutritional support. Because of the improvements in care, more

women with CF are entering reproductive age. Unlike men with CF who are infertile for the most part, women with CF are often fertile.

The first case of CF complicating pregnancy was reported in 1960, and a total of 13 pregnancies in 10 patients with CF were reported in 1966.^{193,194} Cohen and colleagues¹⁹⁵ conducted a survey of 119 CF centers in the United States and Canada and identified a total of 129 pregnancies in 100 women by 1976. Hilman and colleagues¹⁸⁸ surveyed 127 CF centers in the United States between 1976 and 1982. A total of 191 pregnancies were reported during this period in women with CF who were between 16 and 36 years old, with a mean age of 22.6 years.¹⁸⁸ The annual number of CF pregnancies reported to the Cystic Fibrosis Patient Registry doubled between 1986 and 1990, with 52 pregnancies reported in 1986, compared with 111 pregnancies reported in 1990. In 2006 209 women with CF were pregnant. Because the number of women with CF achieving pregnancy is steadily increasing, it is imperative that the obstetrician be familiar with the disease.

Effect of Pregnancy on Cystic Fibrosis

The physiologic changes associated with pregnancy are well tolerated by healthy gravidas, but those with CF may adapt poorly. During pregnancy, there is an increase in resting minute ventilation, which at term may approach 150% of control values.¹⁹⁶ Enlargement of the abdominal contents and upward displacement of the diaphragm leads to a decrease in functional residual volume and a decrease in residual volume.¹⁹⁶ Pregnancy is also accompanied by subtle alterations in gas exchange with widening of the alveolar-arterial oxygen gradient that is most pronounced in the supine position.¹⁹⁶ Alterations in pulmonary function are of little consequence in the normal pregnant woman, but in the gravida with CF, these changes may contribute to respiratory decompensation that can lead to an increase in morbidity and mortality for the mother and the fetus. Women with CF and advanced lung disease also may have pulmonary hypertension.

Nutritional requirements are increased during pregnancy, with approximately 300 kcal/day in additional fuel needed to meet the requirements of mother and fetus.¹⁹⁷ Most patients with CF have pancreatic exocrine insufficiency. Digestive enzymes and bicarbonate ions are diminished, resulting in maldigestion, malabsorption, and malnutrition.¹⁹⁷ Gastrointestinal manifestations of CF include steatorrhea, abdominal pain, distal intestinal obstruction syndrome, and rectal prolapse. Gastroesophageal reflux, peptic ulcer disease, acute pancreatitis, and intussusception occur to different degrees in patients with CF. Partial or complete obstruction of the gastrointestinal tract in older children and adults, also known as distal obstruction syndrome, can be precipitated by dehydration, a change in eating habits, a change in enzyme brand or dose, or immobility. It is treated with a combination of laxatives and enemas. Patients with CF are encouraged to eat a diet that provides 120% to 150% of the recommended energy intake of normal age- and sex-matched controls. This is only a guideline, because in practice, the energy requirement for a patient with CF is that of their ideal body weight when malabsorption has been minimized. Research done by the United Kingdom Dieticians Cystic Fibrosis Interest Group found that women with CF who received preconception counseling had a significantly greater mean maternal weight gain and significantly heavier infants than women who had not received preconception advice.¹⁹⁸

Grand and colleagues¹⁹⁴ reported 13 pregnancies in 10 women with CF. Of these, five women had a progressive decline in their pulmonary function, two of whom died of cor pulmonale in the immediate postpartum period. Pregnancy was well tolerated in 5 of 10 women, 2 of

whom went on to have subsequent pregnancies that were similarly well tolerated.¹⁹⁴ In this study, the pregravid pulmonary status of the patient was the most important predictor of outcome. However, there was no quantification of pulmonary function. A case report by Novy and colleagues¹⁹⁹ described pulmonary function and gas exchange in a pregnant woman with CF. The patient had severe disease as evidenced by a vital capacity of only 0.72 L and a PaO₂ of 50 mm Hg at presentation. The patient suffered a progressive increase in residual volume and decline in vital capacity that was accompanied by worsening hypoxemia and hypercapnia, resulting in respiratory distress and right-sided heart failure in the early postpartum period.¹⁹⁹ Based on the experience with this patient and a review of the literature, the investigators recommended therapeutic abortion for any patient demonstrating progressive pulmonary deterioration and hypoxemia despite maximal medical management.¹⁹⁹

In 1980, Cohen and associates¹⁹⁵ described 100 patients and a total of 129 pregnancies. Ninety-seven pregnancies (75%) were completed, and 89% of these women delivered viable infants. Twenty-seven percent of these fetuses were delivered preterm. There were 11 perinatal deaths and no congenital anomalies. In this study, 65% of patients required antibiotic therapy before delivery. In 1983, Palmer and colleagues²⁰⁰ retrospectively reviewed the pre-pregnancy status of eight women with CF who subsequently completed 11 pregnancies. They found that five women tolerated pregnancy without difficulty but that three had irreversible deterioration in their clinical status. The investigators identified four maternal factors that predicted outcome: clinical status (i.e., Shwachman score), nutritional status (i.e., percent of predicted weight for height), the extent of chest radiologic abnormalities (i.e., Brasfield chest radiographic score), and the magnitude of pulmonary function impairment. Women with good clinical study results, good nutritional status (i.e., within 15% of their predicted ideal body weight for height), nearly normal chest radiographs, and only mild obstructive lung disease tolerated pregnancy well without deterioration.²⁰⁰

Several reports suggest that patients with mild CF, good nutritional status, and less impairment of lung function tolerate pregnancy well. However, those with poor clinical status, malnutrition, hepatic dysfunction, or advanced lung disease are at increased risk from pregnancy.²⁰¹⁻²⁰³ Kent and Farquharson²⁰³ reviewed the literature and reported 217 pregnancies. In this series, the frequency of preterm delivery was 24.3%, and the perinatal death rate was 7.9%. Poor outcomes were associated with a maternal weight gain of less than 4.5 kg and a forced vital capacity of less than 50% of the predicted value. Edenborough and colleagues²⁰⁴ also described pregnancies in women with CF. There were 18 live births (81.8%), one third of which were preterm deliveries, and 18.2% of patients had abortions. There were four maternal deaths within 3.2 years after delivery. In this series, lung function was available before delivery, immediately after delivery, and after pregnancy. The investigators demonstrated a decline of 13% in FEV₁ and 11% in forced vital capacity during pregnancy. Most patients returned to baseline pulmonary function after pregnancy. Although most of the women in this series tolerated pregnancy well, those with moderate to severe lung disease (i.e., FEV₁ < 60% of the predicted value) more often had preterm infants and had increased loss of lung function compared with those with milder disease.²⁰⁴

In two other series, pre-pregnancy FEV₁ was found to be the most useful predictor of outcomes in pregnant women with CF.^{204,205} There was also a positive correlation of pre-pregnancy FEV₁ with maternal survival. For the 72 pregnancies identified, the outcomes were known for 69; there were 48 live births (70%), of which 22 were premature (46%); 14 therapeutic abortions (20%); and 7 miscarriages (10%).

There were no stillbirths, neonatal deaths, or early maternal deaths. Three major fetal anomalies were seen, but no infant had CF. Another report similarly documented the outcome of 72 pregnancies with CF.²⁰⁶

Pulmonary involvement in CF includes chronic infection of the airways and bronchiectasis. There is selective infection with certain microorganisms, such as *S. aureus*, *H. influenzae*, *P. aeruginosa*, and *Burkholderia cepacia*. In one report, three of four deaths during pregnancy occurred in gravidas colonized with *B. cepacia*.²⁰⁷ Gilljam and associates²⁰⁸ reported outcomes for a cohort of pregnancies for women with CF from 1963 to 1998. For 92 pregnancies in 54 women, there were 11 miscarriages and 7 therapeutic abortions. Forty-nine women gave birth to 74 children. The mean follow-up time was 11 ± 8 years. One patient was lost to follow-up shortly after delivery, and one was lost after 12 years. The overall mortality rate was 19% (9 of 48 patients). Absence of *B. cepacia* ($P < .001$), pancreatic sufficiency ($P = .01$), and pre-pregnancy FEV₁ more than 50% of the predicted value ($P = .03$) were associated with better survival rates. When adjusted for the same parameters, pregnancy did not affect survival compared with the entire adult female CF population. The decline in FEV₁ was comparable with that in the total CF population. Three women had diabetes mellitus, and seven developed gestational diabetes. There were six preterm infants and one neonatal death. CF was diagnosed in two children. Gilljam and coworkers²⁰⁸ concluded that the maternal and fetal outcomes were good for most women with CF. Risk factors for mortality are similar to those for the nonpregnant CF population. Pregnancies should be planned so that there is an opportunity for counseling and optimization of the medical condition. Good communication between the CF team and the obstetrician is important.²⁰⁸

A recent review of 10 pregnancies in 10 cystic fibrosis lung transplant recipients document 9 live births and 1 therapeutic abortion. Five were preterm births but all were well at follow-up. Three transplant recipients developed rejection during the pregnancy. One woman had evidence of rejection prior to conception. All 4 women died within 38 months of delivery. Pregnancy CF in lung transplant patients is feasible but carries a high risk of maternal mortality.²⁰⁹

Counseling Pregnant Women with Cystic Fibrosis

Women with CF should be advised about the potential adverse affects of pregnancy on maternal health status. Factors that may predict poor outcome include pre-pregnancy evidence of poor nutritional status, significant pulmonary disease with hypoxemia, and pulmonary hypertension. Liver disease and diabetes mellitus are also poor prognostic factors. Gravidas with poor nutritional status, pulmonary hypertension (e.g., cor pulmonale), and deteriorating pulmonary function early in gestation should consider therapeutic abortion, because the risk of maternal mortality may be unacceptably high.

The woman with CF who is considering pregnancy should consider the need for strong psychosocial and physical support after delivery. The rigors of child rearing may add to the risk of maternal deterioration during this period. Her family should be willing to provide physical and emotional support and should be aware of the potential for deterioration in the mother's health and the potential for maternal mortality. The need for care of a potentially preterm, growth-restricted neonate, with all of its attendant morbidities and potential mortality, should be discussed. Long term, the woman and her family should consider the fact that her life expectancy may be shortened by CF, and plans should be made for rearing of the child in the event of maternal death.

Management of the Pregnancy Complicated by Cystic Fibrosis

Care of the gravida with CF should be a coordinated team effort. Physicians familiar with the complications and management of CF should be included, as well as a maternal-fetal medicine specialist and neonatal team.

The gravida should be assessed for potential risk factors, such as severe lung disease, pulmonary hypertension, poor nutritional status, pancreatic failure, and liver disease, preferably before attempting gestation but certainly during the early months of pregnancy. Gravidas should be advised to be 90% of ideal body weight before conception if possible. A weight gain of 11 to 12 kg is recommended.¹⁸⁸ Frequent monitoring of weight; levels of blood glucose, hemoglobin, total protein, serum albumin, and fat-soluble vitamins A and E; and the prothrombin time is suggested.¹⁸⁸ At each visit, the history of caloric intake and symptoms of maldigestion and malabsorption should be taken, and pancreatic enzymes should be adjusted if needed. Patients who are unable to achieve adequate weight gain through oral nutritional supplements may be given nocturnal enteral nasogastric tube feeding. In this situation, the risk of aspiration should be considered, especially in patients with a history of gastroesophageal reflux, which is common in CF.¹⁸⁸ If malnutrition is severe, parenteral hyperalimentation may be necessary for successful completion of the pregnancy.²¹⁰

Baseline pulmonary function should be assessed, preferably before conception. Assessment should include forced vital capacity, FEV₁, lung volumes, pulse oximetry, and arterial blood gas measurements, if indicated. These values should be serially monitored during gestation, and deterioration in pulmonary function should be addressed immediately. An echocardiogram can assess the patient for underlying pulmonary hypertension and cor pulmonale. If pulmonary hypertension or cor pulmonale is diagnosed, the gravida should be advised about the high risk of maternal mortality.

Early recognition and prompt treatment of pulmonary infections is important in the management of the pregnant woman with CF. Treatment includes intravenous antibiotics in the appropriate dose, keeping in mind the increased clearance of these drugs because of pregnancy and CF. Plasma levels of aminoglycosides should be monitored and adjusted as indicated by the results. Chest physical therapy and bronchial drainage are also important components of the management of pulmonary infections in CF. Because *P. aeruginosa* is the most frequently isolated bacterium associated with chronic endobronchitis and bronchiectasis, antibiotic regimens should include coverage for this organism.

If the patient with CF has pancreatic insufficiency and diabetes mellitus, careful monitoring of blood glucose levels and insulin therapy are indicated. Pancreatic enzymes may need to be replaced to optimize the patient's nutritional status. Because of malabsorption of fats and frequent use of antibiotics, the CF patient is prone to vitamin K deficiency. The prothrombin time should be checked regularly, and parenteral vitamin K should be administered if the prothrombin time is elevated.

The fetus of a woman with CF is at risk for uteroplacental insufficiency and intrauterine growth restriction. The maternal nutritional status and weight gain during pregnancy affect fetal growth. Nonstress testing should be started at 32 weeks' gestation or sooner if there is evidence of fetal compromise. If there is evidence of severe fetal compromise, delivery should be accomplished. Likewise, evidence of profound maternal deterioration, such as a marked and sustained decline in pulmonary function, development of right-sided heart

failure, refractory hypoxemia, and progressive hypercapnia and respiratory acidosis, may be maternal indications for early delivery. If the fetus is potentially viable, the administration of betamethasone may be beneficial. Vaginal delivery should be attempted when possible.

Labor, delivery, and the postpartum period can be particularly dangerous for the patient with CF. The augmentation in cardiac output stresses the cardiovascular system and can lead to cardiopulmonary failure in the patient with pulmonary hypertension and cor pulmonale. These patients are also more likely to develop right-sided heart failure. Heart failure should be treated with aggressive diuresis and supplemental oxygen. Management may be optimized by insertion of a pulmonary artery catheter to monitor right- and left-sided filling pressures. Pain control can reduce the sympathetic response to labor and tachycardia. This benefits the patient who is demonstrating pulmonary or cardiac compromise. In the patient with a normal partial thromboplastin time, insertion of an epidural catheter for continuous epidural analgesia may be beneficial. This is also useful in the event a cesarean delivery is indicated because general anesthesia and its possible effects on pulmonary function can be avoided. If general anesthesia is needed, preoperative anticholinergic agents should be avoided because they tend to promote drying and inspissation of airway secretions. Close fetal surveillance is essential because the fetus might have been suffering from uteroplacental insufficiency during gestation and is more prone to develop evidence of compromise during labor. Delivery by cesarean section should be reserved for the usual obstetric indications.

In summary, more women with CF are living to childbearing age and are capable of conceiving. Clinical experience has demonstrated that pregnancy in women with mild CF is well tolerated. Women with severe disease have an associated increase in maternal and fetal morbidity and mortality. The potential risk to any one individual with CF desiring pregnancy should be assessed and discussed in detail with the patient and her family.

Chapter 46

Diabetes in Pregnancy

Thomas R. Moore, MD, and Patrick Catalano, MD

Global and National Prevalence of Diabetes

Worldwide Perspective on Diabetes

An epidemic of diabetes and obesity is sweeping the globe, largely because of marked shifts in dietary practices and physical activity. In 2000, 171 million persons on the planet were known to have diabetes, and by 2030, this figure is expected to increase to 366 million. More than 80% of people with diabetes worldwide live in low- and middle-income countries. During the next 2 decades, the world population is expected to increase by 37%, but the prevalence of diabetes will increase by 114%. In India, sub-Saharan Africa, and Latin America, diabetes prevalence is projected to increase by 150% to 160%.¹

In the United States and other developed economies, the rise in diabetes prevalence is projected to be higher than 50%. As shown in Figure 46-1, in 2005, 20.8 million people (7% of the population) have been diagnosed with some form of diabetes. Another 6.2 million with diabetes are undiagnosed. Of women 20 years or older, 8.8% have overt diabetes, but there is a strong predilection for this disease among ethnic groups. Higher-than-expected rates of pregestational diabetes in women of childbearing age have been reported for 13.3% of non-Hispanic blacks, 9.5% of Hispanic and Latino Americans, and 12.8% of Native Americans.²

Epidemiology of Diabetes in U.S. Women

Studies suggest that the prevalence of diabetes among women of childbearing age is increasing in the United States.^{3,4} Continued immigration among populations with high rates of type 2 diabetes and the impact of changes in diet (i.e., increased calories and fat content) and lifestyle (i.e., sedentary) have brought marked increases in the percentage of patients with preexisting diabetes who will become pregnant in the future. A virtual epidemic of childhood obesity is occurring in the United States, bringing with it a sharp rise in childhood and adolescent diabetes. This trend will have a profound impact on obstetrics and pediatrics in the next 2 decades and beyond.⁵ Increased outreach efforts to provide care to the populations experiencing rising rates of pregestational diabetes will be necessary if a significant increase in maternal and newborn morbidity is to be avoided. When offspring of diabetic mothers are compared with weight-matched controls, the risk of serious birth injury is doubled, the likelihood of cesarean section is

tripled, and the incidence of newborn intensive care unit admission is quadrupled.⁶

Before the 20th century, pregnancy in the diabetic woman portended death of mother or child, or both. In the 21st century, centers providing meticulous metabolic and obstetric surveillance report perinatal loss rates approaching but still higher than those seen in the nondiabetic population.^{7,8} Nevertheless, major problems with fetal and maternal management persist. Stillbirth rates have fallen dramatically but remain threefold or fourfold greater than rates for the normoglycemic population. Congenital fetal anomalies, many of them life threatening and debilitating, remain three to four times more common in diabetic pregnancies than in nondiabetic pregnancies.⁹ Macrosomia and birth injury occur 10 times more frequently in diabetic fetuses. Studies indicate that the magnitude of such risks is proportional to the degree of maternal hyperglycemia.^{10,11} To a great extent, the excessive fetal and neonatal morbidity of diabetes in pregnancy is preventable or at least reducible by meticulous prenatal and intrapartum care. This chapter reviews the pathophysiology of this complex group of disorders and identifies the obstetric interventions that can improve outcome.

Classification and Pathobiology of Diabetes Mellitus

Diagnostic and classification criteria for diabetes were issued by the American Diabetes Association (ADA) in 1997.¹² These criteria were further modified in 2003 regarding the diagnosis of impaired fasting glucose.¹³ This nomenclature is useful because it categorizes patients according to the underlying pathophysiology, although we recognize that the criteria are not as mutually exclusive as once thought. The classification includes four clinical types:

1. Type 1 diabetes, formerly referred to as insulin-dependent or juvenile-onset diabetes.
2. Type 2 diabetes, formerly referred to as non-insulin-dependent or adult-onset diabetes
3. Other specific types of diabetes related to a variety of genetic-, drug-, or chemical-induced diabetes
4. Gestational diabetes mellitus

An alternative classification that is commonly used in obstetrics was proposed by Priscilla White when she was at the Joslin Clinic in Boston

in 1932.¹⁴ This classification (Table 46-1) was based on the duration of the disease and secondary vascular damage to retinal, renal, and cardiovascular structures. Because the White classification is primarily descriptive and because it does not reflect the increase in type 2 diabetes in the population and the discovery of better-defined genetic causes, the ADA classification is preferred. The pathophysiology of the various types of diabetes is discussed subsequently.

Type 1 Diabetes

Type 1 diabetes accounts for approximately 5% to 10% of patients diagnosed with diabetes in the general population. However, type 1 diabetes may represent a slightly greater fraction of women in the reproductive age group because of the relatively earlier age of onset of type 1 diabetes compared with type 2 diabetes. Type 1 diabetes results from a cellular-mediated autoimmune destruction of the beta cells of

the pancreas. Markers of the immune response include islet cell autoantibodies, autoantibodies to insulin, autoantibodies to glutamic acid decarboxylase (GAD2, formerly designated GAD65), and autoantibodies to the tyrosine phosphatase IA-2 and IA-2 β . One and usually more of these autoantibodies are present in 85% to 90% of individuals with elevated fasting glucose and type 1 diabetes.¹⁵

Autoimmune destruction of beta cells has many genetic predispositions and is related to environmental factors. Although viruses were initially implicated, the environmental conditions leading to auto destruction of the beta cells remain largely undefined. Most evidence indicates a genetic predisposition related to an individual's human leukocyte antigen (HLA) associations with linkage to *DQA* and *DQB* genes. Type 1 diabetes is concordant in 33% to 50% of monozygotic twins, suggesting that environmental triggers are required to initiate the disease process in genetically predisposed individuals.

Type 1 diabetes usually is characterized by an abrupt clinical onset after a period of immune destruction of the beta cells that might have been in progress for some time. The beta cell destruction continues after the clinical onset of diabetes, usually leading to an absolute insulinopenia with resultant life-long requirements for insulin replacement. Although type 1 diabetes was previously referred to as juvenile-onset diabetes, it can occur at virtually any age. The disease is particularly common in whites, especially those of Northern European ancestry, and Sardinians.

Type 2 Diabetes

Type 2 diabetes involves a loss of balance between insulin sensitivity and insulin (i.e., beta cell) response. The relationship between these two factors can be expressed as the disposition index (i.e., the normal inverse relationship between the two factors can be expressed as a constant).¹⁶ A decline in the disposition index is associated with the development of type 2 diabetes. Both insulin resistance and beta cell dysfunction exist in individuals who develop type 2 diabetes. There is little agreement about whether the beta cell function is an independent event or is coincident with decreased insulin sensitivity and whether the abnormalities are causally linked.

The decreased insulin sensitivity and inadequate insulin response leads to an increase in circulating glucose concentrations, and the decreased insulin sensitivity in individuals with type 2 diabetes results in the inability of insulin to suppress lipolysis in adipose tissue. Many predisposing factors are related to decreased insulin sensitivity (i.e., increased insulin resistance). They include obesity, a sedentary lifestyle, family history and genetics, puberty, advancing age, and of particular concern to the obstetrician, the intrauterine environment. Although it

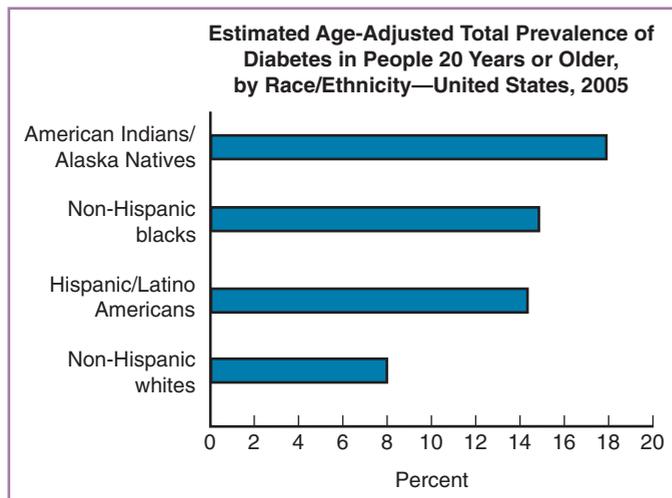

FIGURE 46-1 Estimated prevalence of diabetes in the United States 2005. For American Indians/Alaska Natives, the estimate of total prevalence was calculated using the estimate of diagnosed diabetes from the 2003 outpatient database of the Indian Health Service and the estimate of undiagnosed diabetes from the 1999-2002 National Health and Nutrition Examination Survey (NHANES). For the other groups, the 1999-2002 NHANES estimates of total prevalence (diagnosed and undiagnosed) were projected to the year 2005. TABLE 46-1 THE WHITE CLASSIFICATION OF DIABETES IN PREGNANCY

White Class	Age at Onset (Years)	Duration (Years)	Complications
A	Any	Any	Diagnosed before pregnancy; no vascular disease
B	≥20	or	No vascular disease
C	10-19	or	No vascular disease
D	<10	or	Background retinopathy only or hypertension
E		≥20	Calcification of pelvic arteries (no longer used)
F			Nephropathy (>500 mg of proteinuria per day)
H			Arteriosclerotic heart disease
R			Proliferative retinopathy or vitreous hemorrhage
T			After renal transplantation

TABLE 46-2 CRITERIA FOR THE DIAGNOSIS OF DIABETES

Symptoms of diabetes and a casual plasma glucose level ≥ 200 mg/dL (11.1 mmol/L). Casual is defined as any time of day without regard to time since the last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

or

Fasting plasma glucose level ≥ 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours.

or

Two-hour plasma glucose ≥ 200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75-g anhydrous glucose dissolved in water.

Adapted from American Diabetes Association: Clinical practice recommendations: Standards of medical care for diabetes—2007. *Diabetes Care* 30:S4-S41, 2007.

was formerly believed that type 2 diabetes was primarily a disorder of older individuals (accounting for its being called adult-onset diabetes), there has been a significant increase in the prevalence of type 2 diabetes since 1990. At the turn of the 21st century, an estimated 13.8 million people had a diagnosis of diabetes, 5 million people had undiagnosed diabetes, and 41 million people had prediabetes.¹⁷

Although it is not in the scope of this chapter to review the spectrum of possible causes of type 2 diabetes, the increase in obesity in the general population is a contributing factor; it is estimated that approximately two thirds of the population in the United States are overweight or obese.¹⁸ **Obesity, particularly central obesity, which is estimated by waist circumference, is a well-described risk factor.** This increase in visceral obesity affects hepatic metabolic function and is a rich source of cytokines and inflammatory factors, which are recognized as contributing to increasing insulin resistance.

Criteria for the diagnosis of diabetes in nonpregnant adults are shown in Table 46-2. **Although the 75-g, 2-hour oral glucose tolerance test (OGTT) is the most sensitive and specific diagnostic test for type 2 diabetes, because of the ease of administration and reproducibility, the fasting glucose test is often used as a first-line diagnostic test, particularly in the nongravid population.** Because the onset of type 2 diabetes is usually insidious, hyperglycemia not sufficient to make the diagnostic criteria for type 2 diabetes is often categorized as impaired fasting glucose (IFG) (100 mg/dL to 125 mg/dL) or, if the 75-g OGTT is employed, as impaired glucose tolerance (IGT) (2-hour glucose level of 140 mg/dL to 199 mg/dL). **The IFG and IGT have been officially designated prediabetes, and prediabetic individuals are at high risk for the development of type 2 diabetes.**¹⁹

Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) as defined by the Fourth International Workshop-Conference on Gestational Diabetes as “carbohydrate intolerance of various degrees of severity, with onset or first recognition during pregnancy.”²⁰ This definition does not preclude the possibility that glucose intolerance might have predated the pregnancy or that medications might be needed for optimal glucose control. The underlying pathophysiology of GDM in most instances is similar to that observed for type 2 diabetes: an inability to maintain an adequate insulin response because of the significant decreases in insulin sensitiv-

ity with advancing gestation. **About 2% to 13% of women diagnosed as having GDM have detectable antibodies directed against specific beta cell antigens.**^{21,22} Some of these deficiencies are population dependent. Other patients diagnosed with GDM have genetic variants that have been identified as causes of diabetes in the general population, including autosomal dominant (discussed later) and maternal or mitochondrial inheritance patterns.^{23,24}

It is estimated that as many as 3% to 9% of the population of pregnant women will be diagnosed with GDM.¹⁵ This translates into approximately 135,000 cases of GDM per year in the United States alone. This is not surprising, because in many respects, GDM is the harbinger of type 2 diabetes for many women, based on the underlying pathophysiology of GDM and the increase in obesity in women of reproductive age. Similarly, there is an increase in the incidence of GDM in women immigrating to the United States, presumably because of changes in diet and lifestyle. Clinical recognition of GDM is important because therapy can reduce pregnancy complications and potentially reduce long-term sequelae in the offspring.

Genetic and Other Causes of Diabetes

The ADA's fourth classification of diabetes includes specific types of diabetes attributed to “other causes.” These causes include genetic defects in insulin action, diseases of the exocrine pancreas (e.g., cystic fibrosis), and drug- or chemical-induced diabetes, such as in the treatment of human immunodeficiency virus (HIV) infection or after organ transplantation.¹⁹ One of the well-characterized genetic defects is often included under the heading of maturity-onset diabetes of the young (MODY) (i.e., the glucokinase [GK] mutation). In 1998, Hattersley and colleagues²⁵ described the various phenotypic permutations associated with the mutations of the glucokinase gene. Glucokinase phosphorylates glucose to glucose-6 phosphate in the pancreas and liver. A heterozygous glucokinase mutation results in hyperglycemia, usually with a mildly elevated fasting glucose and abnormal OGTT result. This occurs because of a defect in the sensing of glucose by the beta cell, resulting in decreased insulin release, and to a lesser degree because of reduced hepatic glycogen synthesis. In pregnancy, it is estimated that 3% of women with GDM and an elevated fasting glucose level greater than 110 mg/dL have this mutation. If the heterozygous mutation is present in the fetus, then the altered glucose sensing by the fetal pancreas will result in a decrease in insulin secretion. In the fetus, insulin is a primary stimulus for growth, and any defect in fetal insulin secretion results in decreased fetal growth and possible growth restriction. Depending on whether the mother or fetus, or both, have a defect in the glucokinase gene, the phenotype of the infant can vary from intrauterine growth restriction (IUGR) through normal fetal growth and to macrosomia.

Maternal-Fetal Metabolism in Normal and Diabetic Pregnancy

There are significant changes in maternal metabolism in normal pregnancy. **These include changes in maternal nutrient metabolism (i.e., carbohydrate, lipid, and protein metabolism) and changes in factors such as energy expenditure.** The overall goal of these maternal metabolic adaptations is to prepare the pregnant woman to meet the increased energy needs of the mother and growth of the fetus in the

latter third of pregnancy, when approximately 70% of fetal growth takes place.²⁶ The alterations in maternal metabolism are relatively uniform during pregnancy unless there are major perturbations such as starvation conditions. The metabolic changes during pregnancy therefore take place on the background of a woman's pregestational metabolic status. For example, if a woman is healthy and lean before conception, there is an increased need to store adipose tissue in early pregnancy to meet the increased energy demands of late gestation and to develop insulin resistance in late gestation to provide nutrients for the growing fetus. If a woman is obese before conception, there is little need to gain additional adipose tissue, but there is the requirement to provide nutrients for the fetus in late gestation.

Normal Glucose-Tolerant Pregnancy

Glucose homeostasis is primarily a balance between insulin resistance and insulin secretion. The alterations in insulin resistance affect endogenous glucose production (primarily hepatic glucose metabolism) and peripheral glucose metabolism, which takes place in skeletal muscle.

In the lean pregnant woman with normal glucose tolerance, there is a significant 30% increase in basal hepatic glucose production by the third trimester of pregnancy (Fig. 46-2). This is associated with a significant increase in basal or fasting insulin concentrations.²⁷ The decrease in fasting glucose concentrations most likely is the result of increasing plasma volumes in early gestation and increased fetoplacental use in late pregnancy. In the postprandial state, the increasing insulin concentrations enhance glucose uptake into skeletal muscle and adipose tissue, and they almost completely suppress hepatic glucose production. Although this is the case in lean women, obese women with normal glucose tolerance have a decreased ability for insulin to completely suppress hepatic glucose production in late pregnancy.²⁸ These data support the concept of decreased insulin sensitivity in late gestation that is more severe in obese women compared with non-obese counterparts.

Peripheral insulin resistance is defined as the decreased ability of insulin to affect glucose uptake primarily in skeletal muscle and to a

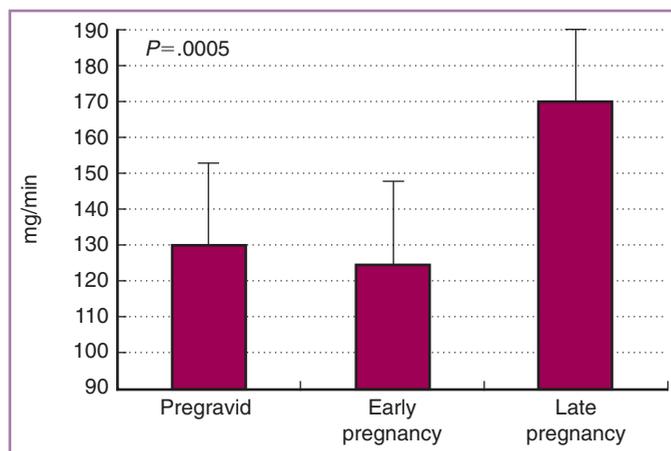

FIGURE 46-2 Alterations in glucose production. Longitudinal changes in total basal endogenous (primarily hepatic) glucose production (mean \pm SD) from pregravid through early gestation (12 to 14 weeks) and late gestation (34 to 36 weeks). (Adapted from Catalano PM, Tyzbir ED, Wolfe RR, et al: Longitudinal changes in basal hepatic glucose production and suppression during insulin infusion in normal pregnant women. *Am J Obstet Gynecol* 167:913-919, 1992.)

lesser degree in adipose tissue. Various methods are used to assess insulin sensitivity in vivo, including mathematical models of fasting glucose and insulin modeling (e.g., homeostasis model assessment [HOMA],²⁹ OGTT³⁰), the intravenous glucose tolerance test (i.e., Bergman minimal model),³¹ and what many consider to be the gold standard: the hyperinsulinemic-euglycemic clamp.³² Most of these measures have identified a significant 50% to 60% decrease in insulin sensitivity in late gestation.³³ The changes in insulin sensitivity during gestation are a reflection of a woman's pregravid insulin sensitivity status. Lean women usually have greater pregravid insulin sensitivity compared with overweight or obese women. These differences manifest before pregnancy, and when evaluated against the metabolic background of pregnancy, the relationships are similar in late pregnancy, albeit reduced by approximately 50% to 60% (Fig. 46-3). The decreases in insulin sensitivity in late pregnancy are accompanied by an increase in insulin response. The increased insulin response to a glucose load increases approximately threefold compared with pregravid measures (Fig. 46-4).

Diabetic Pregnancy

Alterations in glucose metabolism in women with diabetes have been most extensively examined in women with GDM, although the alterations in glucose metabolism in women with type 2 diabetes are most likely very similar but with increased insulin resistance and further decompensation of beta cell function. In lean and obese women with GDM with mildly elevated fasting glucose levels, there is a similar increase in basal endogenous glucose production, as was observed in subjects with normal glucose tolerance, although fasting insulin concentrations, particularly in late gestation, are greater than observed in normal glucose-tolerant women.^{28,34} However, during insulin infusion during euglycemic clamps, the ability of insulin to suppress endogenous glucose production is decreased (approximately 80% versus 95%) in GDM compared with a matched control group. There is also a sig-

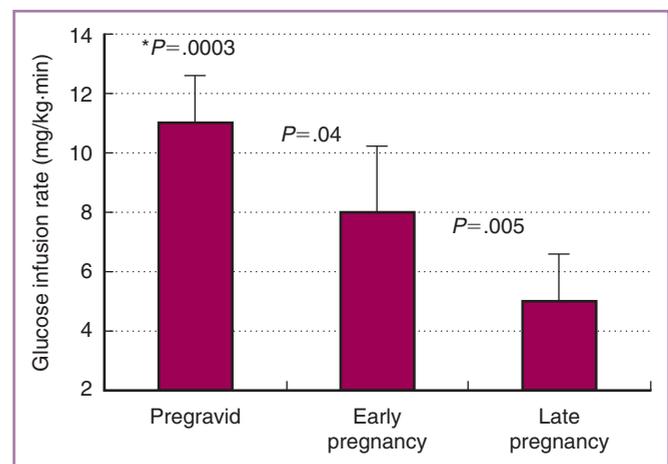

FIGURE 46-3 Alterations in insulin resistance. Longitudinal changes in glucose infusion rate (i.e., insulin sensitivity) in lean women from pregravid through early (12 to 14 weeks) and late (34 to 36 weeks) pregnancy during hyperinsulinemic-euglycemic clamp (mean \pm SD). The asterisk indicates change over time from pregravid status through late pregnancy (ANOVA). (Adapted from Catalano PM, Tyzbir ED, Roman NM, et al: Longitudinal changes in insulin release and insulin resistance in non-obese pregnant women. *Am J Obstet Gynecol* 165:1667-1672, 1991.)

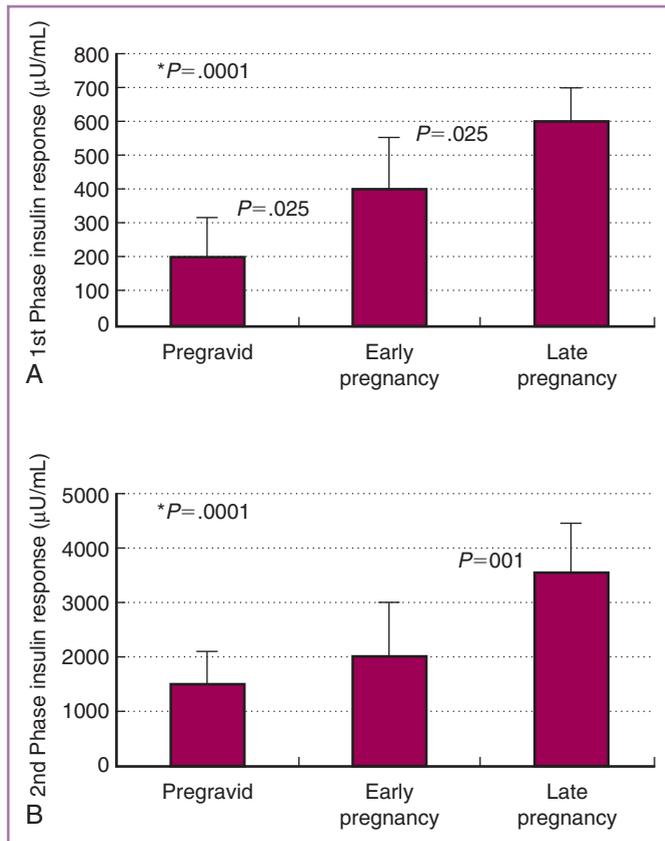

FIGURE 46-4 Increased insulin response. Changes in first (A) and second (B) phase pregravid through early (12 to 14 weeks) and late (34 to 36 weeks) pregnancy insulin response during an intravenous glucose tolerance test (mean ± SD). The asterisk indicates change over time from pregravid status through late pregnancy (ANOVA). (Adapted from Catalano PM, Tyzbir ED, Roman NM, et al: Longitudinal changes in insulin release and insulin resistance in non-obese pregnant women. Am J Obstet Gynecol 165:1667-1672, 1991.)

nificant decrease in insulin sensitivity in women who go on to develop GDM, when estimated before conception or after delivery,³⁵ compared with a matched control group. During pregnancy, the percent decrease in insulin sensitivity is approximately the same as the percent change in a matched control group (i.e., approximately 50% to 60%). The decreased insulin sensitivity observed during pregnancy in the woman who develops GDM is a function of her pregravid metabolic status, and clinically, the increased glucose concentrations represent the inability of pancreatic beta cells to normalize glucose levels (Fig. 46-5).

The relationship between insulin sensitivity and insulin response has been characterized by Bergman and colleagues¹⁶ as a hyperbolic curve or, when multiplied, as the disposition index. A curve that is “shifted to the left” can be plotted for individuals who go on to develop GDM (Fig. 46-6). Whether the insulin resistance precedes the beta cell defect or they occur concomitantly is not known with certainty. However, Buchanan³⁶ proposed that insulin resistance caused the beta cell dysfunction in susceptible individuals. The increased risk of type 2 diabetes in women who formerly had GDM may be a function of decreasing insulin sensitivity (i.e., worsening insulin resistance) exacerbated by increasing age, adiposity, and the inability of the beta cells to fully compensate.

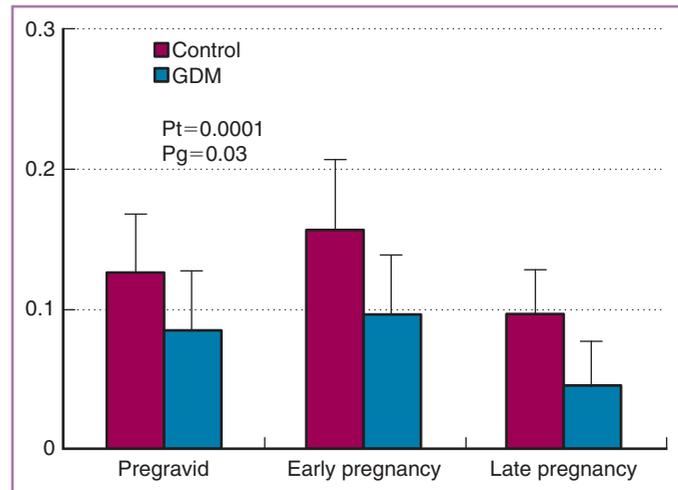

FIGURE 46-5 Alterations in insulin sensitivity. Longitudinal changes in insulin sensitivity during clamp 40 mU·m⁻²·min⁻¹ insulin infusion in obese women (mean ± SD). GDM, gestational diabetes mellitus; Pg, difference between groups; Pt, individual longitudinal changes with time. (Adapted from Catalano PM, Huston L, Amini SB, Kalhan SC: Longitudinal changes in glucose metabolism during pregnancy in obese women with normal glucose tolerance and gestational diabetes. Am J Obstet Gynecol 180:903-916, 1999.)

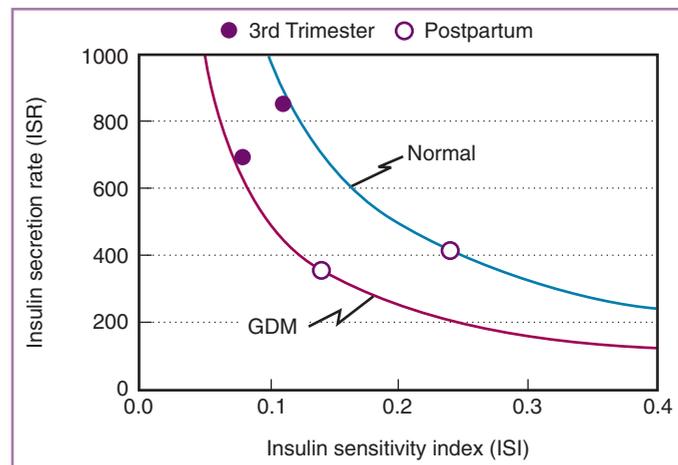

FIGURE 46-6 Insulin sensitivity and secretion relationships in normal women and women with gestational diabetes mellitus. Prehepatic insulin secretion was assessed during steady-state hyperglycemia using plasma insulin and C-peptide concentrations and C-peptide kinetics in individual patients. (Printed with permission from Buchanan TA: Pancreatic β-cell defects in gestational diabetes: Implications for the pathogenesis and prevention of type 2 diabetes. J Clin Endocrinol Metab 86:989-993, 2001.)

The data on the changes on glucose metabolism in women with type 1 diabetes are not as well examined. Schmitz and coworkers³⁷ evaluated the longitudinal changes in insulin sensitivity in women with type 1 diabetes in early and late pregnancy and after delivery. There was a 50% decrease in insulin sensitivity in late gestation. There was no significant difference in insulin sensitivity in these women in early pregnancy or within 1 week of delivery compared with nonpregnant women with type 1 diabetes. Based on the available data, women with

type 1 diabetes have similar alterations in insulin sensitivity compared with women with normal glucose tolerance.

Mechanism of Insulin Resistance

The mechanisms related to the changes in insulin resistance during pregnancy are better characterized because of research in the past decade. The insulin resistance of pregnancy is almost completely reversed shortly after delivery,³⁸ consistent with the clinically marked decrease in insulin requirements. The placenta has long been suspected of producing hormonal factors related to these alterations in metabolism. The placental mediators of insulin resistance in late pregnancy have been ascribed to alterations in maternal cortisol concentrations and placenta-derived hormones such as human placental lactogen (HPL), progesterone, and estrogen.³⁹⁻⁴¹ Kirwan and associates⁴² reported that circulating tumor necrosis factor- α (TNF- α) concentrations had an inverse correlation with insulin sensitivity as estimated from clamp studies. Among leptin, HPL, cortisol, human chorionic gonadotropin, estradiol, progesterone, and prolactin, TNF- α was the only significant predictor of the changes in insulin sensitivity from the pregravid period through late gestation. TNF- α and other cytokines are produced by the placenta, and 95% of these molecules are transported to maternal rather than fetal circulations.⁴² Other factors, such as circulating free fatty acids, may contribute to the insulin resistance of pregnancy.⁴³

Studies in human skeletal muscle and adipose tissue have demonstrated defects in the post-receptor insulin-signaling cascade during pregnancy. Friedman and colleagues showed that women in late pregnancy have reduced insulin receptor substrate-1 (IRS-1) concentrations compared with those of matched nonpregnant women.⁴⁴ Downregulation of the IRS-1 protein closely parallels insulin's decreased ability to induce additional steps in the insulin signaling cascade that result in the transporter (GLUT-4) arriving at the cell surface to allow glucose to enter the cell. Downregulation of IRS-1 closely parallels the decreased ability of insulin to stimulate 2-deoxyglucose uptake in vitro in pregnant skeletal muscle. During late pregnancy in women with GDM, in addition to decreased IRS-1 concentrations, the insulin receptor- β (i.e., component of the insulin receptor within the cell rather than on the cell surface) has a decreased ability to undergo tyrosine phosphorylation.⁴⁴ This is an important step in the action of insulin after it has bound to the insulin receptor on the cell surface. This additional defect in the insulin-signaling cascade is not found in pregnant or nonpregnant women with normal glucose tolerance and results in a 25% lower glucose transport activity. TNF- α also acts by means of a serine/threonine kinase, thereby inhibiting IRS-1 and tyrosine phosphorylation of the insulin receptor.⁴⁵ These post-receptor defects may contribute in part to the pathogenesis of GDM and an increased risk for type 2 diabetes in later life.

Complications of Diabetes during Pregnancy

Maternal Morbidity

Women with pregestational diabetes are at risk for a number of obstetric and medical complications. The relative risk of these problems is proportional to the duration and severity of disease. Evers and coworkers reported the maternal morbidity of a cohort of 323 type 1 diabetic

pregnancies followed prospectively in the Netherlands.⁴⁶ Glycemic control was excellent (Hb A_{1c} \leq 7.0% in 75%), but the rates of pre-eclampsia (12.7%), preterm delivery (32%), cesarean section (44%), and maternal mortality (60 deaths per 100,000 pregnancies) were considerably higher than in the nondiabetic population.

Retinopathy

Diabetic retinopathy is the leading cause of blindness between the ages of 24 and 64 years.⁴⁷ Some form of retinopathy is present in virtually 100% of women who have had type 1 diabetes for 25 years or more; approximately 20% of these women are legally blind. The topic of diabetic retinopathy has been reviewed elsewhere.⁴⁸

The pattern of progression of diabetic retinopathy is predictable, proceeding from mild nonproliferative abnormalities, which are associated with increased vascular permeability, to moderate and severe nonproliferative diabetic retinopathy, which is characterized by vascular closure, to proliferative diabetic retinopathy, which is characterized by the growth of new blood vessels on the retina and posterior surface of the vitreous. It has been proposed that pregnancy accelerates these changes, although the mechanism is controversial.⁴⁹ Trials have not shown any acceleration in microvascular complications when pregnant and nonpregnant diabetic subjects were closely followed and compared.⁵⁰

Vision loss resulting from diabetic retinopathy results from several mechanisms. First, central vision may be impaired by macular edema or capillary nonperfusion. Second, the new blood vessels of proliferative diabetic retinopathy and contraction of the accompanying fibrous tissue can distort the retina and lead to tractional retinal detachment, producing severe and often irreversible vision loss. Third, the new blood vessels may bleed, adding the further complication of preretinal or vitreous hemorrhage.

FACTORS AFFECTING PROGRESSION OF RETINOPATHY DURING PREGNANCY

Although past studies suggested that rapid induction of glycemic control in early pregnancy stimulated retinal vascular proliferation,⁵¹ later investigations indicate that the severity and duration of diabetes before pregnancy have a greater effect. Temple and colleagues⁵² studied 179 women with pregestational type 1 diabetes, performing dilated fundal examination at the first prenatal visit, 24 weeks, and 34 weeks. Progression to proliferative diabetic retinopathy occurred in only 2.2%, and moderate progression occurred in 2.8%. However, progression was significantly greater in women who had had diabetes for more than 10 years (10% versus 0%; $P = .007$) and in women with moderate to severe background retinopathy before pregnancy (30% versus 3.7%; $P = .01$). In the European Diabetes (EURODIAB) Prospective Complications Study, 793 potentially childbearing women at baseline completed the follow-up, and 21% gave birth. Duration of diabetes and high HbA_{1c} levels at recruitment were significant risk factors for retinopathy progression, whereas giving birth was not.⁵⁰

OPHTHALMOLOGIC MANAGEMENT DURING PREGNANCY

Screening for retinopathy by a qualified ophthalmologist is recommended before pregnancy and again during the first trimester for patients with pregestational diabetes because of the demonstrated effectiveness of laser photocoagulation therapy in arresting progression. Patients with minimal disease should be re-examined once or twice during the pregnancy and at 3 and 6 months after delivery. Those with significant retinal pathology may require monthly follow-up.⁵³

Nephropathy

Diabetes is the most common cause of end-stage renal disease in the United States and Europe. In the United States, diabetic nephropathy accounts for about 45% of new cases of this condition. In 2003, the cost for treatment of diabetic patients with end-stage renal disease was in excess of \$55,000 annually per person and more than \$5 billion in aggregate.⁵⁴ About 20% to 40% of patients with type 1 or type 2 diabetes develop evidence of nephropathy over time, but the rate and extent of progression are highly individual.⁵³

The pathophysiology of diabetic renal disease is incompletely understood, but several factors play a role, including genetic susceptibility, control of hyperglycemia, and the duration and severity of coexisting hypertension. Additional insults, such as repeated urinary tract infections, excessive glycogen deposition, and papillary necrosis, all hasten deterioration of renal function. The kidney is normal at the onset of diabetes, but within a few years, glomerular basement membrane thickening can be identified. By 5 years, there is expansion of the glomerular mesangium, resulting in diffuse diabetic glomerulosclerosis. All patients with marked mesangial expansion exhibit proteinuria exceeding 400 mg in 24 hours. The peak incidence of nephropathy occurs after about 16 years of diabetes.

CATEGORIES OF DIABETIC NEPHROPATHY

Categories of diabetic nephropathy are distinguished by the level of urinary protein excretion. Table 46-3 shows normal values and the current clinical criteria for microalbuminuria and nephropathy. Screening for microalbuminuria can be performed by three methods: measurement of the albumin-to-creatinine ratio in a random spot collection; 24-hour collection with creatinine, allowing the simultaneous measurement of creatinine clearance; and timed (e.g., 4-hour or overnight) collection. The first method is preferred because it is the easiest to carry out in an ambulatory setting, and it provides adequately accurate information. The other methods are rarely used.⁵⁵

EFFECT OF PREGNANCY ON PROGRESSION OF NEPHROPATHY

Although some clinicians discourage pregnancy in women with diabetic renal disease because of concerns of permanent renal deterioration as a result of the pregnancy, recent data consistently indicate that pregnancy does not measurably alter the time course of diabetic renal disease.

Progression of diabetic nephropathy is closely related to the degree of glycemic control. To the extent that most women have better glyce-

mioration can be expected. A study of renal function for 4 years before and 4 years after pregnancy in 11 patients with diabetic nephropathy⁵⁶ showed that the gradual rise in serum creatinine over that period was unaffected by the intervening pregnancy. Imbasciati and coworkers⁵⁷ performed a longitudinal study of 58 women with chronic renal disease, following each through pregnancy. The mean serum creatinine level was 6 mg/dL at the start of the study and 6 mg/dL after delivery. Although they found that women with glomerular filtration rates less than 40 mL/min and with proteinuria greater than 1 g/day had increased risk of delivering a child with a birth weight less than 2500 g (odds ratio [OR] = 5.1; 95% confidence interval [CI], 1.03 to 25.6), the association was not related to renal disease, hypertension, and maternal age. When the cohort was taken as a whole, even those with lower glomerular filtration rates and higher levels of proteinuria had similarly modest changes in renal function when after- and before-pregnancy indices were compared.⁵⁷

Rossing and colleagues⁵⁸ evaluated the effect of pregnancy on deterioration of renal function in 93 women older than 20 years. They compared groups of never-pregnant and ever-pregnant women who received similar medical therapy and who had similar degrees of renal function at the start of the study. The results are shown in Figure 46-7. Based on this excellent prospective study, it is evident that pregnancy neither alters the time course of renal disease nor increases the likelihood of transition to end-stage renal disease.

COURSE OF DIABETIC NEPHROPATHY DURING PREGNANCY

In general, patients with underlying renal disease before pregnancy can be expected to experience various degrees of deterioration during pregnancy. The physiologic changes associated with normal pregnancy increase renal blood flow and glomerular filtration by 30% to 50%. Most women with preexisting diabetic nephropathy experience this improvement in renal function, especially during the second trimester.⁵⁹ During the third trimester, however, when mean arterial pressure and peripheral vascular resistance typically increase, women with diabetic microvascular disease may experience marked diminution of renal function, an exacerbation in hypertension, and in many cases, preeclampsia. The third-trimester increase in maternal blood pressure and serum creatinine concentration are among the most common

Category*	Albumin-to-Creatinine Ratio (µg/mg) [†]
Normal	<30
Microalbuminuria	30-299
Nephropathy	≥300

*Categories of diabetic nephropathy are distinguished by the level of urinary protein excretion. Two of three collections in a 3- to 6-month period should be abnormal for a diagnosis of microalbuminuria or nephropathy.

[†]The ratio of albumin to creatinine was determined by random spot collection.

precipitating events leading to indicated preterm delivery in diabetic women. Although delivering the fetus to interrupt the precipitous rise in blood pressure may result in premature birth, this is usually preferable to the risk of maternal renal failure or stroke (discussed later).

Reece and colleagues⁶⁰ reviewed the outcomes of 315 pregnant women with preexisting diabetic nephropathy. Of these, 17% ultimately developed end-stage renal disease, and 5% died as a result of renal insufficiency. During pregnancy, proteinuria and mean arterial pressure significantly increased from the first to the third trimester ($P < .05$). Another study by Purdy and coworkers⁶¹ demonstrated a rise in the mean serum creatinine level from 1.8 mg/dL before pregnancy to 2.5 mg/dL in the third trimester. Renal function was stable in 27%, transiently worsened during pregnancy in 27%, and demonstrated a permanent decline in 45%. Proteinuria increased during pregnancy in 79%, and exacerbation of hypertension or preeclampsia occurred in 73%.

Ekbom and colleagues⁶² compared the outcomes of pregnancies in women with microalbuminuria or overt nephropathy and those without. Their results (Fig. 46-8) indicate that the likelihood of preterm

delivery is considerably increased for women with microalbuminuria, mainly because of preeclampsia.

RENAL DIALYSIS IN DIABETIC PREGNANT WOMEN

Although women receiving dialysis for end-stage renal disease are often amenorrheic or at least anovulatory, pregnancies have become increasingly common⁶³ during therapy (3% to 7%).⁶⁴ Unfortunately, the prognosis for pregnancy in diabetic women with end-stage renal disease continues to be exceedingly poor, with fetal loss rates remaining in the range of 30% to 50% over the past decade. Neonatal death rates are between 5% and 15%, and less than one half of pregnancies among women with end-stage renal disease result in viable children. About 60% of births are premature, often because of uncontrollable hypertension, renal failure, or fetal growth failure.⁶⁵ Of the 20% to 25% of pregnancies ending in live births, 40% of babies are severely growth restricted.

A major practical problem with achieving a successful pregnancy outcome while on hemodialysis is proper maintenance of maternal vascular volume. Dialysis teams are accustomed to removing significant vascular volume at each session. However, during a normal pregnancy, there is a progressive expansion in vascular volume of at least 20% to 30% above nonpregnant values from 8 to 30 weeks' gestation. This volume augmentation is required to maintain uteroplacental perfusion and fetal growth. Pregnancies in which vascular volume does not increase appropriately have a high incidence of fetal growth restriction and stillbirths. Difficulties with vascular underfill (e.g., hypertension, poor fetal growth, asphyxia) and overfill (e.g., hypertension) are common in pregnant patients on hemodialysis and often are difficult to rectify.

The poor prognosis associated with hemodialysis combined with other considerations has prompted increased interest in continuous ambulatory peritoneal dialysis. Several successful pregnancy series have been reported.⁶⁵⁻⁶⁷ Although fluid and chemical balance is constant and heparinization is not necessary, intrauterine deaths, abruptio, prematurity, hypertension, and fetal distress still occur. The best strategy for most diabetic women on dialysis desiring pregnancy is to undergo kidney transplantation.

RENAL TRANSPLANTATION

Successful pregnancy after renal transplantation is now a reality. Davison's⁶⁷ review of 1569 pregnancies in women with renal allografts found that of the 60% of pregnancies that continued beyond the first trimester, 92% resulted in a viable infant. Preeclampsia occurred in 30%, preterm delivery in about 50%, and IUGR in 20%. Patients with the worst renal function had the poorest pregnancy outcomes. Similar results were reported by Yassaee and Moshiri.⁶⁸ The most common maternal complications in 95 pregnancies were anemia in 65%, and preeclampsia in 47%. Three patients lost their graft, and six had impaired kidney allograft function 2 years after pregnancy.⁶⁸

In a historical cohort study, 86 women who had at least one post-transplantation pregnancy were compared with 125 who had no pregnancy after renal transplantation. Patients were matched for age, cause of end-stage renal disease, treatment protocol, and first serum creatinine level. The 5-year patient and graft survival rates were not significantly different between the study groups. Among the women with at least one pregnancy, only 10% had serum creatinine levels above 1.5 mg/dL at the end of 46 months of follow-up, compared with 28% of the never-pregnant group.⁶⁹ Based on these findings, it appears that perinatal outcomes are better in patients who have undergone renal

transplantation than in those with end-stage renal disease who are on dialysis.

Cardiovascular Complications

Cardiovascular complications experienced by pregnant women with diabetes include chronic hypertension, pregnancy-induced hypertension, and rarely, atherosclerotic heart disease. In composite studies of all types of diabetic pregnancies, the incidence of hypertensive disorders during pregnancy varies from 15% to 30%,^{70,71} with the rate of hypertension increased fourfold over that for the nondiabetic population.⁷²

CHRONIC HYPERTENSION

Chronic hypertension (i.e., blood pressure at or above 140/90 mm Hg before 20 weeks' gestation)⁷³ complicates 10% to 20% of pregnancies in diabetic women and up to 40% of those in diabetic women with preexisting renal or retinal vascular disease.⁷⁴ The perinatal problems encountered with chronic hypertension include IUGR, maternal stroke, preeclampsia, and abruptio placentae. In pregestational diabetes, the prevalence of chronic hypertension increases with duration of diabetes and is closely associated with nephropathy.^{72,75}

The Diabetes in Early Pregnancy (DIEP) study reported that women with type 1 diabetes have higher mean blood pressures throughout pregnancy than do normal controls.⁷⁶ In a significant proportion of patients, this difference is probably evidence of underlying renal compromise. Preexisting chronic hypertension should be suspected when the diabetic patient's systolic blood pressure exceeds 130/80 mm Hg before the third trimester. The diagnosis is strengthened by finding a failure of mean blood pressure to decline normally in the late second trimester, elevation in the blood urea nitrogen level above 10 mg/dL, serum creatinine concentration above 1 mg/dL, creatinine clearance less than 100 mL/min, or a combination of these factors.

PREECLAMPSIA

Preeclampsia is more common among women with diabetes, occurring four times as frequently in women with pregestational diabetes as in those without diabetes.⁷² The risk of developing preeclampsia is proportional to the duration of diabetes before pregnancy and the existence of nephropathy and hypertension; more than one third of pregnant women who have had diabetes for more than 20 years develop this condition. As is shown in Figure 46-9, patients with White class B diabetes have a risk profile similar to that of nondiabetic patients, but women with evidence of renal or retinal vasculopathy (classes D, F, or R) have a 50% excess risk of hypertensive complications over the rate observed for those with no hypertension. Women with diabetic nephropathy have similar rates of preeclampsia.

Renal function assessments should be performed in each trimester in women with overt diabetic vascular disease and in those who have had diabetes for more than 10 years. Significant proteinuria, plasma uric acid levels above 6 mg/dL, or evidence of HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets) should prompt a workup for preeclampsia.

HEART DISEASE

Although coronary heart disease is rarely encountered in pregnant women with diabetes, a study by Airaksinen and colleagues⁷⁷ suggests that such women may have preclinical cardiomyopathy and autonomic neuropathy. The diabetic women studied had less than the expected increase in left ventricular size and stroke volume in pregnancy, lower heart rate increases, and smaller increments in cardiac output.

Although uncommon, atherosclerotic heart disease (White class H) may afflict diabetic patients in the later reproductive years. Patients with this complication have a mean age of 34 years and exhibit other evidence of diabetic vascular involvement (White class D or R).⁷⁸ For diabetic women with cardiac involvement, pregnancy outcome is

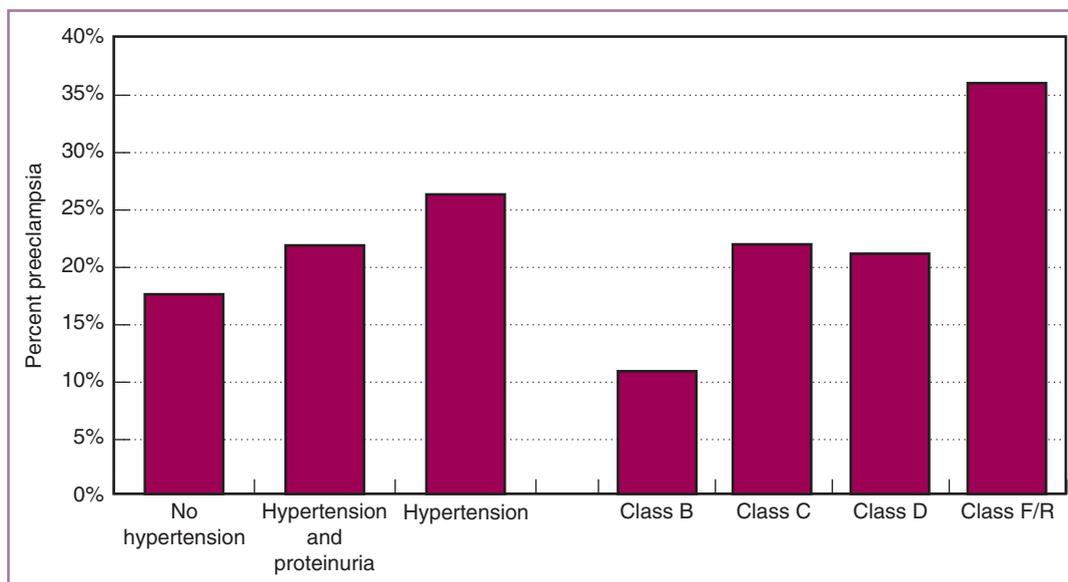

FIGURE 46-9 Likelihood of preeclampsia in diabetic pregnancy by White's class and preexisting hypertension. The risk of developing preeclampsia is proportional to the duration of diabetes before pregnancy and the existence of nephropathy and hypertension. (From Sibai BM, Caritis S, Hauth J, et al: Risks of preeclampsia and adverse neonatal outcomes among women with pregestational diabetes mellitus. National Institute of Child Health and Human Development Network of Maternal-Fetal Medicine Units. Am J Obstet Gynecol 182:364, 2000.)

dismal, with a maternal mortality rate of 50% or higher and perinatal loss rates approaching 30%.⁷⁹ Recognition of cardiac compromise in pregnant women with diabetes may be difficult because of the decrease in exercise tolerance that occurs during normal pregnancy. Compromised cardiac function may also be difficult to detect in patients restricted to bed rest for hypertension or poor fetal growth. It is prudent to obtain a detailed cardiovascular history in all diabetic patients and to consider electrocardiography and maternal echocardiography in patients who have type 1 diabetes and are older than 30 years or in patients who have had diabetes for 10 years or more. With intensive monitoring, successful pregnancy is possible, albeit hazardous for women with significant cardiac disease.⁸⁰

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) during pregnancy is a medical emergency for the mother and fetus. Pregnant women with type 1 diabetes are at increased risk for DKA, although the incidence and morbidity of this complication have decreased from 20% or more in the older literature to approximately 2% in later reports.⁸¹ The rate of intrauterine fetal death, formerly as high as 35% with DKA during pregnancy, has dropped to 10% or less.

Precipitating factors for ketoacidosis include pulmonary, urinary, or soft tissue infections; poor compliance; and unrecognized new onset of diabetes. Because severe DKA threatens the life of the mother and fetus, prompt treatment is essential. Fetal well-being in particular is in jeopardy until maternal metabolic homeostasis is reestablished. High levels of plasma glucose and ketones are readily transported to the fetus, which may be unable to secrete sufficient quantities of insulin to prevent DKA in utero.

DKA evolves from inadequate insulin action and functional hypoglycemia at the target tissue level. This leads to increased hepatic glucose release but decreased or absent tissue disposal of glucose. Glucose-lacking tissues release ketone bodies, and vascular hyperglycemia promotes osmotic diuresis. Over time, the diuresis causes profound vascular volume depletion and loss of electrolytes. The release

of stress hormones (i.e., catecholamines, glucagon, growth hormone, and cortisol) further impairs insulin action and contributes to insulin resistance. Left unchecked, this cycle of dehydration, tissue hypoglycemia, and electrolyte depletion can lead to multisystem collapse, coma, and death.

Early in the illness, hyperglycemia and ketosis are moderate. If hyperglycemia is not corrected, diuresis, dehydration, and hyperosmolality follow. Pregnant women in the early stages of ketoacidosis respond quickly to appropriate treatment of the initiating cause (e.g., broad-spectrum antibiotics), additional doses of regular insulin, and volume replacement.

Patients with advanced DKA usually present with typical findings, including hyperventilation, normal or obtunded mental state (depending on severity of the acidosis), dehydration, hypotension, and a fruity odor to the breath. Abdominal pain and vomiting may be prominent symptoms. The diagnosis of DKA is confirmed by the presence of hyperglycemia (glucose >200 mg/100 mL) with positive test results for serum ketones at a level of 1:4 or greater.

As many as one third of patients in the early or very late stages of DKA may have initial blood glucose levels less than 200 mg/dL.⁸² A pregnant diabetic patient with a history of poor food intake or vomiting for more than 12 to 16 hours should have a thorough workup for DKA, including a complete blood cell count and electrolyte determinations. A serum bicarbonate level below 18 mg/dL should prompt performance of an arterial blood gas analysis. In all cases of DKA, the diagnosis is confirmed by arterial blood gases demonstrating a metabolic acidemia (i.e., base excess of -4 or lower).⁸³

Table 46-4 contains a protocol for treatment of DKA. The important steps in management should include the following:

- **Search for and treat the precipitating cause.** Typical initiators include pyelonephritis and pulmonary or gastrointestinal viral infections.
- **Perform vigorous and sustained volume resuscitation.** The patient will continue to generate vascular volume deficits

TABLE 46-4 TREATMENT PROTOCOL FOR DIABETIC KETOACIDOSIS*

Measures	Initial Phase (6-24 hr)	Recovery Phase
General	Search for initiating cause of ketoacidosis. Insert bladder catheter. If patient is unconscious, establish nasogastric tube.	Continue treatment of initiating cause. Remove bladder catheter when vascular volume is replaced.
Fluids	Administer 0.9% NaCl at 1000 mL/hr × 2 hr and then 500 mL/hr until 5-8 L infused.	Continue 0.9% NaCl at 100 mL/hr for at least 48 hours to avoid return of ketoacidosis.
Insulin	Administer 20 U of insulin by IV bolus and then 5-10 U/hr by IV infusion.	When acidosis is resolved and plasma glucose <160 mg/dL, reduce insulin infusion to 0.7-2.0 U/hr. Return to patient's prior SC insulin dosing after plasma glucose is stable for at least 12 hr.
Glucose	When plasma glucose is <250 mg/dL, add 5% dextrose to 0.9% NaCl.	
Potassium	If serum K ⁺ level is normal or low, infuse KCl at 20 mEq/hr. If serum K ⁺ level is high, wait until K ⁺ is normal, then KCl at 20 mEq/hr. Measure serum K ⁺ level every 2-4 hr.	Use oral potassium supplementation for 1 week.
Bicarbonate	If pH is <7.1, add one ampule of bicarbonate (50 mEq) to IV; repeat until pH >7.1.	

*These are general guidelines. Because there may be wide variation in individual patient needs, there is no substitute for careful monitoring of each patient, particularly in the initial phase of therapy.

IM, intramuscular; IV, intravenous; KCl, potassium chloride; NaCl, sodium chloride; SC, subcutaneous.

Adapted from American College of Obstetricians and Gynecologists (ACOG): Clinical management guidelines for obstetrician-gynecologists. ACOG practice bulletin no. 60, March 2005. Pregestational diabetes mellitus. *Obstet Gynecol* 105:675-685, 2005.

until her glucose levels and acidosis are largely resolved. A physiologic fluid such as 0.9% NaCl with 20 mEq/L of potassium should be used and continued until the acidosis is substantially corrected (base excess of -2 or less). This usually requires an infusion at 1 to 2 L/hr for the first 1 to 2 hours, followed by reduced rates (150 to 200 mL/hr) until the base deficit approaches a normal level.

- Place a bladder catheter to monitor urine output.
- Use insulin to correct hyperglycemia. Although intermittent injections can be used, a continuous infusion of regular or short-acting insulin (i.e., lispro or aspart) allows frequent adjustments. When giving insulin as a continuous infusion, 1 to 2 units/hr gradually corrects the patient's glucose abnormality over 4 to 8 hours. Attempts to normalize plasma glucose levels rapidly (i.e., in less than 2 to 3 hours) may result in hypoglycemia and further physiologic counterregulatory responses.
- Monitor serum bicarbonate levels and arterial blood gas base deficits every 1 to 3 hours to guide management. Even when the plasma glucose level is normalized, acidemia may persist, as evidenced by continuing abnormalities in the patient's electrolyte concentrations. Unless volume therapy is continued until the patient's electrolyte stores and plasma concentrations have substantially returned to normal, DKA may reappear, and the cycle of metabolic derangement will be renewed.

When DKA occurs after 24 weeks' gestation, fetal status should be continuously monitored by fetal heart rate monitoring or a biophysical profile, or both. However, even when fetal status is questionable during the phase of therapeutic volume and plasma glucose correction, emergency cesarean section should be avoided. Usually, correction of the maternal metabolic disorder is effective in normalizing fetal status. Nevertheless, if a reasonable effort has been expended in correcting the maternal metabolic disorder and the fetal status remains a concern, delivery should not be delayed.

Fetal Morbidity and Mortality

Perinatal mortality in diabetic pregnancy has decreased 30-fold since the discovery of insulin in 1922 and the institution of intensive obstetric and infant care in the 1970s. Improved techniques of maintaining maternal euglycemia have led to later timing of delivery and reduced iatrogenic respiratory distress syndrome. Nevertheless, the perinatal mortality rates reported for diabetic women remain approximately twice those observed in the nondiabetic population (Table 46-5). Congenital malformations, respiratory distress syndrome, and extreme prematurity account for most perinatal deaths in diabetic pregnancies.

Group	Gestational	Overt	Normal [†]
Fetal mortality rate (%)*	4.7	10.4	5.7
Neonatal mortality rate (%)*	3.3	12.2	4.7
Perinatal mortality rate (%)*	8.0	22.6	10.4

*Mortality rates = deaths per 1000 live births.
[†]Normal was determined from California data from 1986; figures were corrected for birth weight, sex, and race.

Miscarriage

Studies of miscarriage rates from a decade ago indicated an increased incidence of spontaneous abortion among women with pregestational diabetes, especially those with poor glucose control during the periconceptional period. Given the well-documented association between congenital anomalies and hyperglycemia, such a finding is not surprising. Sutherland and Pritchard⁸⁴ reported the outcomes of 164 diabetic pregnancies managed with relaxed glycemic control and found a spontaneous abortion rate of almost double the expected rate. Miodovnik and coworkers⁸⁵ studied spontaneous abortion in diabetic pregnancy prospectively and found an increasing rate among patients with more advanced classes of diabetes (rates for classes C, D, and F were 25%, 44%, and 22%, respectively). Later studies of populations with better glycemic control report miscarriage rates similar to those in the nondiabetic population,^{86,87} indicating that diabetic women with excellent glycemic control have a risk of miscarriage equivalent to those without diabetes.

These studies can be used to encourage patients who have not yet conceived to achieve excellent glycemic control. Patients presenting in early pregnancy with normal glycohemoglobin values can be reassured that the overall elevation in risk of miscarriage is modest. However, for patients with glycohemoglobin values 2 to 3 standard deviations above the norm, intense early pregnancy surveillance is indicated.

Congenital Anomalies

Among women with overt diabetes before conception, the risk of a structural anomaly in the fetus is increased fourfold to eightfold,⁸⁸ compared with the 1% to 2% risk for the general population. In a cohort study of 2359 pregnancies in women with pregestational diabetes, the major congenital anomaly rate was 4.6% overall, with 4.8% for type 1 diabetes and 4.3% for type 2 diabetes, more than double the expected rate. Neural tube defects were increased 4.2-fold and congenital heart disease by 3.4-fold. Of all anomalies confirmed in the neonate, only 65% were diagnosed antenatally.⁹ The typical congenital anomalies observed in diabetic pregnancies and their frequency of occurrence are listed in Table 46-6.

There is no increase in birth defects among offspring of diabetic fathers and nondiabetic women and women who develop gestational diabetes after the first trimester, indicating that glycemic control during embryogenesis is the main factor in the genesis of diabetes-associated birth defects. A classic report by Miller and coauthors⁸⁹ compared the frequency of congenital anomalies in patients with normal or high first-trimester maternal glycohemoglobin levels and found only a 3.4% rate of anomalies with an Hb A_{1c} value less than 8.5%, whereas the rate

TABLE 46-6 CONGENITAL MALFORMATIONS IN INFANTS OF INSULIN-DEPENDENT DIABETIC MOTHERS

Anomaly	Approximate Relative Risk	Percent Risk (%)
All cardiac defects	18	8.5
All central nervous system anomalies	16	5.3
Anencephaly	13	
Spina bifida	20	
All congenital anomalies	8	18.4

of malformations in patients with poorer glycemic control in the periconceptional period (Hb A_{1c} above 8.5) was 22.4%. Lucas and coworkers⁹⁰ reported an overall malformation rate of 13.3% in 105 diabetic patients. However, the risk of delivering a malformed infant was zero with an Hb A₁ value less than 7%, 14% with Hb A₁ between 7.2% and 9.1%, 23% with Hb A₁ between 9.2% and 11.1%, and 25% with Hb A₁ greater than 11.2%.

PATHOGENESIS

The mechanism by which hyperglycemia disturbs embryonic development is multifactorial. The potential teratologic role of disturbances in the metabolism of inositol, prostaglandins, and reactive oxygen species has been established.⁹¹ Embryonic hyperglycemia may promote excessive formation of oxygen radicals in susceptible fetal tissues, which are inhibitors of prostacyclin.⁹² The resulting overabundance of thromboxanes and other prostaglandins may then disrupt the vascularization of developing tissues. In support of this theory, addition of prostaglandin inhibitors to mouse embryos in culture medium prevented glucose-induced embryopathy.⁹³ The pathogenic role of free radical species in teratogenesis with diabetes has been underscored by demonstrating the effect of dietary antioxidants experimentally. High doses of vitamins C and E decreased fetal dysmorphogenesis to nondiabetic levels in rat pregnancy and rat embryo culture.^{94,95}

PREVENTION

Because the critical time for teratogenesis is during the period 3 to 6 weeks after conception, nutritional and metabolic intervention must be instituted preconceptionally to be effective. Several clinical trials of preconceptional metabolic care have demonstrated that malformation rates equivalent to those in the general population can be achieved with meticulous glycemic control.⁹⁶ Although studies of dietary folate and vitamin C supplementation have demonstrated success in reducing the incidence of congenital anomalies in experimental diabetes in rats,⁹⁷ the efficacy of a high-antioxidant diet in preventing diabetes-induced structural anomalies in humans has not been adequately explored. Preconceptional management of pregestational diabetics is discussed in the following sections.

Intrauterine Growth Restriction

Although the weights of infants of diabetic mothers (IDMs) usually are skewed into the upper range, IUGR occurs with significant frequency in diabetic pregnancies, especially in women with underlying vascular disease. Additional factors that increase the risk for IUGR in a diabetic pregnancy include the higher incidence of structural anomalies and maternal hypertension.

Asymmetrical IUGR is encountered most frequently in diabetic patients with vasculopathy (i.e., retinal, renal, or chronic hypertension).⁸⁸ This association suggests that uteroplacental vasculopathy may promote restricted fetal growth in these patients.⁹⁸ Patients with poor glycemic control and frequent episodes of ketosis and hypoglycemia are also prone to preeclampsia and poor fetal growth. Whether fetal growth restriction results from poor maternal-placental blood flow or intrinsically poor placental function is unresolved.⁹⁹

Fetal Obesity

Macrosomia has been defined using various criteria, which include birth weight greater than the 90th percentile, birth weight greater than 4000 g, and estimates of neonatal adiposity based on body composition measures. As early as 1923, research by Moulton¹⁰⁰ described variability in weight among various mammalian species that was attributed to the amount of adipose tissue or fat mass rather than lean body mass.

Using autopsy data and chemical analysis of 169 stillbirths, Sparks¹⁰¹ described a relatively comparable rate of accretion of lean body mass in fetuses that were small for gestational age (SGA), average for gestational age (AGA), and large for gestational age (LGA), but he found considerable variation in the accretion of fetal fat in utero. The human fetus at term has the greatest percent of body fat (approximately 10% to 12%) compared with other mammals.¹⁰²

GROWTH DYNAMICS

The increased growth of the mother is composed primarily of total body water and adipose tissue in early gestation.²⁶ Relative to the fetoplacental unit, the human placenta attains most of its growth by the middle of the second trimester. In contrast, approximately 70% of fetal growth occurs over the last third of gestation (1000 g at 28 weeks to 3500 g at term). Yang and associates⁶ reported that IDMs with diabetes still have an increased relative risk (RR) of being LGA (RR = 3.59; 95% confidence interval [CI], 1.55 to 5.84) compared with the infants of women with normal glucose tolerance.¹⁰⁰ Ogata and colleagues,¹⁰³ using serial ultrasound measures of the fetus of women with diabetes, described an increase in the rate of abdominal circumference growth after 24 weeks' gestation. The increase in growth appears to affect primarily insulin-sensitive tissues such as the subcutaneous fat included in measures of abdominal circumference.¹⁰⁴ Ninety-five percent of the variance in fetal abdominal circumference can be accounted for by subcutaneous fat rather than intra-abdominal measures such as liver size. This is consistent with the inability of the fetal liver to store much glycogen in early third trimester. Reece and coworkers¹⁰⁵ showed that fetuses of diabetic mothers have normal growth of lean body mass such as head and skeletal growth, even when there is marked hyperglycemia. In longitudinal ultrasound studies, Bernstein and associates¹⁰⁶ reported that fetal fat and lean body mass demonstrate unique growth profiles. These unique ultrasound profiles potentially provide a more sensitive marker of abnormal fetal growth, particularly in infants of women with diabetes based on the increased fat mass rather than lean mass of these neonates.¹⁰⁶ At delivery, body composition studies by Catalano and colleagues¹⁰⁷ have shown that birth weight alone, even when AGA, may not be a sensitive enough measure of fetal growth in the infant of the diabetic mother. They reported that although there were no significant differences in birth weight or lean body mass, the infants of women with GDM had increased fat mass and percent body fat compared with a normoglycemic control group (Table 46-7).

PATHOPHYSIOLOGY OF FETAL OVERGROWTH

Maternal Glucose Concentrations. Because glucose is the most easily measured nutrient and marker of diabetes, most studies evaluating the effect of diabetes on fetal growth have used measures of glucose as a reference. Findings from the DIEP indicate that birth weight correlated best with second- and third-trimester postprandial glucose measures. When 2-hour postmeal glucose measures averaged 120 mg/dL or less, approximately 20% of infants were macrosomic. In contrast, when 2-hour postprandial glucose measures averaged up to 160 mg/dL, the rate of macrosomia reached 35%.¹⁰⁸ Similarly, Combs and coworkers¹⁰⁹ reported that macrosomia was significantly associated with postprandial glucose levels between 29 and 32 weeks' gestation.¹⁰⁹ In contrast, Persson and associates¹¹⁰ showed that fasting glucose concentrations account for 12% of the variance in birth weight and correlated best with estimates of neonatal fat. Uvena and colleagues¹¹¹ found the strongest correlation was between fasting glucose and neonatal adiposity, rather than postprandial measures.

Fetal Insulin Concentrations. Based on the early work of Pedersen,¹¹² fetal insulin has long been considered a principal driving

factor of in utero fetal growth. Experimental data gathered from non-human primates by Susa and coworkers¹¹³ showed that in the rhesus monkey when implanted with an Alzet pump, which delivered continuous, increasing insulin concentrations to the fetus independent of the mother's metabolic condition, there was evidence of fetal overgrowth.¹¹¹ In contrast, when genetic mutations such as glucokinase deficiencies existed only in the fetus, the inability of the beta cell to respond to increasing glucose concentrations results in fetal growth restriction.²⁵ Many studies have confirmed the correspondence of increased cord insulin concentrations with fetal macrosomia. Schwartz and associates¹¹⁴ found that umbilical cord insulin concentrations at delivery correlated with the degree of macrosomia. Cordocentesis studies in late third trimester showed that the ratio of fetal plasma insulin to glucose and the degree of macrosomia were strongly correlated.¹¹⁵ Krew and colleagues¹¹⁶ reported that amniotic fluid C-peptide measures at term had a strong correlation with fetal adiposity but not lean body mass.

The relationship between elevated insulin concentrations and fetal macrosomia exists in late pregnancy, and there is evidence of altered metabolic function in early gestation. Carpenter and colleagues¹¹⁷ reported that elevated amniotic fluid insulin concentrations obtained from normoglycemic patients at 14 to 20 weeks' gestation and adjusted for maternal age and weight correlated with the likelihood of subsequently diagnosed GDM (OR = 1.9; CI, 1.3 to 2.4). Each increase in amniotic fluid insulin multiple of the median (MOM) was associated with a threefold increase in fetal macrosomia.¹¹⁷ These data support the concept that the underlying pathophysiology of GDM and fetal macrosomia may exist earlier in gestation than is routinely screened for and that it is consistent with subclinical pregravid maternal metabolic disturbances.

Growth Factors. There has been considerable interest in the role of insulin-like growth factors (IGFs) and fetal growth. Members of the IGF family have been implicated in abnormalities of increased and decreased fetal growth in humans. IGF-1 and the ratio of IGF-2 to the IGF-2 soluble receptor have been positively correlated with the Ponderal index.¹¹⁸ However, there is also direct evidence using rodent

knockout models. Baker and coworkers¹¹⁹ reported that null mutations for the *IGF1* or *IGF2* gene decreases neonatal weight by 40% in mice. The effect of both genes is additive.¹¹⁹ Liu and associates¹²⁰ previously reported that IGF-1, IGF-2, and IGF-binding protein-3 (IGFBP-3) were significantly elevated in women with type 1 and 2 diabetes compared with a control group. These data are consistent with the findings of other investigators, including data for women with type 1 and 2 diabetes.^{121,122} Roth and colleagues¹²³ reported that cord levels of IGF-1 were significantly greater in macrosomic IDMs than in nonmacrosomic infants of glucose-tolerant or diabetic mothers. Radaelli and coworkers¹²⁴ showed that there was a strong negative correlation between maternal circulating IGFBP-1 and lean body mass in the infants. The study authors speculated that IGFBP-1 might influence fetal growth by affecting IGF mediated placental nutrient transport, particularly of glucose or amino acids rather than lipids. Decreased IGFBP-1 levels are in keeping with a potential negative transcriptional regulation of the *IGFBP1* gene by insulin.¹²⁴

Maternal Obesity. Obesity is an epidemic in developed countries and the developing world.¹²⁵ In the United States, the prevalence of obesity, defined as a body mass index (BMI = weight/height²) greater than 30 rose to 30.5% in 2000, compared with 22.9% from 1994 through 1998. The proportion of the population meeting the definition of overweight (BMI > 25) increased from 55.9% to 64.5% during the same period.¹⁸ The risk of obesity is disproportionate among the races, increasing most among African Americans and Hispanics, the same populations at risk for type 2 diabetes. Several studies suggest that maternal obesity before conception has an independent effect on fetal macrosomia. Vohr and associates¹²⁶ analyzed various risk factors for neonatal macrosomia in women with overt and GDM compared with obese and normal weight controls.¹²⁶ Multiple regression analyses revealed the pre-pregnancy weight and weight gain were significant predictors for infants of GDM and control mothers. In an effort to better understand the potential independent effect of maternal obesity on growth of infants of GDM and normoglycemic women, Catalano and colleagues¹²⁷ performed a stepwise logistic regression analysis on data for 220 infants of mothers with normal glucose tolerance and 195 infants of GDM (Table 46-8). Gestational age at term had the strongest correlation with birth weight and lean body mass. In contrast, maternal pregravid BMI had the strongest correlation (approximately 7%) with fat mass and percent body fat. Although almost 50% of the subjects had GDM, only 2% fraction of the variance was correlated to fat mass.¹²⁷ These data support an independent effect of maternal pregravid obesity on fetal growth, particularly fat mass, independent of GDM.

Other Fuels. Many factors are related to fetal overgrowth of the infant of a woman with diabetes. The significant decreases in insulin sensitivity in late gestation affect glucose and lipid and amino acid metabolism. Although we clinically concentrate on glucose, other nutrients most probably contribute to fetal overgrowth. This concept is consistent with the hypothesis of fuel-mediated teratogenesis first proposed by Freinkel in 1980.¹²⁸ Circulating amino acid concentrations reflect the balance between protein breakdown and synthesis. Dugleby and Jackson¹²⁹ estimated that there is a 15% increase in protein synthesis during the second trimester and a further 25% increase in the third trimester compared with levels in nonpregnant women. These differences appear to have a strong relationship to fetal growth, particularly lean body mass. Butte and coworkers¹³⁰ and Metzger and associates¹³¹ independently reported higher amino acid concentrations in women with GDM compared with a normoglycemic control group. Zimmer and colleagues¹³² reported no significant difference in amino acid turnover in women with GDM and a control group. However, the

investigators found that hyperinsulinemia was required to maintain normal amino acid turnover in the GDM women.¹³² Kalhan and coworkers¹³³ reported that leucine turnover and oxidation were greater in the obese woman with GDM compared with less obese control subjects. The increased insulin concentrations required to maintain appropriate amino acid levels in the woman with diabetes may be another manifestation of the increased insulin resistance in pregnant women with GDM.

Knopp and associates¹³⁴ found that there is a twofold to fourfold increase in triglyceride concentrations and a 25% to 50% increase in cholesterol during gestation. This group also reported a further increase in triglyceride and high-density lipoprotein cholesterol concentrations in type 2 and GDM patients.¹³⁵ Similarly, Xiang and colleagues⁴³ described increased basal free fatty acid concentrations in Hispanic women with GDM in the third trimester compared with a matched control group.¹³⁶ Knopp and coworkers¹³⁷ also reported that mid-tri-

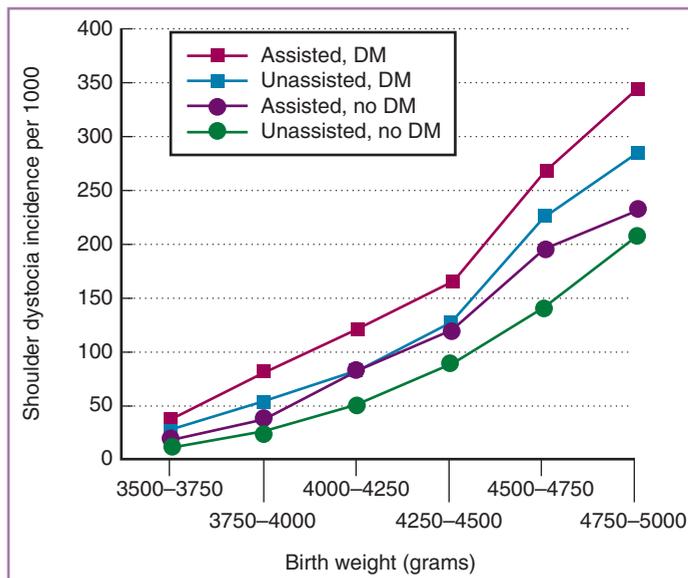

FIGURE 46-10 Risk of shoulder dystocia by diabetes status and instrumental delivery. Shoulder dystocia occurred more often in diabetic deliveries requiring operative vaginal assistance and in fetuses above the 90th percentile of birth weight for age. DM, diabetes mellitus. (From Nesbitt TS, Gilbert WM, Herrchen B: Shoulder dystocia and associated risk factors with macrosomic infants born in California. *Am J Obstet Gynecol* 179:476, 1998.)

mester triglyceride concentrations were a better predictor of macrosomia than glucose values during the glucose tolerance test. Similarly, Kitajima and colleagues¹³⁸ examined lipid profiles in women with an abnormal glucose challenge test in pregnancy and reported that the triglycerides had a significant correlation with birth weight, even after adjusting for significant covariables. Although lipid transport from the mother to fetus is not well understood, maternal lipid metabolism may play a significant role in fetal growth, particularly in accrual of adipose tissue.

Birth Injury

Birth injury is more common among the offspring of diabetic mothers, and macrosomic fetuses are at the highest risk.¹³⁹ The most common birth injuries associated with diabetes are brachial plexus palsy, facial nerve injury, humerus or clavicle fracture, and cephalhematoma. Athukorala and associates¹⁴⁰ studied women with gestational diabetes and found a positive relationship between the severity of maternal fasting hyperglycemia and the incidence of shoulder dystocia, with a doubling of risk with each 1-mmol increase in the fasting plasma glucose value on the OGTT. Shoulder dystocia occurred more often in diabetic deliveries requiring operative vaginal assistance (RR = 9.58; CI, 3.70 to 24.81; $P < .001$) and in fetuses above the 90th percentile of birth weight for age (RR = 4.57; CI, 1.74 to 12.01; $P < .005$) (Fig. 46-10).

Most of the birth injuries occurring in infants of diabetic pregnancy are associated with difficult vaginal delivery and shoulder dystocia. Although shoulder dystocia occurs in 0.3% to 0.5% of vaginal deliveries among normal pregnant women, the incidence is twofold to fourfold higher for women with diabetes because the excessive fetal fat deposition associated with hyperglycemia in poorly controlled diabetic pregnancy causes the fetal shoulder and abdominal widths to become massive.¹⁴⁰ Although one half of shoulder dystocias occur in infants of normal birth weight (2500 to 4000 g), the incidence of shoulder dys-

tocia rises 10-fold to 5% to 7% among infants weighing 4000 g or more. However, if maternal diabetes is present, the risk at each birth-weight class is increased fivefold.¹⁴¹ These risks are further magnified if a forceps or vacuum delivery is performed.¹⁴²

The level of glycemic control is strongly correlated with the risk of shoulder dystocia and birth injury, presumably because increasing levels of hyperglycemia are associated with greater fetal fat deposition. Athukorola and colleagues¹⁴⁰ reported a positive correlation between the severity of maternal fasting hyperglycemia and the risk of shoulder dystocia, with each 1-mmol increase in the fasting value in the OGTT associated with an increasing relative risk of 2.09 (CI, 1.03 to 4.25).

Although it would be desirable to predict shoulder dystocia on the basis of warning signs during labor such as labor protraction, a suspected macrosomic infant, or the need for midpelvic forceps delivery, less than 30% of these events can be predicted from clinical factors.¹⁴³

Neonatal Morbidity and Mortality

Polycythemia and Hyperviscosity

Polycythemia (i.e., central venous hemoglobin concentration >20 g/dL or hematocrit >65%) occurs in 5% to 10% of IDMs and is apparently related to glycemic control. Hyperglycemia is a powerful stimulus for fetal erythropoietin production, which is probably mediated by decreased fetal oxygen tension.¹⁴⁴ Untreated, neonatal polycythemia may promote vascular sludging, ischemia, and infarction of vital tissues, including the kidneys and central nervous system.

Neonatal Hypoglycemia

Approximately 15% to 25% of neonates delivered from women with diabetes during gestation develop hypoglycemia during the immediate newborn period.¹⁴⁵ Neonatal hypoglycemia is less common when tight glycemic control is maintained during pregnancy¹⁴⁶ and in labor.

A detailed study by Taylor and associates¹⁴⁷ found no correlation between the likelihood of neonatal hypoglycemia and Hb A_{1c}, whereas mean maternal glucose levels during labor were strongly predictive. Because unrecognized postnatal hypoglycemia may lead to neonatal seizures, coma, and brain damage, it is imperative that the neonatal team caring for the neonate follow a protocol of frequent postnatal glucose monitoring until metabolic stability is ensured.

Neonatal Hypocalcemia and Hyperbilirubinemia

Low levels of serum calcium (<7 mg/100 mL) have been reported in up to 50% of IDMs during the first 3 days of life, although later series record an incidence of 5% or less with better-managed pregnancies.¹⁴⁸ Neonatal hyperbilirubinemia occurs in approximately 25% of IDMs, a rate approximately double that for normal infants, with prematurity and polycythemia being the primary contributing factors. Close monitoring of the newborn of diabetic pregnancy is necessary to avoid the further morbidity of kernicterus, seizures, and neurologic damage.

Hypertrophic and Congestive Cardiomyopathy

In some macrosomic, plethoric infants of mothers with poorly controlled diabetes, a thickened myocardium and significant asymmetrical septal hypertrophy has been described.¹⁴⁹ The prevalence of clinical and subclinical asymmetrical septal hypertrophy in IDMs has been estimated to be as high as 30% at birth, with resolution by 1 year of age.¹⁵⁰ Kjos and colleagues¹⁵¹ found that cardiac dysfunction associated with this entity often leads to respiratory distress, which may be mistaken for hyaline membrane disease.

IDMs who manifest cardiac dysfunction in the neonatal period may have congestive or hypertrophic cardiomyopathy. This condition is often asymptomatic and unrecognized. Echocardiograms show a hypercontractile, thickened myocardium, often with septal hypertrophy disproportionate to the ventricular free walls.¹⁵² The ventricular chambers are often smaller than normal, and there may be anterior systolic motion of the mitral valve, producing left ventricular outflow tract obstruction.

Neonatal septal hypertrophy may be a response to chronic hyperglycemia. The maternal level of IGF-1, which is elevated in suboptimally controlled diabetic pregnancy, is significantly elevated in neonates with asymmetrical septal hypertrophy. Because IGF-1 does not cross the placenta, it may exert its action through binding to the IGF-1 receptor on the placenta.¹⁵³ Halse and coworkers¹⁵⁴ found that the level of B-type natriuretic protein (BNP), a marker for congestive cardiac failure, is elevated in neonates whose mothers had poor glycemic control during the third trimester.

Septal hypertrophy can be identified with sonography in the prenatal period. Cooper and coworkers¹⁵⁵ performed serial fetal echocardiography on 61 pregnant, diabetic women, demonstrating excessive ventricular septal thickness in the fetuses that were diagnosed postnatally with asymmetrical septal hypertrophy. When the newborns with asymmetrical septal hypertrophy were compared with normal infants, birth weights (4009 versus 3457 g; $P < .01$) and maternal glycosylated hemoglobin levels (6.7% versus 5.7%) were higher in infants with cardiomyopathy.

Respiratory Distress Syndrome

Until recently, respiratory distress syndrome was the most common and most serious disease in IDMs. In the 1970s, improved prenatal maternal management for diabetes and new techniques in obstetrics for timing and mode of delivery resulted in a dramatic decline in its incidence, from 31% to 3%.¹⁵⁶ However, even when matched by gestational week of pregnancy, IDMs are more than 20 times as likely as infants from normal pregnancies to develop respiratory distress syndrome.¹⁵⁷

The increased susceptibility to respiratory distress may result from altered production of alveolar surfactant or abnormal pulmonary function. Kulovich and Gluck¹⁵⁸ reported delayed timing of phospholipid production in diabetic pregnancy, as indicated by a delay in the appearance of phosphatidylglycerol in the amniotic fluid. In their study, maturational delay occurred only in gestational diabetes (White class A patients); fetuses of women with other forms of diabetes showed normal or accelerated maturation of pulmonary phospholipid profiles.

Although some investigators have failed to demonstrate a delay in lung maturation in diabetic pregnancy,^{159,160} most reports in the literature indicate a significant biochemical and physiologic delay in IDMs. Tyden and colleagues¹⁶¹ and Landon and coworkers¹⁶² reported that fetal lung maturity occurred later in pregnancies with poor glycemic control (mean plasma glucose level >110 mg/dL), regardless of class of diabetes, when the infants were stratified by maternal plasma glucose levels. These findings were confirmed by Moore,¹⁶³ who demonstrated no differences in the rate of rise of the amniotic fluid lecithin-to-sphingomyelin ratio among types of diabetes or degree of glucose control but found that amniotic fluid phosphatidylglycerol was delayed approximately 1.5 weeks in women with pregestational or GDM diabetes compared with controls (Fig. 46-11). The delay in phosphatidylglycerol was associated with an earlier and higher peak in the level of phosphatidyl inositol, suggesting that elevated maternal plasma levels of myo-inositol in diabetic women may inhibit or delay the production of phosphatidylglycerol in the fetus.

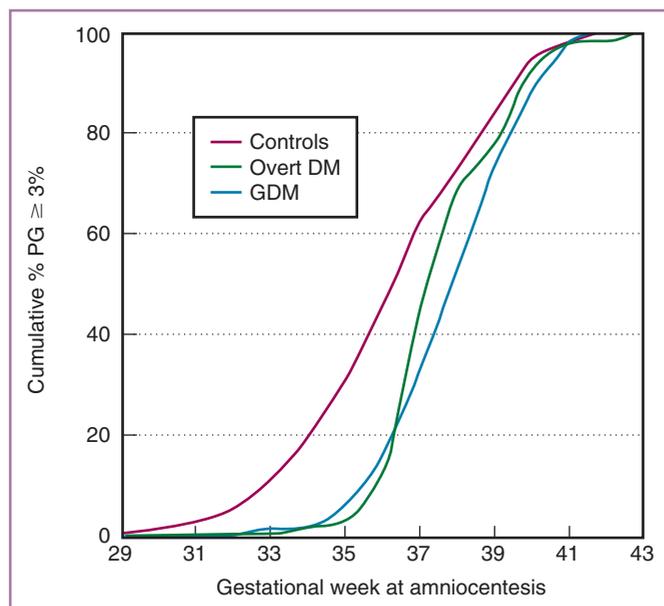

FIGURE 46-11 Delay in fetal pulmonary phosphatidyl glycerol. The delay in fetal pulmonary phosphatidyl glycerol was associated with a sustained peak in phosphatidyl inositol in diabetic pregnancy, suggesting that elevated maternal plasma levels of myoinositol in a diabetic woman may inhibit or delay the production of phosphatidyl glycerol in the fetus. DM, diabetes mellitus; GDM, gestational diabetes mellitus; PG, phosphatidyl glycerol. (From Moore TR: A comparison of amniotic fluid fetal pulmonary phospholipids in normal and diabetic pregnancy. *Am J Obstet Gynecol* 186:641, 2002.)

It is possible that poor neonatal respiratory performance in the IDM may have a histologic basis in addition to a biochemical cause. Kjos and coauthors¹⁵¹ identified respiratory distress in 3.4% of infants delivered of diabetic women, but surfactant-deficient airway disease accounted for less than one third of cases, with transient tachypnea, hypertrophic cardiomyopathy, and pneumonia responsible for most.

The near-term infant of a mother with poorly controlled diabetes is more likely to have neonatal respiratory dysfunction than is the infant of a nondiabetic mother. The observations of Moore¹⁶³ indicate that the average nondiabetic fetus achieves pulmonary maturity at 34 to 35 weeks' gestation, with more than 99% of normal newborns having a mature phospholipid profile by 37 weeks. In diabetic pregnancy, however, it cannot be assumed that lung maturity exists until approximately 10 days after the nondiabetic time (38.5 gestational weeks). Any delivery contemplated before 38.5 weeks' gestation for other than the most urgent fetal and maternal indications should be preceded by documentation of pulmonary maturity by amniocentesis. The neonatal complications of the offspring of diabetic pregnancy is discussed further in Chapter 58.

Long-Term Risks for the Fetus of the Obese Mother

Although much has been written about the increased risk of the metabolic syndrome (i.e., obesity, hypertension, insulin resistance, and dyslipidemia) in infants born SGA, evidence points toward an increase in adolescent and adult obesity in infants born LGA or macrosomic. There has been abundant evidence linking higher birth weights to increased obesity of adolescents and adults for at least 25 years.¹⁶⁴ Large

cohort studies such as the Nurses Health Study¹⁶⁵ and the Health Professional Follow-up Study¹⁶⁶ report a J-shaped curve (i.e., a slightly greater BMI among subjects born small but a much greater prevalence of overweight and obesity in those born large).¹⁶⁷ The increased prevalence of adolescent obesity is related to an increased risk of the metabolic syndrome. The increased incidence of obesity accounts for much of the 33% increase in type 2 diabetes, particularly among the young. Between 50% and 90% of adolescents with type 2 diabetes have a BMI greater than 27,¹⁶⁸ and 25% of obese children between 4 and 10 years old have impaired glucose tolerance.¹⁶⁹ The epidemic of obesity and subsequent risk for diabetes and components of the metabolic syndrome may begin in utero with fetal overgrowth and adiposity, rather than undergrowth.

A retrospective cohort study by Whitaker¹⁷⁰ enrolling more than 8400 children in the United States in the early 1990s reported that children who were born to obese mothers (based on BMI in the first trimester) were twice as likely to be obese when they were 2 years old. If a woman had a BMI of 30 or more in the first trimester, the prevalences of childhood obesity (BMI > 95th percentile based on criteria of the Centers for Disease Control and Prevention [CDC]) at ages 2, 3, and 4 years were 15.1%, 20.6%, and 24.1%, respectively. This was between 2.4 and 2.7 times the prevalence of obesity observed in children of mothers whose BMI values were in the normal range (18.5 to 24.9). This effect was only slightly modified by birth weight.

There is an independent effect of maternal pregravid weight and diabetes on birth weight and on the adolescent risk of obesity. Langer and colleagues¹⁷¹ reported that in obese women with GDM whose glucose was well controlled on diet alone, the odds of fetal macrosomia (birth weight >4000 g) were significantly increased (OR = 2.12) compared with women with well-controlled (diet only) GDM and normal BMIs. Similar results were reported for women with GDM who were poorly controlled with diet or with insulin. In well-controlled, insulin-requiring women with GDM, there was no significant increased risk of macrosomia with increasing pregravid BMI. Dabelea and associates¹⁷² reported that the mean adolescent BMI was 2.6 kg/m² greater in sibling offspring of diabetic pregnancies compared with the index siblings born when the mothers previously had normal glucose tolerance. Both maternal pregravid obesity and the presence of maternal diabetes may independently affect the risk of adolescent obesity in the offspring.

This risk of developing the metabolic syndrome in adolescents was addressed by Boney and colleagues¹⁷³ in longitudinal cohort study of AGA and LGA infants of women with normal glucose tolerance and GDM. The metabolic syndrome was defined as the presence of two or more of the following components: obesity, hypertension, glucose intolerance, and dyslipidemia. Maternal obesity was defined as a pregravid BMI higher than 27.3. Children who were LGA at birth had an increased hazard ratio (HR) for metabolic syndrome (HR = 2.19; CI, 1.25 to 3.82; *P* = .01) by age 11 years, as did children of obese women (HR = 1.81; CI, 1.03 to 3.19; *P* = .04). The presence of maternal GDM was not independently significant, but the risk for developing metabolic syndrome was significantly different between LGA and AGA offspring of GDM by age 11 years (RR = 3.6).

Childhood Neurologic Abnormalities

Several reports have suggested childhood neurodevelopmental abnormalities in offspring of diabetic mothers. Rizzo and colleagues¹⁷⁴ compared the offspring of 201 mothers with diabetes with 83 children of normal mothers and correlated subsequent childhood obesity in the offspring of diabetic mothers with internalizing behavior problems,

somatic complaints, anxiety or depression, and social problems. Ornoy and associates¹⁷⁵ assessed IQ scores on the Wechsler Intelligence Scale for Children–Revised (WISC-R) and Bender tests of the children born to diabetic mothers. No differences were found between the study groups in various sensorimotor functions compared with controls, but the children of diabetic mothers performed less well than controls in fine and gross motor functions, and they scored lower on the Pollack taper test, which is designed to detect inattention and hyperactivity. These investigators also found a negative correlation between the severity of maternal hyperglycemia, as assessed by glycosylated hemoglobin levels in the third trimester, and performance on neurodevelopmental and behavioral tests.

Preconceptional Management of Women with Pregestational Diabetes

Although widely underused,¹⁷⁶ preconceptional care programs have consistently been associated with decreased morbidity and mortality.¹⁷⁷ Patients enrolled in preconceptional diabetes-management programs obtain earlier prenatal care and have lower Hb A_{1c} values in the first trimester.¹⁷⁸ A comparison of outcomes among women participating in a intensive preconceptional program with outcomes among women receiving standard care demonstrated lower perinatal mortality (0% versus 7%) and reduced congenital anomalies (2% versus 14%). When the preconceptional program was discontinued because of a lack of funds, the congenital anomaly rate increased by more than 50%.⁷

Risk Assessment

Several factors should be considered in preconceptional diabetes risk assessment (Table 46-9):

- Glycemic control should be assessed directly from glucose logs and by glycosylated hemoglobin levels.

- For patients who have had diabetes for 10 years or longer, an electrocardiogram, an echocardiogram, and microalbuminuria and serum creatinine studies should be performed.
- Because retinopathy can progress during pregnancy, the patient should establish a relationship with a qualified ophthalmologic provider. A baseline retinal evaluation should be completed within the year before conception, with laser photocoagulation performed if needed. Previous laser treatment is not a contraindication to pregnancy and may avoid significant hemorrhage during pregnancy.
- Thyroid function (i.e., thyroid-stimulating hormone and free thyroxine) should be evaluated and corrected as necessary in all patients with pregestational diabetes because of the frequent coincidence of autoimmune thyroid disease and diabetes.
- A daily prenatal vitamin that provides 1 mg of folic acid should be prescribed for a minimum of 3 months before conception, because folate supplementation significantly reduces the risk of congenital neural tube defects.
- The patient’s occupational, financial, and personal situation should be reviewed, because job and family pressures can become barriers to achieving and maintaining excellent glycemic control. In patients with pre-pregnancy hypertension or proteinuria, particular emphasis should be given to defining support systems that permit extended bed rest in the third trimester, if it becomes necessary.
- The patient’s preconception medications should be reviewed and altered to avoid teratogenicity and potential embryonic toxicity. Statins are pregnancy category X drugs and should be discontinued before conception. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) should be discontinued before conception because of first trimester teratogenicity and fetal renal toxicity in the second half of pregnancy. Among oral antidiabetic agents used by reproductive-aged women, metformin and acarbose are classified as pregnancy category B drugs, although systematic data on safety are lacking. All other agents are category C drugs, and unless the potential risks and benefits of oral antidiabetic agents in the preconception period have been

TABLE 46-9 PRECONCEPTIONAL EVALUATION OF THE DIABETIC PATIENT

Procedure	Tests	Recommendations
Medical history, family history, review of symptoms	Selected patients: fasting and postprandial C-peptide determinations to clarify type of diabetes	Avoid pregnancy until Hb A _{1c} value is in the normal, nonpregnant range

ECG, electrocardiogram; Hb, hemoglobin; T₄, thyroxine.

carefully weighed, they usually should be discontinued in pregnancy.

Metabolic Management

The goal of preconceptional metabolic management is to achieve an Hb A_{1c} level within the normal range before conception using a safe and reliable medication regimen that permits a smooth transition through the first trimester. The patient should be skilled in managing her glucose levels in a narrow range well before pregnancy begins, so that the inevitable insulin adjustments necessitated by the appetite, metabolic, and activity changes of early pregnancy can be accomplished smoothly.

A regimen of regular monitoring of preprandial and postprandial capillary glucose levels should be instituted. Although there are no data indicating that postprandial glucose monitoring is required before pregnancy to achieve adequate control, monitoring these levels increases the preconceptional woman's awareness of the interaction of dietary content and quality with postprandial glycemic excursions.¹⁷⁹ The insulin regimen should result in a smooth glucose profile throughout the day, with no hypoglycemic reactions between meals or at night.

Oral Hypoglycemic Agents

A longitudinal trial in the United Kingdom of intensified metabolic therapy in nonpregnant women with type 2 diabetes¹⁸⁰ demonstrated that oral agents were more effective than insulin in lowering Hb A_{1c} levels. This effect was attributed to improved compliance and fewer hypoglycemic reactions. For this and other reasons, most women with type 2 diabetes use one or more oral agents for glycemic control—typically metformin and a sulfonylurea or thiazolidinediones. Details of the mechanism of action and pharmacology of these oral hypoglycemic agents are discussed later. Despite the absence of evidence of teratogenicity for most of these compounds, none is recommended for use in pregnancy. Standard practice is to transition these patients to insulin management preconceptionally.

A possible exception is the use of metformin in infertile patients with polycystic ovary syndrome who are otherwise oligo-ovulatory. These patients have higher conception and lower miscarriage rates with metformin treatment.¹⁸¹ Although two small series documenting the apparent safety of continuing metformin during pregnancy have been published,^{182,183} discontinuing metformin after pregnancy is established is recommended.

Metformin readily crosses the placenta, exposing the fetus to concentrations approaching those in the maternal circulation. The sequelae of such exposure (i.e., effects on neonatal obesity and insulin resistance) remain unknown. A study of perfused human placental lobules from gestational diabetic and normoglycemic women demonstrated that metformin was readily transferred from the maternal to the fetal circulation.¹⁸⁴

A more direct assessment of maternal and fetal pharmacodynamics was performed by Charles and coworkers¹⁸⁵ by obtaining maternal blood in the third trimester from metformin takers with gestational or type 2 diabetes. Cord blood also was obtained. Mean metformin concentrations in cord and maternal plasma were 0.81 and 1.2 mg/L, respectively. The maternal plasma half-life is 5.1 hours. Because these pharmacokinetics are similar to those in nonpregnant patients, no dosage adjustment is warranted.¹⁸⁵

With regard to teratogenicity associated with metformin use in pregnancy, Gilbert and associates performed a meta-analysis of eight

available studies. The malformation rate in the disease-matched control group was approximately 7.2%, statistically significantly higher than the rate found in the metformin group (1.7%). After adjustment for confounders, first-trimester metformin treatment was associated with a statistically significant 57% reduction in birth defects.¹⁸⁶

In a study of women with type 2 diabetes mellitus, 93 of whom took metformin (61 in the first trimester and 32 throughout the pregnancy) and 121 of whom did not take metformin, there was no difference between the metformin and control groups in the rate of preeclampsia (13% versus 14%; $P = .84$), perinatal loss (3% versus 2%; $P = .65$), or neonatal morbidity, including rate of prematurity (23% versus 22%; $P = .7$), admission to the neonatal unit (40% versus 48%; $P = .27$), respiratory distress (9% versus 18%; $P = .07$), and neonatal hypoglycemia (20% versus 31%; $P = .08$).¹⁸⁷

The concentrations of metformin in breast milk are generally low, and the mean infant exposure to metformin has been reported in the range of 0.28% to 1.08% of the weight-normalized maternal dose. No adverse effects on blood glucose of nursing infants have been reported.¹⁸⁸

Antihypertensive Medications

Hypertension is a common comorbidity of diabetes and is found in 20% to 30% of women who have had diabetes for longer than 10 years. Although treatment of modest degrees of hypertension (<160 mm Hg systolic) during pregnancy has not been shown to be beneficial in improving perinatal outcome,⁷⁴ treatment in nonpregnant diabetic women is recommended when blood pressure is consistently higher than 130/80 mm Hg.¹⁹ The U.K. Prospective Diabetes Study and the Hypertension Optimal Treatment trial demonstrated improved outcomes, especially in preventing stroke, in patients assigned to lower blood pressure targets. Patients frequently enter the preconceptional period taking one or more antihypertensive medications.¹⁸⁹ In preconceptional and pregnant patients with diabetes and chronic hypertension, blood pressure target goals of 110/65 to 129/79 mm Hg are recommended in the interest of long-term maternal health and minimizing impaired fetal growth.¹⁹

None of the commonly used antihypertensive medications (e.g., calcium channel blockers, β -blockers, methyldopa) is teratogenic. ACE inhibitors deserve special mention because in nonpregnant subjects with diabetic nephropathy, they have been shown to ameliorate proteinuria and delay progression to end-stage renal disease. These medications are therefore considered first-line agents for diabetic women with significant proteinuria.¹⁸⁰ Many women with type 1 diabetes present for consultation preconceptionally or even in early pregnancy while taking these medications. It is not clear whether these medications have teratogenic effects when used in the first trimester, but use in the second trimester and beyond can cause a marked reduction in fetal renal blood flow, resulting in oligohydramnios and even frank fetal renal failure.¹⁹⁰ These medications should not be used during pregnancy, especially after the first trimester. Similar concerns exist for other agents in this family (i.e., ARBs and angiotensin receptor antagonists).¹⁹¹

Diagnosing Diabetes

Overt Diabetes

Patients with type 1 diabetes are typically diagnosed during an episode of hyperglycemia, ketosis, and dehydration. Type 1 diabetes is rarely

diagnosed during pregnancy. The diagnosis of type 2 diabetes cannot be accomplished during pregnancy because of the overlap with early-onset gestational diabetes. **Although the finding of an elevated Hb A_{1c} level in early pregnancy may be suggestive, definitive diagnosis of type 2 diabetes must be made after pregnancy.** The diagnostic criteria recommended by the ADA for diabetes are listed in Table 46-2.

Hyperglycemia not sufficient to meet the diagnostic criteria for diabetes is categorized as IFG or IGT, depending on whether it is identified through a fasting plasma glucose level or a 75-g, 2-hour OGTT¹⁹:

IFG: fasting plasma glucose level of 100 to 125 mg/dL (5.5 to 6.9 mmol/L)

IGT: 2-hour plasma glucose level of 140 to 199 mg/dL (7.8 to 11 mmol/L)

Patients with IFG or IGT before pregnancy should be considered at extremely high risk for developing GDM. GDM patients whose postpartum testing results in the diagnosis of IFG or IGT are at significant risk for the disease evolving into frank diabetes within 5 to 10 years.

Patients with IFG or IGT should be counseled regarding weight loss and provided instruction for increasing physical activity. **Monitoring for the development of diabetes in those with prediabetes should be performed every 1 to 2 years.** Screening for and appropriate treatment for other cardiovascular risk factors (e.g., tobacco use, hypertension, dyslipidemia) is important. There is insufficient evidence to support the use of drug therapy in women with IFG or IGT.

Gestational Diabetes

Risk Factor Screening

Risk factor assessment for GDM should be performed at the first prenatal visit. High-risk clinical characteristics include the following:

- Age older than 35 to 40 years
- Obesity (BMI > 30)
- History of GDM
- Delivery of a previous LGA infant
- Polycystic ovary syndrome
- A strong family history of diabetes

Patients with these risk factors should receive plasma glucose screening without delay. **High-risk women not found to have GDM at the initial screening should be tested again between 24 and 28 weeks' gestation.**

Previously, screening of all pregnant women for GDM was recommended, but the ADA¹⁹² modified this recommendation such that screening can be omitted for low-risk women meeting all of the criteria listed in Table 46-10. This policy is based on the findings of Naylor and colleagues,¹⁹³ who reported that women with one or no risk factors had a 0.9% risk of GDM, whereas 4% to 7% of those with two to five risk factors were diagnosed with GDM, resulting in a sensitivity of approximately 80% with a false-positive rate of 13%.

One- or Two-Step Screening

The diagnosis of GDM is based on a positive OGTT result. Guidelines issued by the Fourth International Workshop-Conference on Gestational Diabetes Mellitus¹⁹⁴ and reaffirmed by the Fifth International Conference¹⁹⁵ and the American College of Obstetricians and Gynecologists (ACOG)¹⁹⁶ recommend the use of the Carpenter and Coustan diagnostic criteria for the 3-hour, 100-g glucose OGTT (Table 46-11). However, these expert bodies also acknowledge the alternative use of a single-step, 2-hour, 75-g glucose OGTT.

TABLE 46-10 LOW-RISK CRITERIA FOR GESTATIONAL DIABETES SCREENING

American Diabetes Association: Gestational diabetes mellitus: A position statement. *Diabetes Care* 27(Suppl 1):S88, 2004.

TABLE 46-11 THREE-HOUR 100-GRAM ORAL GLUCOSE TOLERANCE TEST FOR GESTATIONAL DIABETES

Test Prerequisites

1-hr, 50-g glucose challenge result ≥ 135 mg/dL

Overnight fast of 8-14 hr

Carbohydrate loading for 3 days, including ≥ 150 g of carbohydrate

Seated, not smoking during the test

Two or more values must be met or exceeded for a diagnosis of GDM

Assessment for Gestational Diabetes Mellitus	Plasma Glucose Level after a 100-g Glucose Load mg/dL (mmol/L)
Fasting	95 (5.3)
1 hr	180 (10.0)
2 hr	155 (8.6)
3 hr	140 (7.8)

cologists (ACOG)¹⁹⁶ recommend the use of the Carpenter and Coustan diagnostic criteria for the 3-hour, 100-g glucose OGTT (Table 46-11). However, these expert bodies also acknowledge the alternative use of a single-step, 2-hour, 75-g glucose OGTT.

ONE-STEP OPTION

The one-step, 75-g glucose, 2-hour OGTT, which is commonly used outside the United States, is no longer recommended because of its inferior detection rate of GDM. Mello and colleagues¹⁹⁷ compared the diagnostic efficiency of the 75-g, 2-hour OGTT with the 3-hour, 100-g OGTT and found that the **2-hour test was less than one half as sensitive in diagnosing GDM (5% versus 12%).**

The current one-step option involves direct administration of the 3-hour, 100-g glucose OGTT. **Two or more values must be met or exceeded for the diagnosis of GDM.** The critical cutoff values for the 3-hour OGTT are listed in Table 46-11. Direct, one-step administration of the 3-hour, 100-g OGTT test should be considered in women with prior GDM, especially those with additional risk factors such as obesity.

TWO-STEP OPTION

In the two-step approach, a screening glucose challenge test (GCT) is administered using 50 g of glucose in the fasting or nonfasting state.

TABLE 46-12 SENSITIVITY AND COST ASSOCIATED WITH UNIVERSAL AND SELECTIVE SCREENING WITH VARIOUS GLUCOSE CHALLENGE THRESHOLDS

Factor	Threshold Value for 1-hr, 50-g Glucose Challenge	
	130 mg/dL	140 mg/dL
Sensitivity (%)	100	79
Percent of population (%) requiring OGTT	22	13
	Threshold Value (mg/dL)	Sensitivity (%)
Universal	140	90
	130	100
Risk factors + age ≥ 25 yr	140	85
	130	95

OGTT, oral glucose tolerance test.

Adapted from Coustan DR, Nelson C, Carpenter MW, et al: *Maternal age and screening for gestational diabetes: A population based study. Obstet Gynecol* 73:557, 1989.

For those whose plasma glucose value obtained after 1 hour exceeds a critical threshold value, a 100-g, 3-hour OGTT is administered, using the diagnostic criteria listed in Table 46-11.

THRESHOLD VALUE FOR THE GLUCOSE CHALLENGE TEST

The sensitivity of the GDM testing regimen depends on the threshold value used for the 50-g GCT. Recommendations from the ADA¹⁹ and ACOG¹⁹⁶ explain that using a threshold value of 140 mg/dL results in approximately 80% detection of GDM, whereas using a threshold of 130 mg/dL results in 90% detection. A potential disadvantage of using the lower value of 130 mg/dL is an approximate doubling in the number of OGTTs performed. The Canadian study,¹⁹³ based on receiver-operator curve analysis, calculated that diagnostic efficiency was optimized when a GCT threshold of 130 mg/dL was used for intermediate-risk women (i.e., two to four risk factors) and 128 mg/dL for higher-risk women. These issues are summarized in Table 46-12.

A threshold plasma glucose value of 130 mg/dL is recommended for use in practices with a significant proportion of higher-risk gravidas (e.g., multiracial, obese). This approach provides excellent test sensitivity for GDM (>90%) with acceptable cost. Definitive randomized trials regarding cost-effectiveness with respect to perinatal outcomes and neonatal costs have not yet been performed.¹⁹⁸

MAXIMUM VALUE FOR THE GLUCOSE CHALLENGE TEST

The risk of GDM is approximately proportional to the result of the 1-hour GCT. Dooley and coworkers¹⁹⁹ found that among nonwhite women, the risk of GDM with a 1-hour glucose value of 200 mg/dL or more is greater than 90%. Bobrowski and colleagues²⁰⁰ reported that all patients with a screening result above 216 mg/dL had a positive 3-hour OGTT result. Most experts omit the 3-hour OGTT for patients with GCT results of 200 mg/dL or greater and manage the patient as a gestational diabetic.

SINGLE ABNORMAL VALUE ON THE 3-HOUR ORAL GLUCOSE TOLERANCE TEST

A fasting plasma glucose level exceeding 126 mg/dL should be considered highly suspicious for diabetes in pregnant and nonpregnant patients. Individuals with fasting plasma glucose levels above 126 mg/dL should have another fasting test; if the result of the second test is high, GDM is confirmed.

Patients with a single abnormal OGTT value are at increased risk for infants with macrosomia and neonatal morbidity. Berkus and colleagues²⁰¹ followed 764 patients with GDM, stratified by the number of abnormal values on their OGTTs. Patients with one or more abnormal OGTT values had double the incidence of macrosomic infants (23% to 27% versus 13%; $P < .01$). When Langer and coworkers²⁰² compared perinatal outcomes in patients with a single abnormal OGTT value with normal women and with aggressively managed GDM patients, they found the incidence of macrosomia to be more than threefold higher in the single abnormal value group than in the normal (34% versus 9%) and GDM (34% versus 12%) groups. Neonatal morbidity was fivefold higher in the single abnormal OGTT value group (15%) compared with the control and GDM groups (3%).

McLaughlin and colleagues²⁰³ reviewed the perinatal outcomes of 14,036 women who had normal 1-hour or 3-hour glucose levels using standard criteria (i.e., 1-hour GCT cutoff of 140 mg/dL and 3-hour OGTT [see Table 46-11]). Of these, 3% had a single elevated value on the 3-hour test. Comparing the single elevated value group to those with all normal values, higher rates of cesarean delivery, preeclampsia, chorioamnionitis, birth weights higher than 4000 g and 4500 g, and neonatal intensive care unit admission were recorded (adjusted OR = 1.6, 1.5, 1.5, 1.7, 2.2, and 1.5, respectively; $P < .03$).²⁰³

These results underscore the problems associated with the methods used to identify patients with GDM. The relationships among carbohydrate metabolism, macrosomia, and neonatal morbidity create a continuum that defies a single, clear-cut criterion for diagnosis in all populations. The recommended schemes identify at most 90% of pregnancies susceptible to hyperglycemia and fetal macrosomia. The astute clinician should approach women with several GDM risk factors and a single abnormal OGTT value with caution. When in doubt, a trial of capillary glucose testing may help to clarify the patient's metabolic status.

Other Tests for Gestational Diabetes

Several investigators have searched for a single, nonglucose blood test that can accurately predict the results of the OGTT. Because of the proportional relationship of glycated proteins and long-term plasma glucose concentrations, fructosamine and Hb A_{1c} screening have been evaluated. Roberts and colleagues²⁰⁴ suggested that fructosamine screening for GDM could produce a sensitivity of 85% with a specificity of 95%. A positive relationship between fructosamine levels and macrosomia was demonstrated.^{205,206} However, subsequent studies have reported significantly lower sensitivities.^{207,208}

Inferior sensitivity and predictive values have been reported for glycohemoglobin measurements (i.e., Hb A₁ and Hb A_{1c}) by Shah and colleagues,²⁰⁹ Baxi and associates,²¹⁰ and Artal and coworkers²¹¹ (22%, 63%, and 74%, respectively). A study by Agarwal and associates²¹² assessed the use of lower cutoffs for fructosamine and Hb A_{1c} to exclude subjects from further GDM screening and higher cutoffs for one-step diagnosis. The lower cutoffs achieved sensitivities of 90% and negative predictive values of more than 85%. However, the upper cutoff values did not achieve acceptable positive predictive values to be useful for diagnosing GDM. Thus the role of these tests would be to identify patients rather than to screen for GDM, but using them would impose

TABLE 46-13 PREVALENCE OF GESTATIONAL DIABETES IN VARIOUS NATIONAL AND ETHNIC GROUPS

an additional step and cost on the diagnostic regimen. Although screening with glycosylated proteins could theoretically reduce the number of two-step diagnostic procedures, their lack of sensitivity in diagnosis and the additional time and cost have left these studies of limited use in screening for GDM.

Timing of Gestational Diabetes Screening

FIRST-TRIMESTER SCREENING

The timing of glucose tolerance testing during pregnancy is critical, because delayed diagnosis increases the duration of deranged maternal metabolism and accelerated fetal growth. However, because the prevalence of GDM increases with advancing gestation due to rising insulin resistance mediated by placental hormones, testing too early can overlook some patients who will develop disease later.

A surprising percentage of patients (6% to 20%) with GDM can be diagnosed in the first trimester. Most have significant risk factors for glucose intolerance. Moses and associates²¹³ assessed the prevalence of GDM in patients with various risk factors. GDM was identified in 6.7% overall, in 8.5% of women 30 years old or older, in 12.3% of women with a BMI of 30 or more, and in 11.6% of women with a family history of diabetes. A combination of risk factors predicted GDM in 61% of cases compared with 4.8% of those without risk factors. The additional effect of ethnicity on the prevalence of GDM is summarized in Table 46-13.

Risk factor assessment for GDM (i.e., maternal age, ethnicity, obstetric and family history, body habitus, prior GDM, prior IGT, prior macrosomic infant, or unexplained stillbirth) should be performed at the first prenatal visit of all pregnant women. Patients with any of these risk factors (Table 46-14) should undergo screening as soon as feasible, and if results are negative, tests should be repeated at 24 to 28 weeks' gestation.

THIRD-TRIMESTER SCREENING

Because the insulin resistance that causes hyperglycemia increases as the third trimester progresses, early testing may miss some patients who later become glucose-intolerant. Performing the test too late in

TABLE 46-14 RISK FACTORS FOR GESTATIONAL DIABETES

Patients with any of these factors should be screened for GDM at the first prenatal visit:

- Maternal age >25 yr
- Previous macrosomic infant
- Previous unexplained fetal demise
- Previous pregnancy with GDM
- Strong immediate family history of NIDDM or GDM
- Obesity (>90 kg)
- Fasting glucose >140 mg/dL (7.8 mM) or random glucose >200 mg/dL (11.1 mM)

GDM, gestational diabetes mellitus; NIDDM, non-insulin-dependent diabetes mellitus.

the third trimester limits the time in which metabolic intervention can take place. **For this reason, it is recommended that glucose tolerance testing be performed in all patients at 24 to 28 weeks' gestation.**²¹⁴

Whether administered at 12 or 26 weeks, the GCT can be performed without regard to recent food intake (i.e., nonfasting state). Coustan and coworkers²¹⁵ have shown that tests performed in fasting subjects are more likely to yield falsely elevated results than are tests conducted between meals. This finding was confirmed by Sermer and colleagues.²¹⁶

Metabolic Management of Women with Pregestational Diabetes

The primary goals of metabolic management (i.e., glycemic monitoring, dietary regulation, and insulin therapy) in diabetic pregnancy are to prevent or minimize the postnatal sequelae of diabetes—macrosomia, shoulder dystocia, birth injury, and postnatal metabolic instability—in the newborn. A secondary goal is to reduce the risk of pediatric and adult metabolic syndrome in the offspring. If this goal is to be achieved, glycemic control must be instituted early and aggressively.

Principles of Medical Nutritional Therapy

There is a surprising lack of well-controlled research on the optimal diet for lean or obese women with diabetes. Most recommendations regarding dietary therapy are based on common sense and experience. Because women with all types of diabetes experience inadequate insulin action after feeding, the goal of medical nutritional therapy is to avoid single, large meals containing foods with a high percentage of simple carbohydrates that release glucose rapidly from the maternal gut. **Three major meals and three snacks are preferred, because this multiple-feeding regimen limits the amount of calories presented to the bloodstream during any given interval. The use of nonglycemic foods that release calories from the gut slowly also improves metabolic control. Examples include foods with complex carbohydrates and fiber, such as whole-grain breads and legumes. Carbohydrates should account for no more than 50% of the diet, with protein and fats equally accounting for the remainder.**¹⁹

Medical nutritional therapy should be supervised by a trained professional—ideally, a registered dietitian. In many programs, die-

tary counseling is capably provided by a certified diabetes educator. In any case, formal dietary assessment and counseling should be provided at several points during the pregnancy to design a dietary prescription that can provide adequate quantity and distribution of calories and nutrients to meet the needs of the pregnancy and support achieving the plasma glucose targets that have been established. For obese women (BMI > 30 kg/m²), a 30% to 33% calorie restriction (to 25 kcal/kg of actual weight per day or less) has been shown to reduce hyperglycemia and plasma triglycerides with no increase in ketonuria.

Moderate restriction of dietary carbohydrates to 35% to 40% of calories has been shown to decrease maternal glucose levels and improve maternal and fetal outcomes.²¹⁷ In a nonrandomized study, subjects with low-carbohydrate intake (<42%) frequently required the addition of insulin for glucose control (RR = 0.14; *P* < .05), had a significantly lower rate of macrosomia (RR = 0.22; *P* < .04), and had a lower rate of cesarean deliveries for cephalopelvic disproportion and macrosomia (RR = 0.15; *P* < .04).

Low-Glycemic Foods

Manipulation of the type of carbohydrate in the diet can provide additional benefits in glycemic control. Crapo and coauthors²¹⁸ compared the blood glucose excursions induced by the ingestion of 50 g of carbohydrate from dextrose, rice, potatoes, corn, and bread. They observed that the highest glucose response occurred with dextrose and potatoes, with much lower peaks occurring after intake of corn and rice. This led to the concept of classifying foods by their glycemic index related to their tendency to induce hyperglycemia. In general, low-glycemic foods, such as complex (rather than simple) carbohydrates and those with higher soluble fiber content, are associated with a more gradual release of glucose into the bloodstream.

Formal dietary consultation at periodic intervals during the pregnancy improves metabolic control. Timing and content of meals should be reviewed at each visit together with the patient's individual food preferences. In all pregnant women, the continuing fetal consumption of glucose from the maternal bloodstream results in a steady downward drift in maternal glucose levels unless feeding occurs. In patients taking insulin or oral hypoglycemics, prolonged periods (>4 hours) without food intake increase the risk of hypoglycemic episodes. In these patients, a rather rigid schedule of three meals plus snacks at mid-morning, mid-afternoon, and bedtime is often necessary to achieve smooth control. Because insulin resistance changes dynamically during pregnancy, the dietary prescription must be continually adjusted according to the patient's weight gain, insulin requirement, and pattern of exercise.

Avoiding Nocturnal Hypoglycemia

Unopposed intermediate-acting insulin action during the hours of sleep frequently results in severe nocturnal hypoglycemia at 3 to 4 AM in individuals with type 1 diabetes. Reducing the insulin dose to avoid this complication typically leads to unacceptably high glucose levels on rising at 6 to 7 AM, whereas adding a bedtime snack helps to moderate the effect of bedtime insulin and to sustain glucose levels during the night. The snack should contain a minimum of 25 g of complex carbohydrate and enough protein or fat to help prolong release from the gut during the hours of sleep.

Avoiding Ketosis

The issue of maternal ketosis and its potential effect on childhood mental performance is a source of continuing controversy. Churchill and associates²¹⁹ reported that ketonuria during pregnancy is associ-

ated with impairment of neuropsychological development of offspring. This report has resulted in admonitions to avoid caloric reduction in any pregnant woman. The methodology in Churchill and associates' study has been criticized, however, because the ketonuria data were obtained from many different hospitals by having a nurse obtain a single urine sample for ketone testing on the day of delivery.

Coetzee and colleagues²²⁰ found morning ketonuria in 19% of women with insulin-independent diabetes on a 1000-calorie diet, 14% of those on a 1400- to 1800-calorie diet, and 7% of normal pregnant women on a free diet. There were no untoward neonatal events in infants of any of the ketonuric mothers. Rizzo and coworkers¹⁷⁴ studied 223 pregnant women with diabetes and their offspring and 35 with normal glucose tolerance and found no relationship between maternal hypoglycemia and intellectual function of the offspring.

There may be a difference between starvation ketosis and the ketosis that develops with poorly controlled diabetes. Ketonuria develops in 10% to 20% of normal pregnancies after an overnight fast and may protect the fetus from starvation in the nondiabetic mother. In the final analysis, significant maternal ketonemia resulting in maternal acidemia is probably unfavorable for the mother and fetus. The small degrees of ketosis occurring in many pregnant women, including those with diabetes, are unlikely to lead to measurable deficits in the newborn.

Principles of Glucose Monitoring

Glycohemoglobin

Measurements of glycosylated hemoglobin have proved to be a useful index of glycemic control over the long term (4 to 6 weeks), providing a numeric index of the patient's overall compliance.²²¹ Although assessing Hb A_{1c} levels every 4 to 6 weeks during pregnancy rarely alters management significantly, it can provide the patient with a score by which she can rate the success of her hourly efforts to keep her blood glucose levels within a narrow range. Glycohemoglobin levels are too crude to guide the adjustments to insulin.

Self-Monitoring of Blood Glucose

The availability of capillary glucose chemical test strips has revolutionized the management of diabetes, and they should be considered the standard of care for pregnancy monitoring. The discipline of measuring and recording blood glucose levels before and after meals has a positive effect on improving glycemic control.²²²

TIMING OF CAPILLARY GLUCOSE MONITORING

The frequency and timing of self-monitoring of blood glucose should be individualized (Table 46-15). However, because postprandial values have the strongest correlation with fetal growth, checking after meals is essential. The DIEP study reported that when postprandial glucose values averaged 120 mg/dL, approximately 20% of infants were macrosomic, whereas a modest 30% rise in postprandial glucose levels to a mean level of 160 mg/dL resulted in a 35% rate of macrosomia.²²³ Similar results emphasizing postprandial blood glucose monitoring were reported by de Veciana and associates,²²⁴ who randomized diabetic women to use of preprandial or postprandial blood glucose levels for dietary and insulin management. The women managed using postprandial levels had markedly better results than did those managed using preprandial levels. In the postprandial group, with the mean (\pm standard deviation) change in the glycosylated hemoglobin value greater ($-3 \pm 2.2\%$ versus $0.6 \pm 1.6\%$; *P* < .001), the birth weights were lower (3469 ± 668 g versus 3848 ± 434 g; *P* = .01), and the rates of

TABLE 46-15 TIMING OF HOME CAPILLARY GLUCOSE MONITORING

Capillary Glucose Assessment	Advantage	Disadvantage
Preprandial	Permits prospective adjustment of food intake, supplementation of preprandial insulin	Preprandial or fasting glucose levels correlate poorly with fetal morbidity. Significant postprandial hyperglycemia may go undetected.
Postprandial	Permits supplementation of insulin to reduce postprandial glucose overshoots; improved postprandial control correlates with improved fetal or neonatal outcome	Results are obtained after food intake.
Bedtime	Permits adjustment of calories at bedtime snack, adjustment of bedtime insulin	
3-4 AM	Enables detection of nocturnal hypoglycemia	Interrupts sleep, may increase stress

neonatal hypoglycemia (3% versus 21%; $P = .05$) and macrosomia (12% versus 42%; $P = .01$) were lower.

With these facts in mind, a typical glucose monitoring schedule involves capillary glucose checks on rising in the morning, 1 or 2 hours after breakfast, before and after lunch, before dinner, and at bedtime. For patients taking intermediate- or long-acting medication at bedtime, a capillary glucose level between 3 and 4 AM (the lowest glucose level of the day) two to three times per week is helpful in interpreting the glucose values in the morning.

The clinician should be aware of the specific type of capillary glucose reflectance meter being used by the patient, because plasma glucose values are 10% to 15% less than those measured in whole blood from the same sample. Most of the newer reflectance meters are calibrated for plasma glucose readings. The target glucose values used in management depend on the type of meter used.

TARGET CAPILLARY GLUCOSE LEVELS

Controversy exists about whether the target glucose levels to be maintained during diabetic pregnancy should be designed to limit macrosomia or to closely mimic nondiabetic pregnancy profiles. The Fifth International Workshop-Conference on Gestational Diabetes¹⁹⁵ recommends the following:

- Fasting plasma glucose level of 90 to 99 mg/dL (5.0 to 5.5 mmol/L)
- and
- 1-hour postprandial plasma glucose level less than 140 mg/dL (<7.8 mmol/L)
- or
- 2-hour postprandial plasma glucose level less than 120 to 127 mg/dL (<6.7 to 7.1 mmol/L)

Only recently have data been reported that describe normal glucose variations during pregnancy in nondiabetic gravidas. The profiles described by Cousins and colleagues²²⁵ (Fig. 46-12) are derived from highly controlled studies in which volunteer subjects were fed test meals with specific caloric content on a rigid schedule. Parretti and coworkers²²⁶ profiled normal pregnant women twice monthly preprandially and postprandially during the third trimester. Testing was done with capillary glucose meters, and the women followed an ad libitum diet. The results of the 95th percentile of the plasma glucose excursions are shown in Figure 46-13. Fasting and premeal plasma glucose levels are usually below 80 mg/dL and often below 70 mg/dL. Peak postprandial plasma glucose values rarely exceed 110 mg/dL.

Yogev and colleagues²²⁷ obtained continuous glucose information from nondiabetic pregnant women using a sensor that monitored

interstitial fluid glucose levels, and they found results similar to those of Parretti and coworkers.²²⁶ The range of normal glucose levels occurring in nondiabetic pregnancy is summarized in Table 46-16.

In consideration of these facts, the target plasma glucose values to be used during pregnancy management of women with diabetes should range from 65 to 95 mg/dL preprandially and never exceed 130 to 140 mg/dL postprandially at 1 hour.²²⁶ Superb glycemic control requires attention to preprandial and postprandial glucose levels.

Principles of Insulin Therapy

Despite the fact that no available insulin delivery method approaches the precise secretion of the hormone from the human pancreas, the judicious use of modern insulins can mimic these patterns remarkably well. The goal of exogenous insulin therapy during pregnancy must be to achieve diurnal glucose excursions similar to those of nondiabetic pregnant women. Given that in normal pregnant women, postprandial blood glucose excursions are maintained within a relatively narrow range (70 to 120 mg/dL), the task of reproducing this profile is daunting and requires meticulous daily attention by both patient and physician.

As pregnancy progresses, the increasing fetal demand for glucose results in lower fasting and between-meal blood glucose levels, increasing the risk of symptomatic hypoglycemia. Upward adjustment of

short-acting insulins to control postprandial glucose surges within the target range only exacerbates the tendency to interprandial hypoglycemia. Any insulin regimen for pregnant women requires combinations and timing of insulin injections different from those that would be effective in the nonpregnant state. The regimens must be modified continually as the patient progresses from the first to the third trimester and as insulin resistance rises. The regimen should always be matched to the patient's unique physiology, work, rest, and food intake schedule.

Types of Insulin

The types of insulin frequently used in diabetes control are listed in Table 46-17. Several newer insulins are available for use, but most have not been extensively evaluated in pregnancy. They include the short-acting insulins lispro (Humalog) and aspart (Novolog) and the newer, very-long-acting, molecularly modified insulins detemir (Levemir) and glargine (Lantus). The activity profiles of the intermediate- and long-acting insulins are shown in Figure 46-14.²²⁸

Typical Insulin Regimens

Flexibility is important in dosing and adjusting insulin during pregnancy. Although most patients find it necessary to organize their meal-times and physical activity around their insulin regimen, changing the timing of insulin injections and types of insulin is frequently necessary

TABLE 46-17 INSULIN PREPARATIONS AND PHARMACOKINETICS

Insulin Preparation	Time to Peak Action (hr)*	Total Duration of Action (hr)*	Comment
Insulin lispro (Humalog)	1	2	Onset within 10 min of injection; no need to delay meal onset after injection
Insulin aspart (Novolog)	1	2	Onset within 10 min of injection; no need to delay meal onset after injection
Regular insulin	2	4	Good coverage of individual meals if injected 20 min before eating; increased risk of postprandial hypoglycemia with unopposed action 2-3 hr after eating.
NPH insulin	4	8	Provides intermediate-acting control; give on rising and at bedtime; risk of 3 AM hypoglycemia
Insulin glargine (Lantus)	5	<24	Prolonged flat action profile; limited pregnancy experience; increased risk of nocturnal hypoglycemia or undertreatment during the day

*Times are approximate in typical pregnant women with diabetes.

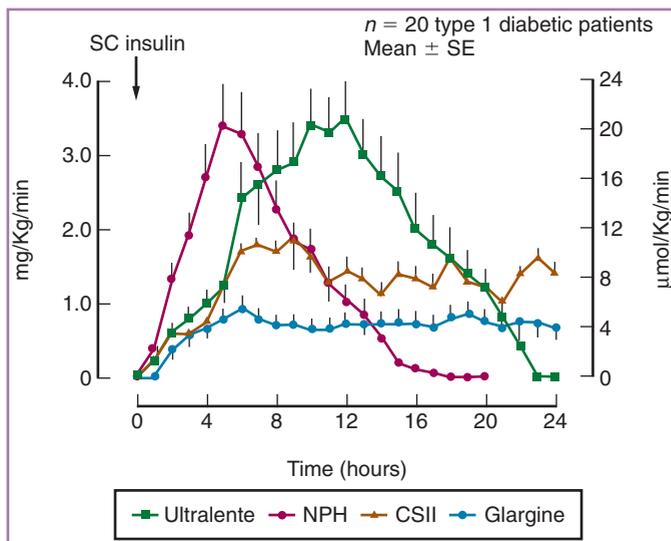

FIGURE 46-14 Activity profiles of intermediate- and long-acting insulins. The kinetics of NPH, Ultralente, glargine (Lantus), and continuous subcutaneous insulin infusion with lispro insulin are graphed. The curves show the glucose infusion rate necessary to maintain plasma glucose at 130 mg/dL. CSII, continuous subcutaneous insulin infusion; SC, subcutaneous; SE, standard error. (From Lepore M, Pampanelli S, Fanelli C, et al: Pharmacokinetics and pharmacodynamics of subcutaneous injection of long-acting human insulin analog glargine, NPH insulin, and Ultralente human insulin and continuous subcutaneous infusion of insulin lispro. *Diabetes* 49:2142, 2000. to match lifestyle and occupational needs and to optimize glycemic control. The following guidelines and examples can help in managing and adjusting insulin during pregnancy:

1. In the first trimester, reduce the insulin dose by 10% to 25% to avoid hypoglycemia. Reduced physical activity and caloric intake associated with the appetite changes and fatigue of early pregnancy lead to increased insulin effectiveness and interprandial hypoglycemia. It is typical to reduce insulin progressively from the 6th to the 14th week and then to begin restoring it as the insulin resistance

FIGURE 46-15 Progressive insulin requirements. The insulin requirements of women with gestational diabetes change throughout pregnancy. (From Langer O: Maternal glycemic criteria for insulin therapy in gestational diabetes mellitus. *Diabetes Care* 21[Suppl 2]: B91, 1998.)

- mediated by rising placental hormones returns in the second trimester. Jovanovic and colleagues¹⁰⁸ reported from the DIEP study that a significant 18% increase in mean weekly dosage was observed between weeks 3 and 7 ($P < .0001$), followed by a significant 9% decline from week 7 through week 15 ($P < .0001$). In women with pregestational diabetes, continual downward adjustment in insulin is typically required from the first prenatal visit until approximately 14 to 16 weeks, after which requirements begin to rise steadily.
2. A typical total insulin dose is 0.7 units/kg in the first trimester, but this must be increased progressively with pregnancy duration from the second trimester onward. In women with type 1 diabetes, insulin increases are usually 20% to 30% over nonpregnant baseline by the end of pregnancy (Figure 46-15).²²⁹ In insulin-resistant type 2 patients, 30% to 150% increases are not unusual. Insulin requirements normally plateau after 35 weeks' gestation and often drop significantly after 38 weeks.

3. The kinetics of NPH insulin are such that care must be taken to time peak action at 5 to 7 AM and avoid peaking at 4 AM, when maternal glucose levels are lowest. For many women, whose bedtime may be at 8 or 9 PM, NPH peaks early and exposes the mother and fetus to nocturnal hypoglycemia. It is often better to administer NPH at a set time between 10 and 11 PM, not the less accurate timing of "bedtime," to optimize needed insulin action during the hours of 5 to 7 AM.
4. A combination of short- and intermediate-acting insulins is employed to maintain glucose levels in an acceptable range. A typical regimen involves intermediate-acting insulin (NPH) before breakfast and at bedtime, with injections of regular or short-acting insulin before breakfast and before dinner. Two thirds of insulin is given in the morning and one third in the afternoon and at bedtime. For example, the regimen may be 20 units of NPH and 10 units of regular insulin in the morning, 8 units of regular insulin with dinner, and 8 units of NPH at 10 PM. The AM dose of NPH covers the periods before and after lunch. Avoid NPH injections at dinnertime because the peak occurs at 2 to 3 AM, creating symptomatic hypoglycemia.
5. Preprandial doses of regular insulin sufficient to keep 1-hour postprandial plasma glucose levels below 130 mg/dL may result in hypoglycemia 2 to 4 hours later (e.g., regular insulin before breakfast often causes hypoglycemia at 10 AM). When regular insulin is used to cover the major meals, snacks are essential in the late morning, the late afternoon, and before bedtime to avoid interprandial hypoglycemia. This interprandial hypoglycemia effect is intensified if the regular insulin injection is not given at least 20 to 30 minutes before the meal. This precaution is particularly relevant for hospitalized patients (because meals do not always arrive on schedule) and when taking meals in restaurants.
6. The short-acting insulins lispro or aspart are preferred during diabetic pregnancy. Lispro is manufactured by inverting a short amino acid sequence within the insulin molecule, resulting in a significantly faster onset of action. Lispro injections immediately before meals reduce the risk of hangover hypoglycemia because of the short duration of action. Using an *in vitro* perfusion model, Holcberg and colleagues²³⁰ reported that lispro does not cross the human placenta. Compared with regular human insulin, the peak serum lispro concentration is three times higher, time to peak is 4.2 times faster, the absorption rate constant is double, and the duration of action is one half as long.²²⁸ These kinetics allow the patient to inject insulin just before eating, rather than having to delay 20 to 30 minutes to allow regular insulin to begin its effect. Compared with regular insulin, lispro reduced postprandial hyperglycemia and decreased the rate of mild hypoglycemic episodes; it was also associated with lower predelivery Hb A_{1c} values and received higher patient satisfaction scores.²³¹ Similar findings have been reported when insulin aspart was compared with regular insulin.²³² In summary, lispro or aspart can be substituted 1:1 for regular insulin, and each is highly effective when given before meals in reducing postprandial glycemia while avoiding insulin hangover, which increases patient compliance. Short-acting insulins are effective when used in the insulin pump (discussed later).²³³ With regard to safety and effectiveness, small studies have indicated equivalent perinatal outcomes.^{234,235} Mathieson and coworkers²³⁶ reported similar perinatal outcomes but improved maternal glycemic control in pregnant women randomized to aspart or regular insulin, demonstrating significantly lower mean postprandial plasma glucose levels with aspart ($P = .003$). A more detailed study of glucose dynamics after administration of aspart or regular insulin to women

with gestational diabetes by Pettitt and associates²³⁷ found that glucose areas under the curve were significantly lower with insulin aspart (180-min area, 7.1 mg·h·dL⁻¹; $P = .018$) but not with regular insulin (30.2 mg·h·dL⁻¹; $P = .997$) or with no insulin (29.4 mg·h·dL⁻¹), indicating the potential for improved glycemic control with short-acting insulins compared with regular insulin.

7. The use of insulin glargine during pregnancy is problematic because of its 20- to 26-hour duration. In three large comparative trials of nonpregnant subjects, glargine decreased glycosylated hemoglobin or fasting blood glucose levels, or both, to an extent similar to that seen with NPH insulin. A lower incidence of hypoglycemia, especially at night, was reported in most trials with insulin glargine compared with NPH insulin.²³⁸ Experience is limited in pregnancy, but the few studies existing demonstrate satisfactory results.^{239,240} Although the relatively flat activity profile of glargine is attractive, the dose must be regulated to keep basal insulin action during the night from causing hypoglycemia. During the day, when insulin resistance and insulin requirements are higher, the nocturnal basal rate is usually inadequate, and NPH must be added. As shown in Figure 46-14, the nocturnal low glucose level (typically at 4 AM) decreases as the third trimester progresses. Great care must be exercised in using glargine to avoid severe nocturnal hypoglycemia. Glargine appears to be safe for use during embryogenesis if glucose control is adequate.²⁴¹

Adjusting Insulin Dosage Using Carbohydrate Counting, Preprandial Glucose Levels, and Insulin Corrections

Intermediate- and long-acting insulins should be adjusted no more frequently than weekly or biweekly to maintain preprandial plasma glucose levels in the target range (70 to 105 mg/dL). However, with short-acting insulins, glycemic control is better when the patient is able to vary, within a reasonable range, the insulin dose she uses to cover a meal, depending on its calorie content (or grams of carbohydrate) and the plasma glucose level existing at the time she begins eating. This often means varying short-acting insulin dosage with every injection.

CARBOHYDRATE COUNTING

Patients with pregestational diabetes are usually taught to count the grams of carbohydrate in their meals and adjust the short-acting insulin dosage accordingly. A typical meal containing 60 grams of carbohydrate may require 4 to 6 units of lispro (ratio of 1 unit of insulin to grams of carbohydrate of 1:15) in the nonpregnant individual. In the first trimester, a typical ratio is approximately 1:12. However, by the second trimester, more insulin is required (1:10 to 1:6), and in the third trimester, especially in patients with some degree of insulin resistance, ratios fall to 1:6 or even 1:2. The clinician should anticipate these increases in insulin as pregnancy progresses, because the patient often interprets these changes as errors or failure.

Carbohydrate counting has limits in accuracy (e.g., miscalculation of carbohydrate content, individual differences in glucose uptake dynamics), which may result in erratic control. During pregnancy, women who relatively strictly regiment their food quantity, content, and timing, so that carbohydrate calculations are within a reasonably narrow range, have better control.

PREPRANDIAL GLUCOSE LEVELS

Given the same calorie content of a meal, achieving target postprandial plasma glucose levels requires more insulin if the preprandial glucose level is higher. Allowing patients to add 2 units of lispro when

the preprandial glucose level exceeds 120 mg/dL and to reduce lispro dosage by 2 units when the preprandial glucose level is below 80 mg/dL provides smoother control and avoids undesired postprandial glycaemic excursions when the preprandial glucose is outside the target range.

INSULIN CORRECTIONS

Women with pregestational diabetes are frequently taught how to perform preprandial and postprandial insulin corrections. A typical regimen is to add 1 to 2 units of lispro for every 50 mg/dL that the glucose level is out of target range. A preprandial glucose level of 130 mg/dL would require 1 unit of lispro over the prescribed dose for that meal. As pregnancy progresses, corrections increase from 1 per 50 mg/dL to 1 per 20 mg/dL. However, the patient must be instructed not to take more than 4 to 6 correction units in a single bolus during pregnancy and instead retest glucose in 1 to 2 hours and apply an additional correction at that time.

Use of the Insulin Pump

Most of the principles described to enhance and smooth glycaemic control by manipulating timing, quantity, and type of insulin can be used with greater facility with continuous, subcutaneous insulin infusion delivered by a programmable pump. These devices, which infuse insulin by means of a convenient catheter placed into the subcutaneous tissue near the abdomen, can be programmed to provide varying basal and bolus levels of insulin, which change smoothly even while the patient sleeps or exercises.

The effectiveness of continuous, subcutaneous insulin infusion in pregnancy is well established.²⁴²⁻²⁴⁴ Hieronimus and colleagues²⁴⁵ compared outcomes of 33 pregnant women managed with insulin pumps with 23 receiving multiple injections and reported similar Hb A_{1c} levels and rates of macrosomia and cesarean deliveries. Lapolla and coworkers²⁴⁶ reported a small cohort of 25 women treated with insulin pumps in pregnancy compared with conventional insulin treatment (*n* = 68) and found no differences in glycaemic control or perinatal outcome.

Use of continuous, subcutaneous, programmable insulin infusion has several advantages over conventional intermittent insulin administration, including the convenience of changing basal rates automatically when the patient is asleep or otherwise occupied and providing adjustable boluses discreetly from a pump worn under the clothing without the need for needles, syringes, and medication vials. Because pump malfunctions, precipitation of insulin inside the pump mechanism, abscess formation, and poor uptake from the infusion site can occur unexpectedly, successful insulin pump use requires a meticulous patient, a knowledgeable diabetologist or perinatologist, and prompt availability of emergency counseling and assistance on a 24-hour basis.²⁴⁷

A properly designed insulin pump infusion scheme allows convenient tailoring of the insulin administration profile to the patient's individual metabolic and lifestyle rhythms. A sample regimen is shown in Table 46-18. The lowest infusion rate of the day is between 11 PM and 4 AM, when it is set at about 70% of the mean rate needed during the day. The basal rate must be increased to 1.3 to 1.5 times the mean daily rate between 5 AM and 10 AM to provide extra insulin coverage for the high insulin-resistance period as the day begins (i.e., dawn effect). For the remainder of the day (10 AM to 11 PM), a steady mean infusion rate is usually sufficient. Insulin boluses, programmed to limit the postprandial excursion to 130 mg/dL or less at 1 hour, are given as often as needed. The enhanced ability for the patient to administer extra insulin doses without syringes and insulin vials is of great value in improving the smoothness of glycaemic control.

Starting Insulin with Gestational Diabetes

Clinicians and patients are reluctant to start insulin in patients with gestational diabetes, but this intervention may be essential if macrosomia is to be reduced or avoided. Because the period of maximum fetal growth velocity (200 g/wk) and fat accretion occurs at approximately 33.5 weeks' gestation, delaying definitive therapy with repeated attempts to correct a suboptimal glucose profile with dietary adjustments may, by 33 to 34 weeks, have missed the time when glycaemic intervention is most effective in modulating fetal growth. It is reasonable to allow a 1- to 2-week trial of dietary management before resorting to other measures, but waiting longer does not significantly increase the likelihood of good control. McFarland and colleagues²⁴⁸ have shown that approximately 50% of patients achieve good glycaemic control during the first 2 weeks of dietary therapy, but by the 4th week, only an additional 10% attain acceptable blood glucose levels.

The value of insulin administration in gestational diabetes was assessed by Crowther and associates,²⁴⁹ who randomized 1000 women with gestational diabetes to insulin treatment or no medical therapy in the Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS trial). Controls with normal OGTT results were included in the trial. In the insulin group, glucose levels were maintained at less than 99 mg/dL before meals and less than 126 mg/dL 2 hours postprandially. The rate of serious perinatal complications was significantly lower among the infants of 490 women in the intervention group than among the infants of 510 women in the routine-care group (1% versus 4%; RR adjusted for maternal age, race or ethnic group, and parity = 0.33; CI, 0.14 to 0.75; *P* = .01). The intervention group had a significantly higher rate of labor induction than the routine-care group (39% versus 29%), but the rates of cesarean delivery were similar. Cord plasma glucose levels were higher in women receiving routine care compared with controls, but it was normalized by treatment for mild GDM (*P* = .01). At 3 months after delivery, the

Time	Basal Rate	Bolus (U)	Comment
12 midnight	0.6 U/hr		Lower basal rate for sleep
5 AM	1.5 U/hr		Higher basal rate opposes the "dawn effect" of rising serum glucose from 4 to 6 AM
7 AM		8	Prebreakfast bolus
9 AM	1.0 U/hr		Lower basal rate to match increased physical activity, decreased insulin needs
12 noon		4	Prelunch bolus
6 PM		4	Predinner bolus
10 PM	0.6 U/hr		Lower basal rate for sleep

intervention group had lower rates of depression and higher quality-of-life scores.

With regard to newborn outcomes in the ACHOIS trial, umbilical cord serum insulin and insulin to glucose ratio were similar between the three groups, but leptin concentration, an indicator of fat mass, was lower in treated women with GDM compared with routine care ($P = .02$), suggesting that treatment of GDM using diet, blood glucose monitoring, and insulin, if necessary, influences the fetal adipoinular axis, which may reduce the risk of childhood and adult obesity late in life.²⁵⁰

Jovanovic-Peterson and colleagues²⁵¹ reported a protocol in which GDM patients were treated with insulin if any fasting glucose level exceeded 90 mg/dL or postprandial glucose level exceeded 120 mg/dL. Over a period of 6 years, this protocol resulted in a decrease in the rate of macrosomic infants from 18% to 7% and a drop in the cesarean rate from 30% to 20%. Buchanan and associates²⁵² used ultrasound screening of fetal abdominal circumference in 303 diet-controlled GDM patients at 28 weeks to identify early macrosomia that might benefit from insulin treatment. When pregnancies with a fetal abdominal circumference above the 75th percentile were randomized to continued diet or twice-daily insulin therapy, birth weights and percentage of macrosomic infants were reduced in the insulin group (3647 ± 67 g versus 3878 ± 84 g; $P < .02$ and 13% versus 45%; $P < .02$). Neonatal obesity, as reflected by skinfold measurements at three sites ($P < .005$), also was lower.

The insulin regimen used in managing women with gestational diabetes should be designed to address the patient's individual glucose profile, because some women require insulin to prevent only fasting AM hyperglycemia and others only for postprandial excursions. Typically, one to several postprandial glucose levels become consistently above target as the patient's ability to compensate for rising insulin resistance becomes inadequate with diet alone. In such cases, giving short-acting insulin such as lispro or aspart (4 to 8 units to start) before meals is helpful. If more than 10 units of short-acting insulin is needed before the noon meal, adding a 6- to 8-unit dose of NPH before breakfast helps to achieve smoother control. If the fasting glucose levels rise above 90 to 95 mg/dL, 4 to 6 units of NPH insulin should be administered between 10 to 11 PM. The doses are scaled up as necessary, twice weekly or more often, to keep glucose levels within the target range.

Use of Oral Hypoglycemic Agents

Maintaining glucose levels within the target range requires meticulous attention to diet and physical activity. For many patients, injecting insulin frequently is impossible, and there are many initiatives to augment glucose control with oral agents, particularly in patients with insulin-resistant type 2 diabetes. An ideal treatment would reduce insulin resistance, improve insulin secretion or action, and delay the uptake of glucose from the gut. Current strategies are aimed at augmentation of insulin supply (i.e., sulfonylurea and insulin therapy), amelioration of insulin resistance (i.e., exercise, weight loss, and metformin and troglitazone therapy), and limitation of postprandial hyperglycemia (i.e., acarbose therapy).

Pharmacology and Safety

Sulfonylurea compounds, commonly prescribed in the past for patients with type 2 diabetes, have been considered contraindicated during pregnancy because of the high degree of transplacental penetration of most of these agents and the clinical reports of drug concentrations in the neonate higher than maternal levels associated with prolonged and severe neonatal hypoglycemia.²⁵³ However, rigorously designed trials

have not been performed to assess these agents during pregnancy. Reports of fetal anomalies have been largely anecdotal. An increased rate of congenital malformations, particularly ear anomalies, has been reported from a small case-control study.²⁵⁴ When Towner and coworkers²⁵⁵ evaluated the frequency of birth defects in fetuses of patients who took oral hypoglycemics during the periconceptional period, they found that the first-trimester glycohemoglobin level and duration of diabetes were strongly associated with fetal congenital anomalies but that use of oral hypoglycemic medications was not.

Interest in glyburide, a second-generation oral sulfonylurea available in the United States since 1984, has recently been rekindled. When glyburide was compared with first-generation sulfonylureas, it was equally effective, had a lower incidence of side effects, and reduced fasting blood glucose and glycohemoglobin levels, without the inconvenience of the additional training required to administer insulin. Because of its ability to enhance target tissue insulin sensitivity, glyburide has been shown to improve glycemic control in many type 2 diabetic patients who have previously failed therapy. As adjunctive therapy, glyburide can reduce the daily dosage for those who require large amounts of insulin.²⁵⁶

Glyburide

A unique characteristic of glyburide that allows its use in pregnancy is its minimal transport across the human placenta.²⁵⁷ A study by Elliott and colleagues²⁵⁸ evaluated glyburide transport in 10 term human placentas with the single-cotyledon placental model and found virtually no transfer of glyburide even at concentrations 100 times the typical therapeutic levels. This surprisingly low placental transfer may result from the very high plasma-protein binding of glyburide coupled with a short elimination half-life of 4 to 8 hours.^{257,259}

Based on findings consistently showing minimal transfer of glyburide across the placenta, Langer and colleagues²⁶⁰ designed a randomized trial to compare this oral agent with insulin in patients with gestational diabetes. They randomized 404 women with second- and third-trimester singleton pregnancies who had gestational diabetes requiring treatment to receive glyburide or insulin in an intensified treatment protocol. At the conclusion of the trial, there was no difference between the groups in mean maternal blood glucose, percentage of infants who were LGA (12% and 13%, respectively), birth weight at or above 4000 g (7% and 4%), or neonatal complications (pulmonary, 8% and 6%; hypoglycemia, 9% and 6%; admission to neonatal intensive care unit, 6% and 7%; fetal anomalies, 2% and 2%). Only 4% of the glyburide group required insulin therapy. Glyburide was not detected in the cord serum of any infant in the glyburide group. However, only 82% of the glyburide and 88% of the insulin-treated patients achieved the target level of glycemic control, representing a glyburide "failure rate" of 18%. With regard to glyburide dosing during the trial, 31% of patients were treated with 2.5 mg, 21% with 5 mg, 19% with 10 mg, 9% with 15 mg, and 20% with 20 mg. The mean glyburide dose was 9.2 mg. Of the maternal outcome variables assessed, none was significantly different between groups except the dramatic ($P = .03$) reduction in maternal hypoglycemic episodes in the glyburide-treated group (2%) compared with the 20% rate for insulin.

Beyond this single encouraging study, further nonrandomized experience with glyburide during pregnancy is accumulating.^{261,262} Chmait and coworkers,²⁶³ describing their experience with 69 patients with gestational diabetes managed on glyburide, reported that 19% of patients required adjunctive insulin therapy to keep glucose values in the target range. The adjunctive insulin rate was higher for women diagnosed earlier in pregnancy (20 versus 27 weeks; $P < .003$) and those whose average fasting glucose in the week before starting glyburide was

higher (126 versus 101 mg/dL). No cases of neonatal hypoglycemia occurred in the glyburide group.

Langer and colleagues²⁶⁴ reanalyzed the previously cited randomized, controlled trial, addressing the issues of glyburide dose, GDM severity, and pregnancy outcome and grouping trial participants into low (≤ 10 mg) and high (> 10 mg) daily glyburide dose groups and low (≤ 95 mg/dL) or high (> 95 mg/dL) GDM severity groups based on fasting OGTT values. The rates of macrosomia were 16% versus 5%, and the rates of infants who were LGA were 22% versus 8%, ($P = .01$), respectively, in the high-dose and low-dose glyburide groups. Stratification by disease severity (using the level of fasting glucose on glucose tolerance testing) revealed equally lower rates of LGA for the glyburide- and insulin-treated subjects in the low-severity group. In the higher-severity group, the rates of macrosomia and LGA were similar in the glyburide and insulin arms. The study authors suggested that achieving an excellent level of glycemic control, rather than the mode of pharmacologic therapy, is the key to improving outcomes in cases of GDM.

There is a growing acceptance of glyburide use as a primary therapy for GDM.²⁶⁵ Although no new randomized trials have been completed, several retrospective series have been published comprising 504 glyburide-treated patients, and these studies have been summarized by Moore.²⁶⁶

Jacobson and coworkers²⁶⁷ performed a retrospective cohort comparison of glyburide and insulin treatment of gestational diabetes. Patients with fasting plasma glucose levels greater than 140 mg/dL on glucose tolerance testing were excluded. The insulin group ($n = 268$) consisted of those diagnosed in 1999 through 2000, and the glyburide group ($n = 236$) was diagnosed in 2001 through 2002. Glyburide dosing was begun with 2.5 mg in the morning and increased by 2.5 to 5.0 mg weekly. If the dose exceeded 10 mg daily, twice-daily dosing was considered. If glycemic goals were not met on a maximum daily dose of 20 mg, patients were changed to insulin. The study size was insufficient to detect less than a doubling of the rate of macrosomia or LGA and a 44% increase in neonatal hypoglycemia, but there were no statistically significant differences in gestational age at delivery, mode of delivery, birth weight, LGA, or percent of macrosomic infants. The rate of preeclampsia doubled in the glyburide group (12% versus 6%; $P < .02$). Women in the glyburide group also had significantly lower post-treatment fasting and postprandial blood glucose levels. The glyburide group was superior in achieving target glycemic levels (86% versus 63%; $P < .001$). The failure rate (i.e., transfer to insulin) was 12%.

Conway and associates²⁶⁸ reported a retrospective cohort of 75 glyburide-treated GDM patients. Good glycemic control was achieved by 84% of the subjects with glyburide, and 16% were switched to insulin. The rate of fetal macrosomia was similar between women successfully treated with glyburide and those who converted to insulin (11.1% versus 8.3%; $P = 1.0$), and the mean birth weight was also similar. A not significantly higher proportion of infants in the glyburide group required intravenous glucose infusions because of hypoglycemia (25.0% versus 12.7%; $P = .37$).

Small cohorts reported by Kremer and colleagues²⁶⁹ and Chmait and coworkers²⁷⁰ demonstrated glyburide failure requiring adjunctive or substitutive insulin rates in the range of 15% to 20%. In these studies, higher GCT results (> 160 to 200 mg/dL) were predictive of an approximate 50% failure rate.²⁷¹

The recommended glyburide dosing regimen, based largely on animal studies and a few human studies of nonpregnant subjects, is to administer the agent once daily, with twice-daily doses reserved for refractory cases. Later studies of glyburide pharmacodynamics suggest that the previously recommended dosing protocols may not be optimal

in pregnancy. During development of the drug in the late 1960s, single-dose studies in nondiabetic subjects demonstrated glyburide absorption within 1 hour, peak levels at about 4 hours, and low but detectable levels at 24 hours. The decrease of glyburide in the serum yielded a terminal half-life of about 10 hours, and the glucose-lowering effect could be expected to persist for 24 hours after a single morning dose.

Later data have shown that glyburide peaks earlier in the serum and has a significantly shorter half-life than previously believed. These effects reflect the fact that glyburide has two major hydroxyl metabolites, both of which are biologically active and excreted equally in the bile and urine. Although advice in the *Physician's Desk Reference* indicates that the glyburide metabolites provide no significant contribution to glyburide's hypoglycemic action ($1/_{400}$ and $1/_{40}$, respectively, of glyburide's potency), these data were obtained in rabbits.

Yin and associates²⁷² studied the glucose and insulin responses to glyburide in a group of nonpregnant, nondiabetic subjects. After a 5-mg oral dose, serum glyburide levels peaked at 2.75 hours and had sustained levels with a half-life ranging from 2 to 4 hours, considerably shorter than the quoted half-life of 10 hours.

To clarify the potential difference in drug action when given as a single dose or chronically over weeks, Jaber and colleagues²⁷³ studied glyburide pharmacodynamics during multiple-dose administration. A significant prolongation in the half-life (week 0 = 4.0 ± 1.9 hr; week 6 = 13.7 ± 10.5 hr; and week 12 = 12.1 ± 8.2 hr) was observed during chronic dosing. **These results suggest possible drug accumulation or tissue sensitization by glyburide.**

Yogev and coworkers²⁷⁴ examined the prevalence of undiagnosed, asymptomatic hypoglycemic events in diabetic patients using a continuous glucose monitoring system for 72 consecutive hours. Hypoglycemia was defined as more than 30 consecutive minutes of a glucose value below 50 mg/dL. Asymptomatic hypoglycemic events were recorded in 63% of insulin-treated patients but in only 28% of glyburide-treated patients. The mean number of hypoglycemic episodes per day was significantly higher in insulin-treated patients (4.2 ± 2.1) than in glyburide-treated patients (2.1 ± 1.1 ; $P = .03$). In insulin-treated patients, most hypoglycemic events were nocturnal (84%), whereas in glyburide-treated patients, episodes occurred equally during the day and night, suggesting a potential benefit of glyburide over insulin therapy in clinical use.

Based on these data, glyburide should be taken at least 30 minutes—and preferably 60 minutes—before meals so that the peak action (2.5 hours after dosing) covers the postprandial glucose surge. Because of its extended duration of action, glyburide taken at 10 to 11 PM is effective in lowering fasting plasma glucose levels in the morning. Significant interprandial hypoglycemia can occur with glyburide, and patients should carry glucose tablets with them at all times as a precaution. The maximum dose is 20 mg per day, and no more than 7.5 mg should be taken at a single time.

Other Agents

Metformin is frequently employed in patients with polycystic ovary syndrome and type 2 diabetes to improve insulin resistance and fertility.²⁷⁵ Although it has been documented that metformin therapy improves the success of ovulation induction²⁷⁶ and probably reduces first-trimester pregnancy loss in women with polycystic ovary syndrome,¹⁸¹ the effects of continuing metformin during pregnancy are not clear. **Coetzee and Jackson²⁷⁷ treated pregestational and gestational diabetics with metformin, but the treatment failed in 54% and 29%, respectively.** The perinatal mortality rate among the metformin patients was 61 per 1000, and the rate of neonatal jaundice was increased. Hellmuth and colleagues²⁷⁸ reported a series of

women with gestational diabetes treated with metformin or tolbutamide before 1984. Women treated with metformin had a fourfold increase in preeclampsia and a higher perinatal mortality rate compared with those who were receiving tolbutamide. However, metformin-treated women were older, more obese, and treated later in pregnancy.

A cohort study of metformin in pregnancy reported by Hughes and associates¹⁸⁷ in 2006 included 93 women with metformin treatment (only 32 continued until delivery) and 121 controls. There was no difference in perinatal outcomes between the groups. Glueck and coworkers¹⁸³ compared nondiabetic women with polycystic ovary syndrome ($n = 28$) who conceived while taking metformin and continued the agent through delivery with matched women without metformin therapy ($n = 39$). Gestational diabetes developed in 31% of women who did not take metformin and in 3% of those who did (OR = 0.115; CI, 0.014 to 0.938).

Because of the beneficial effect of metformin on first-trimester miscarriage, many patients with polycystic ovary syndrome enter prenatal care taking this medication. Because metformin readily crosses the placenta,¹⁸⁴ greater experience with this agent is necessary before it can be recommended for use throughout pregnancy.²⁷⁹ A large, properly powered, randomized, controlled trial is in progress to explore these issues.²⁸⁰

The α -glucosidase inhibitors, another class of oral agents, reversibly inhibit pancreatic amylase and α -glucosidase enzymes in the small intestine, delaying cleavage of complex sugars to monosaccharides and reducing the increase of blood glucose levels after a meal. Although these agents offer particular promise in pregnant women because of limited uptake from the gut, only a few studies of the drugs in pregnancy are available. Bertini and colleagues²⁸¹ compared insulin treatment ($n = 27$), glyburide ($n = 24$), and acarbose ($n = 19$) in gestational diabetes. No difference was observed in maternal glucose levels or in mean birth weight, although the rates of LGA fetuses were 3.7%, 25%, and 10.5% for the groups, respectively. Neonatal hypoglycemia was observed in eight newborns, six of whom were from the glyburide group. Glucose control was not achieved in five (20.8%) of the patients using glyburide and in eight (42.1%) of the patients using acarbose. Acarbose is given before meals, initially in a dose of 25 mg taken orally three times daily up to a maximum of 100 mg taken orally three times daily.

Pregnancy Management of the Diabetic Patient and Fetus

Fetal Surveillance

The goals of third-trimester management of diabetic pregnancy are to prevent stillbirth and asphyxia while optimizing the opportunity for a safe vaginal delivery. This involves monitoring fetal growth to determine the proper timing and route of delivery and testing for fetal well-being at frequent intervals.

A regimen for fetal surveillance throughout pregnancy is provided in Table 46-19. The goals are to

- Verify fetal viability in the first trimester
- Validate fetal structural integrity in the second trimester
- Monitor fetal growth during most of the third trimester
- Ensure fetal well-being in the late third trimester

TABLE 46-19 FETAL SURVEILLANCE IN TYPES I AND II DIABETIC PREGNANCIES

Time	Test
Preconception	Maternal glycemic control
8-10 wk	Sonographic crown-rump measurement
16 wk	Maternal serum α -fetoprotein level
20-22 wk	High-resolution sonography, fetal cardiac echography in women in suboptimal diabetic control (abnormal Hb A _{1c} value) at first prenatal visit
24 wk	Baseline sonographic growth assessment of the fetus
28 wk	Daily fetal movement counting by the mother
32 wk	Repeat sonography for fetal growth
34 wk	Biophysical testing: Two times weekly nonstress test or Weekly contraction stress test or Weekly biophysical profile
36 wk	Estimation of fetal weight by sonography
37-38.5 wk	Amniocentesis and delivery for patients in poor control (persistent daily hyperglycemia)
38.5-40 wk	Delivery without amniocentesis for patients in good control who have excellent dating criteria

A variety of fetal biophysical tests are available, including fetal heart rate testing, fetal movement counting, ultrasound biophysical scoring, and fetal Doppler studies. These tests, which are described in Chapter 21, are summarized in Table 46-20.

Testing should be initiated early enough to avoid the risk of stillbirth but not so early that a high rate of false-positive results is encountered. Because the risk of fetal death is roughly proportional to the degree of hyperglycemia, testing should begin as early as 28 weeks' gestation in patients with poor glycemic control or significant hypertension. In lower-risk patients, testing should begin at 34 to 36 weeks. Fetal movement counting should be performed in all pregnancies from 28 weeks onward. A fetal movement card for monitoring fetal movement is shown in Figure 46-16.

Timing and Route of Delivery

Assessing Fetal Size

Monitoring fetal growth and predicting birth weight continue to be challenging and highly inexact processes. The purpose of such monitoring is to identify the obese fetus and, if possible, avoid birth injury. Newborns weighing more than 4000 g are responsible for 42% to 74% of shoulder dystocias and 56% to 76% of all brachial plexus injuries, even though they account for only 6% of births.²⁸² To identify the highest-risk fetuses, use of third-trimester ultrasound has been proposed, including serial plotting of biometric parameters, using a cutoff value for estimated fetal weight and applying a cutoff to a specific parameter (e.g., abdominal circumference).²⁸³

Because the risk of birth injury is proportional to birth weight,¹⁴² much effort has been focused on sonographic estimation of fetal weight (EFW). Several polynomial formulas using combinations of head, abdomen, and limb measurements have been developed.^{284,285} Unfortunately, even small errors in measurements of the head, abdomen, and femur are multiplied together in such formulas, resulting in accuracies of no better than $\pm 15\%$. In the obese fetus, the inac-

tions were detected for birth weight and the AFI and EFW percentiles ($r = 0.44$ and $r = 0.72$, respectively; $P < .0001$). The best predictors of macrosomia were an AFI equal to the 60th percentile or higher and an EFW equal to the 71st percentile or higher, with a positive predictive value of 85%. However, even this enhanced protocol had a high-false positive rate.

Considering the inaccuracy of weight prediction from a single set of sonographic measurements, serial analysis of parameters every 1.5 to 3 weeks is commonly used. However, trended serial EFW calculations compared with a single measurement appear to be no better than a single estimate performed near term. Predictions based on the average of serial EFWs, linear extrapolation from two estimates, or extrapolation by second-order equations fitted to four estimates were no better than the prediction from the last estimate before delivery.²⁸⁹

In view of the inadequate methods used to diagnose macrosomia antenatally, the widespread practice of estimating fetal weight using ultrasound near term in diabetic pregnancy must be questioned. Parry and colleagues²⁹⁰ compared the cesarean rate for neonates falsely diagnosed on ultrasound as macrosomic (i.e., false positives) with the rate for those correctly diagnosed as nonmacrosomic (i.e., true negatives). They found that the cesarean rate was significantly higher among the false-positive macrosomics than among the true negatives (42.3% versus 24.3%; RR = 1.74; $P < .05$). Even with nonmacrosomic fetuses, the availability to the clinician of a sonographic estimate of fetal weight significantly increases the risk of cesarean delivery.

Predicting Shoulder Dystocia

Because of the asymmetrical adipose deposition around the fetal chest and trunk, deliveries of macrosomic infants from women with diabetes are at high risk for shoulder dystocia and injury. However, prediction of this risk is not possible with adequate precision to avoid excessive unnecessary interventions.²⁹¹

In a subanalysis of the ACHOIS trial, Athukorala and associates³³⁸ identified a linear increase in the risk of shoulder dystocia and the fasting glucose level on the glucose tolerance test, with an 18-mg/dL (1-mmol) increase in the fasting oral glucose tolerance test result leading to a relative risk of 2.09 (CI, 1.03 to 4.25). As reported by others, shoulder dystocia was 10-fold more common with operative vaginal delivery of GDM infants. However, there was no clear cutoff for the glucose tolerance test fasting value that was adequately predictive of shoulder dystocia.

In an effort to minimize the incidence of shoulder dystocia and associated birth injury associated with suspected macrosomia, a number of management schemes have been proposed. Weeks and colleagues²⁹² assessed the management of 500 pregnancies with suspected macrosomia and found a high bias toward cesarean section and failed induction. Patients with a sonographic EFW greater than 4200 g underwent induction more often (42.5% versus 26.6%), failed to achieve active labor more frequently (49% versus 16.5%), and underwent cesarean section more frequently (52% versus 30%), regardless of actual birth weight. Despite these changes in labor management, the incidence of shoulder dystocia in the predicted and nonpredicted groups was the same (11.8% and 11.7%, respectively).

There is no clinical method of reliably identifying the fetus likely to experience shoulder dystocia and injury during birth without an unacceptably high false-positive rate. Because 8% to 20% of fetuses from diabetic pregnancy weighing 4500 g or more will have shoulder dystocia, 15% to 30% of these will have recognizable brachial plexus injury, and 5% to 15% of these injuries will result in permanent deficit, approximately 443 to 489 cesarean sections would have to be per-

formed for suspected macrosomia to prevent one case of permanent injury from shoulder dystocia.²⁹³

Delivery Timing

Timing of delivery should minimize neonatal morbidity and mortality while maximizing the likelihood of vaginal delivery. Delaying delivery to as near the estimated due date as possible increases cervical ripeness and improves the chances of vaginal birth. However, the risks of fetal macrosomia, birth injury, and fetal death increase as the due date approaches. Earlier delivery may reduce the risk of shoulder dystocia, but the increase in failed labor inductions and neonatal respiratory distress is appreciable.

Rayburn and colleagues²⁹⁴ reported a case-control study of outcomes of women with GDM requiring insulin who delivered at 38 weeks compared with normoglycemic controls. The study group was more likely to have an unfavorable cervix, but cesarean rates were not different between the study and control groups (12.7% versus 11.7%; $P < .8$). Mean birth weights and the frequency of birth weights greater than 4000 g were not different between the groups, suggesting that delivery at 38 to 39 weeks does not compromise maternal and infant outcomes significantly.

When all these factors are considered, the optimal time for delivery of most diabetic pregnancies is between 38.5 and 40 weeks. Indications for delivery of the diabetic pregnancy are summarized in Table 46-21. Because of the apparent delay in fetal lung maturity in diabetic pregnancies, delivery before 38.5 weeks' gestation should be performed only for compelling maternal or fetal reasons.

It may be tempting to consider early delivery in a diabetic pregnancy with evolving macrosomia identified on ultrasonography. Because fetal growth between 37 and 40 weeks' gestation in a 90th-percentile fetus is approximately 100 to 150 g per week, inducing labor 2 weeks early may reduce the risk of shoulder dystocia in some cases. Kjos and coauthors²⁹⁵ compared the outcomes associated with labor induction at 38 weeks with expectant management of women with gestational diabetes. They found that expectant management increased the gestational age at delivery by 1 week, but the cesarean delivery rate was not significantly different. Macrosomia was present in 23% of the expectantly managed group versus 10% in those induced at 38 weeks.

Fetal lung maturity should be verified in all patients delivered before 38.5 weeks by the presence of greater than 3% phosphatidylglycerol or the equivalent on an amniocentesis specimen (Table 46-22). If obstetric dating is suboptimal, amniocentesis should be performed.

TABLE 46-21 INDICATIONS FOR DELIVERY IN DIABETIC PREGNANCY

Type	Indications for Delivery
Fetal	Nonreactive, positive contraction stress test Reactive positive contraction stress test, mature fetus Sonographic evidence of fetal growth arrest Decline in fetal growth rate with decreased amniotic fluid 40-41 weeks' gestation
Maternal	Severe preeclampsia Mild preeclampsia, mature fetus Markedly falling renal function (creatinine clearance <40 mL/min)
Obstetric	Preterm labor with failure of tocolysis Mature fetus, inducible cervix

TABLE 46-22 CONFIRMATION OF FETAL MATURITY BEFORE INDUCTION OF LABOR OR PLANNED CESAREAN DELIVERY IN DIABETIC PREGNANCIES

Phosphatidylglycerol >3% in amniotic fluid collected from vaginal pool or by amniocentesis

Completion of 38.5 weeks' gestation
Normal last menstrual period
First pelvic examination before 12 wk confirms dates
Sonogram before 24 wk confirms dates
Documentation of more than 18 wk of unamplified (fetoscope) fetal heart tones

After more than 40 weeks, the benefits of continued conservative management are less than the danger of fetal compromise. Induction of labor before 42 weeks in diabetic pregnancy—regardless of the readiness of the cervix—is prudent.

Labor or Cesarean

The ACOG²⁹⁶ has recommended that primary cesarean delivery be discussed with diabetic gravidas with an EFW greater than 4500 g. This may reduce the risk of shoulder dystocia to some degree for an individual patient, but the effect on the larger obstetric population is less clear.

Gonen and associates²⁹⁷ retrospectively assessed the impact of a policy of elective cesarean in cases with an EFW above 4500 g. During the 4 years of the study with more than 16,000 deliveries, macrosomia was correctly predicted in only 18% of cases. Of the 115 undiagnosed macrosomic cases, 13 infants were delivered by emergency cesarean, and 99 were delivered vaginally. Three infants (3%) with macrosomia and 14 infants (0.1%) without macrosomia sustained brachial plexus injury. The policy of preemptive cesarean for an EFW greater than 4500 g prevented at most a single case of brachial palsy.

Conway and Langer²⁹⁸ performed a prospective trial enrolling diabetic women among whom those with an EFW of 4250 g or more underwent elective cesarean section. Ultrasonography correctly identified the presence or absence of macrosomia in 87% of patients. The cesarean section rate increased slightly after the protocol was initiated (22% versus 25%), but overall, shoulder dystocia was less common (2.4% versus 1.1%).

Herbst²⁹⁹ conducted a cost-effectiveness analysis of “prophylactic” delivery (i.e., induction or cesarean) of the fetus with an EFW greater than 4500 g using risk and benefit rates estimated from the existing medical literature.²⁹⁹ For an infant of a normoglycemic pregnancy weighing 4500 g or more, routine obstetric management was the least expensive (\$4014 per injury-free child) compared with elective cesarean cost of \$5212 and induction cost of \$5165. However, a sensitivity analysis suggested that with a shoulder dystocia risk higher than 10% (as is the case with a fetus weighing more than 4500 g in a diabetic pregnancy), primary cesarean or early induction is somewhat more financially advantageous. The current recommendation that cesarean section be considered when fetal weight is suspected to exceed 4500 g appears to confer a modest improvement in neonatal outcome.

The decision to attempt vaginal delivery or perform a cesarean delivery is inevitably based on limited data. The patient's obstetric history, the best EFW, a fetal adipose profile (i.e., abdomen larger than head), and clinical pelvimetry should all be considered. Midpelvic operative deliveries should be avoided when macrosomia is suspected,

TABLE 46-23 INTRAPARTUM MATERNAL GLYCEMIC CONTROL

Insulin Infusion Method

1. Withhold AM insulin injection.
2. Begin and continue glucose infusion (5% dextrose in water) at 100 mL/hr throughout labor.
3. Begin infusion of regular insulin at 0.5 U/hr.
4. Begin oxytocin as needed.
5. Monitor maternal glucose levels hourly using a capillary reflectance meter at bedside or laboratory determinations, or both.
6. Adjust insulin infusion.

Plasma/Capillary Glucose (mg/dL)	Infusion Rate (U/hr)
<80	Insulin off
80-100	0.5*
101-140	1.0
141-180	1.5
181-220	2.0*
>220	2.5*

Intermittent Subcutaneous Injection Method

1. Give one half of the usual insulin dose in AM.
2. Begin and continue glucose infusion (5% dextrose in water) at 100 mL/hr throughout labor.
3. Begin oxytocin as needed.
4. Monitor maternal glucose levels hourly using a capillary reflectance meter at bedside or laboratory determinations, or both.
5. Administer regular insulin in small doses (2 to 5 U) to maintain glucose levels of 80 to 120 mg/dL.

*Intravenous bolus of 2 to 5 units when the rate increases.

and low pelvic or even outlet operative deliveries must be approached with extreme caution if labor is protracted. With an EFW greater than 4500 g, a prolonged second stage of labor or arrest of descent in the second stage is an indication for cesarean delivery.²⁹⁶ Most large series of diabetic pregnancies report a cesarean section rate of 30% to 50%. The best means by which this rate can be lowered is by early and strict glycemic control in pregnancy. Conducting long labor inductions in patients with a large fetus and a marginal pelvis may increase, rather than lower, morbidity and costs.

Intrapartum Glycemic Management

Perinatal asphyxia and neonatal hypoglycemia correlate with maternal hyperglycemia during labor.³⁰⁰ Unfortunately, strict maternal euglycemia during labor does not guarantee newborn metabolic stability in infants with macrosomia and islet cell hypertrophy. The use of a combined insulin and glucose infusion during labor maintains the maternal plasma glucose level in a narrow range (80 to 110 mg/dL) and reduces the incidence of neonatal hypoglycemia.³⁰¹ A protocol for administration of a continuous insulin infusion in labor is outlined in Table 46-23. Typical infusion rates are 5% dextrose in Ringer's lactate at 100 mL per hour and lispro or aspart insulin at 0.5 to 1 units per hour. Capillary blood glucose is monitored hourly in these patients. For patients with diet-controlled GDM or mild type 2 diabetes, avoiding dextrose in all intravenous fluids during labor usually maintains excellent glucose control.

When cesarean section is planned in a woman with diabetes, the procedure should be performed early in the day to avoid prolonged

periods of fasting. On the night before surgery, patients should be instructed to take their full dose of NPH or glyburide. No morning insulin or glyburide should be taken. A glucose-containing intravenous line should be established promptly on arrival at the hospital, with insulin given as intravenous boluses on a sliding scale as needed every 1 to 4 hours to maintain maternal plasma glucose in the range of 80 to 160 mg/dL.

Postpartum Metabolic Management

In the recovery room and after delivery, insulin can be given subcutaneously to women with type 2 diabetes using a sliding scale until a regular diet is established. The insulin doses required after delivery are typically 30% to 50% of the preprandial doses required during pregnancy just before delivery. Type 1 diabetes patients require more intensive glucose monitoring after delivery, because many experience a honeymoon phase, in which insulin requirements fall dramatically. The glucose-insulin intravenous infusion should be continued in type 1 diabetes patients, especially those who have had a cesarean delivery, until the diet has normalized.

Management of the Neonate

Neonatal Transitional Management

Unmonitored and uncorrected neonatal hypoglycemia can lead to neonatal seizures, brain damage, and death. The degree of hypoglycemia correlates roughly with the degree of maternal glycemic control during the 6 weeks before birth. Pancreatic hypertrophy and chronic fetal hyperinsulinemia—holdovers from the chronically glucose-rich intrauterine environment—can lead to significant hypoglycemia after the umbilical supply of nutrients is interrupted by delivery. IDMs also appear to have disorders of catecholamine and glucagon metabolism and have diminished capability to mount normal compensatory responses to hypoglycemia. The current recommendations specify frequent blood glucose checks and early oral feeding when possible (ideally from the breast), with infusion of intravenous glucose if oral measures prove insufficient.

Ordinarily, blood glucose levels can be controlled satisfactorily with an infusion of 10% glucose. If greater amounts of glucose are required, bolus administration of 5 mL/kg of 10% glucose is recommended, with gradually increasing concentrations of glucose administered every 30 to 60 minutes, if necessary.

Breastfeeding

Considering the number of perinatal complications experienced by many women with diabetes (e.g., preeclampsia, macrosomia-induced cesarean section, neonatal hypoglycemia), achieving a high rate of breastfeeding may seem to be a superfluous goal. However, mounting evidence indicates that breastfed infants have a much lower risk of developing diabetes than do those exposed to the proteins in cow's milk.^{302,303} Pettitt and associates³⁰⁴ found that children who were exclusively breastfed had significantly lower rates of non-insulin-dependent diabetes mellitus than did those who were exclusively bottle-fed in all age groups. The odds ratio for non-insulin-dependent diabetes mellitus in exclusively breastfed persons, compared with exclusively bottle-fed individuals, was 0.41 (CI, 0.18 to 0.93), adjusted for age, sex, birth date, parental diabetes, and birth weight. A study by Gimeno and de Souza³⁰⁵ found that a shorter duration of exclusive breastfeeding was

a risk factor for childhood diabetes (OR = 2.13; CI, 1.8 to 3.55) and that the introduction to cow's milk products before age 8 days was an important risk factor for the disease. Given the increased risk of diabetes in offspring of women with diabetes, these data underscore the importance of encouraging breastfeeding in all postpartum women with diabetes.

Most neonatologists maintain strict monitoring of glucose levels in newborn IDMs for at least 4 to 6 hours (frequently 24 hours), often necessitating admission to a newborn special care unit. This early separation of mother and neonate impedes breastfeeding and infant attachment, and it may delay the onset of lactogenesis in the diabetic mother. Neubauer and colleagues³⁰⁶ observed that milk of women with insulin-dependent diabetes came in later than it did in controls and had significantly lower lactose and higher total nitrogen at 2 to 3 days after delivery. The infants of these diabetic mothers had significantly less milk intake 7 to 14 days after delivery than did those of the control women. Delayed lactogenesis in the women with insulin-dependent diabetes most likely occurred in those with poor metabolic control. A study by van Beusekom and coauthors³⁰⁷ analyzed concentrations of micronutrients and macronutrients in milk and capillary blood and found that tight glycemic control was associated with normal proportions of milk nutrients, compared with the multitude of milk abnormalities seen with moderate and poor control.

Evidence indicates that with proper encouragement, sustained breastfeeding is possible for a significant proportion of patients with overt diabetes. Webster and coworkers³⁰⁸ longitudinally compared breastfeeding habits between women with diabetes and normal women. At discharge, 63% of mothers with insulin-dependent diabetes and 78% of mothers without diabetes were breastfeeding. At 8 weeks, the proportions of each were nearly identical (58% and 56%, respectively), and when the infants were 3 months old, 47% of mothers with insulin-dependent diabetes and 33% of women without diabetes continued to breastfeed. The study showed that IDMs were delivered atraumatically, and infants who are well oxygenated with mature lungs and who have excellent antecedent glucose control can be kept with their mothers under close glycemic monitoring for the first 1 to 2 hours of life. This permits early breastfeeding, which may reduce the need for intravenous glucose therapy.

The actual techniques of infant nursing require some modification in women with overt diabetes, especially insulinopenic patients with type 1 diabetes. Increased maternal calorie and fluid intake is necessary to maintain milk supply in all women. The calorie expenditure during nursing and for the 30 to 45 minutes thereafter (probably during post-nursing lactogenesis) may precipitate severe hypoglycemia if compensatory calories are not ingested. This is especially common during nursing late at night. Breastfeeding women with type 1 diabetes should be encouraged to take in fluids and food (100 to 300 calories per feeding episode) while nursing to avoid reactive hypoglycemia.

Fortunately, studies of breastfeeding women with diabetes indicate that lactation, even for a short duration, has a beneficial effect on overall maternal glucose and lipid metabolism. For postpartum women who have GDM during their pregnancies, breastfeeding may offer a practical, low-cost intervention that helps to reduce or delay the risk of subsequent diabetes.

Chapter 47

Thyroid Disease and Pregnancy

Shahla Nader, MD

Thyroid disorders are among the most common endocrinopathies in young women of childbearing age. In large areas of the world, iodine deficiency is the predominant cause of these disorders. In the Western Hemisphere, these disorders are most often related to altered immunity. The hormonal and immunologic perturbations of pregnancy and the postpartum period and the dependence of the fetus on maternal iodine and thyroid hormone have profound influences on maternal thyroid function and consequently on fetal well-being. Appropriate antepartum and postpartum care requires a basic knowledge of thyroid function, its alteration in pregnancy, and the more common thyroid diseases afflicting women in the setting of pregnancy, all of which are addressed in this chapter. The combination of thyroid disease and pregnancy has been the topic of several reviews,^{1,2} and the Endocrine Society's guidelines for management of thyroid dysfunction during pregnancy and after delivery have recently been published.³

Maternal-Fetal Thyroid Physiology

Normal Thyroid Physiology

The thyroid gland is located in the anterior neck below the hyoid bone and above the sternal notch. Consisting of two lobes and connected by the isthmus, it weighs approximately 20 to 25 g. Each lobe is divided into lobules, each of which contains 20 to 40 follicles. The follicle consists of follicular cells, which surround a glycoprotein material called colloid.

The hypothalamic-pituitary axis governs the production of thyroid hormone by the follicular cells. Tonic stimulation of thyrotropin-releasing hormone (TRH) is required to maintain normal thyroid function, and hypothalamic injury or disruption of the stalk results in hypothyroidism. TRH, a tripeptide, is produced in the paraventricular nucleus of the hypothalamus, and its local production as determined by mRNA is inversely related to concentrations of circulating thyroid hormones. Traversing the pituitary stalk, TRH is delivered to the pituitary thyrotroph by the pituitary portal circulation, and it affects the production and release of thyrotropin (i.e., thyroid-stimulating hormone [TSH]). A glycoprotein, TSH is composed of α and β subunits, and the β subunit confers specificity. Control of TSH secretion occurs by negative feedback (from circulating thyroid hormone, somatostatin, dopamine) or by stimulation by TRH.

Thyroid gland production of thyroxine (T_4) and triiodothyronine (T_3) is regulated by TSH. On binding to its receptor, TSH induces

thyroid growth, differentiation, and all phases of iodine metabolism from uptake of iodine to secretion of the two thyroid hormones. In the nonpregnant state, 80 to 100 μg of iodine are taken up by the gland daily. Dietary iodine is reduced to iodide, which is absorbed and cleared by the kidney (80%) and thyroid (20%). Iodide is actively trapped by the thyroid and is the rate-limiting step in hormone biosynthesis. The iodide is converted back to iodine and organified by binding to tyrosyl residues, which are part of the glycoprotein thyroglobulin. This process requires the enzyme thyroid peroxidase. Iodination can give rise to monoiodotyrosine or diiodotyrosine, with the ratio depending on prevailing iodine availability. Coupling of two diiodotyrosine molecules forms T_4 , and one diiodotyrosine and one monoiodotyrosine form T_3 . Thyroglobulin is extruded into the colloid space at the center of the follicle, and thyroid hormone is stored as colloid.

Hormone secretion by thyroid cells, which is also under TSH control, involves digestion of thyroglobulin and extrusion of T_4 and T_3 into the capillaries. Daily secretion rates approximate 90 μg of T_4 and 30 μg of T_3 . Both circulate highly bound to protein (mainly thyroxine-binding globulin [TBG]), with less than 1% in free form (0.3% of T_3 and 0.03% of T_4). Other binding proteins include thyroxine-binding prealbumin and albumin. It is the free hormone that enters cells and is active.

Whereas T_4 is completely thyroidal in origin, only approximately 20% of T_3 comes directly from the thyroid. Thyroxine is metabolized in most tissues (particularly in the liver and kidneys) to T_3 by deiodination. It is also metabolized to reverse T_3 , a metabolically inactive hormone. Removal of an iodine by 5' monodeiodination from the outer ring of T_4 results in T_3 , which is metabolically active. When iodine is removed from the inner ring, reverse T_3 is produced (Fig. 47-1). Monodeiodinase type I and type II catalyze the formation of T_3 , whereas reverse T_3 is catalyzed by monodeiodinase type III. Normally, approximately 35% of T_4 is converted to T_3 , and 40% is converted to reverse T_3 , but this balance is shifted in favor of the metabolically inert reverse T_3 in illness, starvation, or other catabolic states.^{4,5} About 80% of circulating T_3 is derived from peripheral conversion. The half-life of T_4 is 1 week; 5 to 6 weeks are necessary before a change in dose of T_4 therapy is reflected in steady-state T_4 values. The half-life of T_3 is 1 day.

Free thyroid hormone enters the cell and binds to nuclear receptors and in this way signals its cellular responses.⁶ The affinity of T_3 for nuclear receptors is tenfold that of T_4 , which helps to explain the greater biologic activity of T_3 . Thyroid hormone receptors belong to a large superfamily of nuclear-hormone receptors that include the steroid hormone, vitamin D, and retinoic acid receptors. Thyroid hormones have diverse effects on cellular growth, development, and metabolism. The major effects of thyroid hormones are genomic,

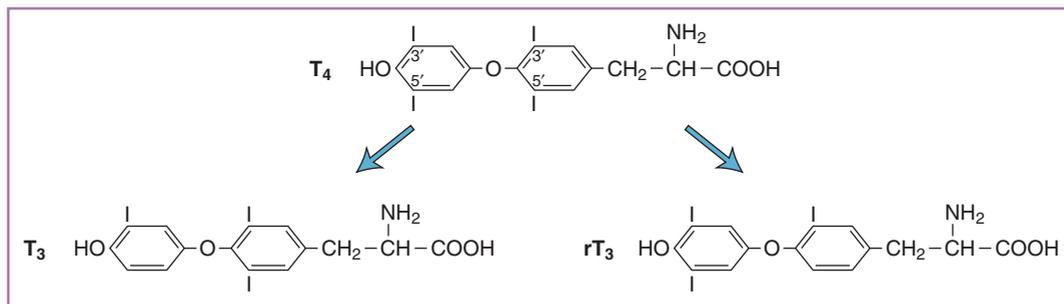

FIGURE 47-1 Iodine removal. Removal of an iodine atom by 5'-monodeiodination from the outer ring of thyroxine (T₄) results in the formation of metabolically active triiodothyronine (T₃). Removal of an iodine atom from the inner ring results in formation of the metabolically inactive reverse triiodothyronine (rT₃).

stimulating transcription and translation of new proteins in a concentration- and time-dependent manner.

Maternal Thyroid Physiology

Pregnancy alters the thyroidal economy, and the hormonal changes of pregnancy result in profound alterations in the biochemical parameters of thyroid function. This section reviews maternal thyroid physiology, the role of maternal hormones in fetal growth and development, and the development of the fetal hypothalamic-pituitary-thyroid axis. This topic was reviewed by Glinöer.⁷

Three series of events occur at different times during gestation. Starting in the first half of gestation and continuing until term, there is an increase in TBG, a direct effect of increasing circulating estrogen concentrations. Basal levels increase twofold to threefold. This increase is accompanied by a trend toward lower free hormone concentrations (T₄ and T₃), which results in stimulation of the hypothalamic-pituitary-thyroid axis. Under conditions of iodine sufficiency, the decrease in free hormone levels is marginal (10% to 15% on average). When the supply of iodine is insufficient, more pronounced effects occur, and these are addressed in later sections. There is usually a trend toward a slight increase in TSH between the first trimester and term.

The second event takes place transiently during the first trimester and is a consequence of thyroid stimulation by increasing concentrations of human chorionic gonadotropin (hCG). As hCG peaks late in the first trimester, there is partial inhibition of the pituitary and transient lowering of TSH between 8 and 14 weeks' gestation (Fig. 47-2). In about 20% of women, TSH falls below the lower limit of normal, and these women often have significantly higher hCG concentrations.⁸ The stimulatory action of hCG has been broadly quantified; an increment of 10,000 IU/L is associated with a lowering of basal TSH of 0.1 mU/L. In most normal pregnancies, this is of minor consequence.⁹

In the third series of events, alterations in the peripheral metabolism of thyroid hormone occur throughout pregnancy but are more prominent in the second half. Three enzymes deiodinate thyroid hormones: deiodinase types I, II, and III. Type I is not significantly modified. Type II, which is expressed in the placenta, can maintain T₃ production locally, which can be critical when maternal T₄ concentrations are reduced. Type III is also found abundantly in the placenta, and it catalyzes the conversion of T₄ to reverse T₃ and conversion of T₃ to T₂; this abundance may explain the low T₃ and high reverse T₃ concentrations characteristic of fetal thyroid hormone metabolism.¹⁰

These physiologic adaptations to pregnancy, depicted in Figure 47-3, are attained without difficulty by the normal thyroid gland in a

state of iodine sufficiency. This does not apply when thyroid function is compromised or iodine supply is insufficient.

Iodine Deficiency and Goiter

Increased vascularity and some glandular hyperplasia can result in mild thyroid enlargement, but frank goiter occurs because of iodine deficiency or other thyroidal disease. Although iodine deficiency is usually not a problem in the United States, Japan, and parts of Europe, 1 to 1.5 billion people in the world are at risk, with 500 million living in areas of overt iodine deficiency. The World Health Organization recommends 150 µg iodine per day for adults and 200 µg for pregnant women. There is increased renal iodine clearance during pregnancy, and in the latter part of gestation, a significant amount of iodine is diverted toward the fetoplacental unit to allow the fetal thyroid to produce its own thyroid hormones. This physiologic adaptation occurs easily with minimal hypothyroxinemia and no goiter formation in areas of iodine sufficiency. Through hypothalamic-pituitary feedback, borderline iodine intake chronically enhances thyroid stimulation. The iodine deficiency manifests as greater hypothyroxinemia, which increases TSH and thyroglobulin levels and produces thyroid hypertrophy (Fig. 47-4).

In a study of otherwise healthy pregnant women living under conditions of relative iodine restriction, thyroid volume, as assessed by ultrasonography, increased an average of 30% during pregnancy.¹¹ In a selected group of these women with goitrogenesis, follow-up a year after delivery did not show a return of thyroid volumes to those found in early pregnancy. Iodine intake should also be increased after delivery, especially in breastfeeding women. Ultrasonography of neonates revealed that thyroid volume was 38% larger in neonates of untreated mothers compared with neonates of mothers treated with iodine supplementation.¹²

Other than iodine deficiency, goiter in pregnancy can be related to the following:

- Graves disease
- Hashimoto thyroiditis
- Excessive iodine intake
- Lymphocytic thyroiditis
- Thyroid cancer
- Lymphoma
- Therapy with lithium or thionamides

In the United States, clinical studies of pregnant women and non-pregnant controls have not revealed an increase in goiter during preg-

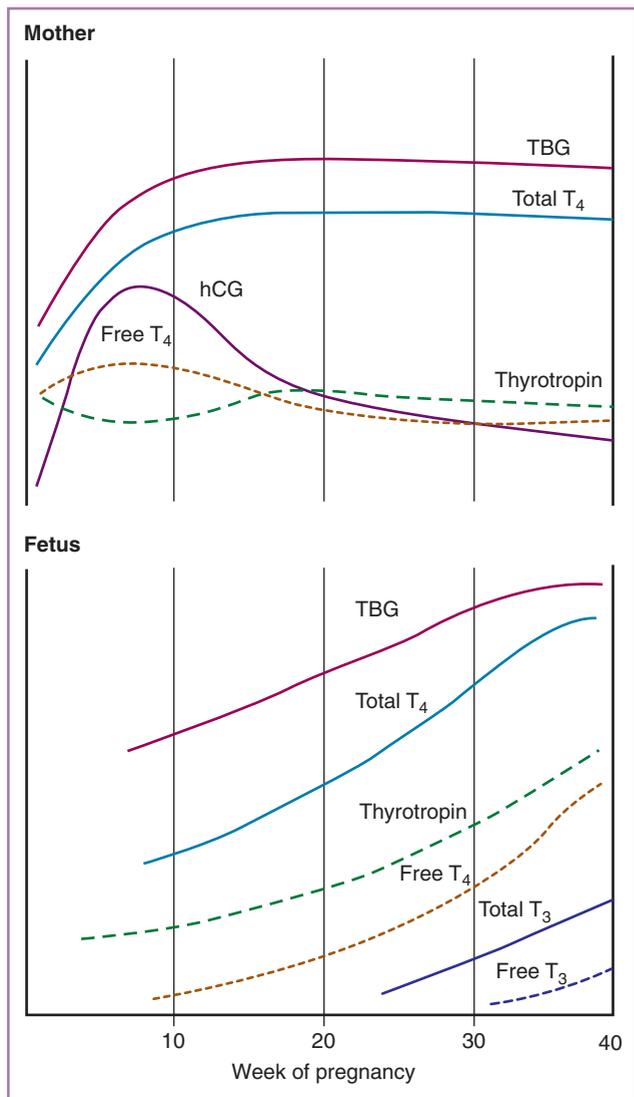

FIGURE 47-2 Relative changes in maternal and fetal thyroid function during pregnancy. The effects of pregnancy on the mother include a marked and early increase in hepatic production of thyroxine-binding globulin (TBG) and placental production of human chorionic gonadotropin (hCG). The increased level of serum TBG increases total serum thyroxine (T_4) concentrations; hCG has thyrotropin-like activity and stimulates maternal T_4 secretion. The transient hCG-induced increase in the serum level of free T_4 inhibits maternal secretion of thyrotropin. (Reprinted by permission from Burrow GN, Fisher DA, Larsen PR: Maternal and fetal thyroid function. *N Engl J Med* 331:1072, 1994.)

nancy.¹³ Ultrasound studies from other areas replete with iodine have confirmed these findings.^{14,15}

Iodine Metabolism in Pregnancy

Although radioactive iodine is absolutely contraindicated in pregnancy, early studies using ^{132}I showed a threefold increase in thyroidal iodine clearance in pregnant women. Another set of studies enrolling 25 pregnant women also revealed increased radioactive iodine uptake during pregnancy compared with the nonpregnant or postpartum state.^{16,17} The mean renal iodine clearance almost doubles because

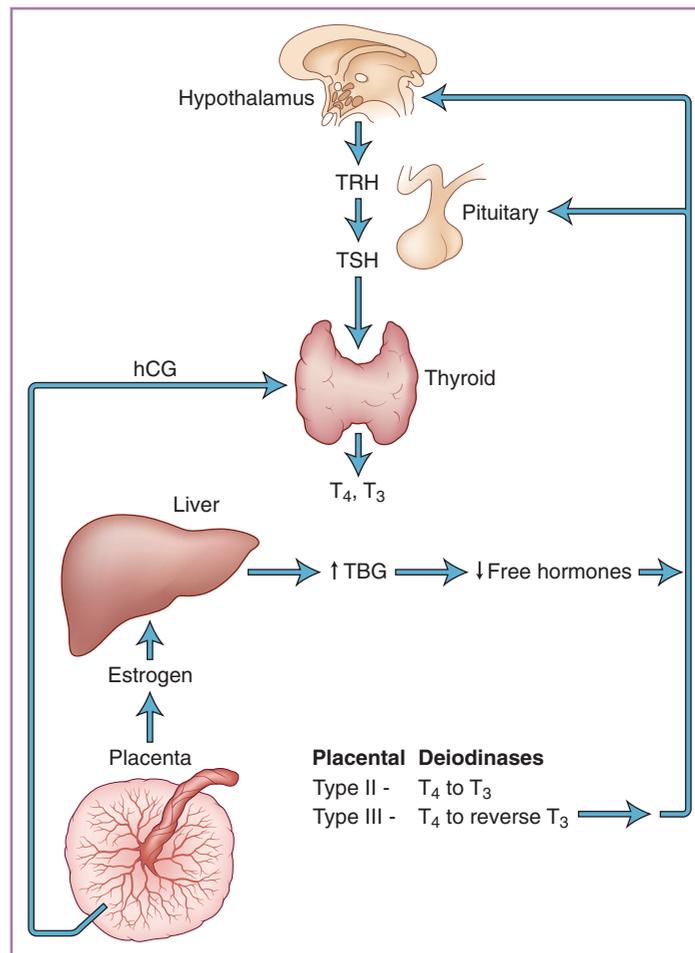

FIGURE 47-3 Physiologic adaptation to pregnancy. Schematic representation of the physiologic adaptation to pregnancy shows increased thyroxine-binding globulin (TBG) concentrations, increased levels of human chorionic gonadotropin (hCG) with its thyrotropin-like activity, and alterations in the peripheral metabolism of thyroid hormones in the placenta. TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone; T_4 , thyroxine; T_3 , triiodothyronine. (Adapted from Glinoe D: What happens to the normal thyroid during pregnancy? *Thyroid* 9:631, 1999.)

of increased renal blood flow and an increase in glomerular filtration rate of as much as 50%.¹⁸ If iodine excretion is greater than 100 μg in a 24-hour period, the patient's iodine intake is assumed to be sufficient.^{19f}

Placental-Fetal Thyroid Physiology

The thyroid gland forms as a midline outpouching of the anterior pharyngeal floor, migrates caudally, and reaches its final position by 7 weeks' gestation. Lateral contributions from the fourth and fifth pharyngeal pouches give it its bilateral shape by 8 to 9 weeks' gestation. Active trapping of iodide is detectable by week 12, and the first indication of T_4 production is detectable by week 14. Hypothalamic TRH is detectable at weeks 8 to 9, and the pituitary portal circulation is func-

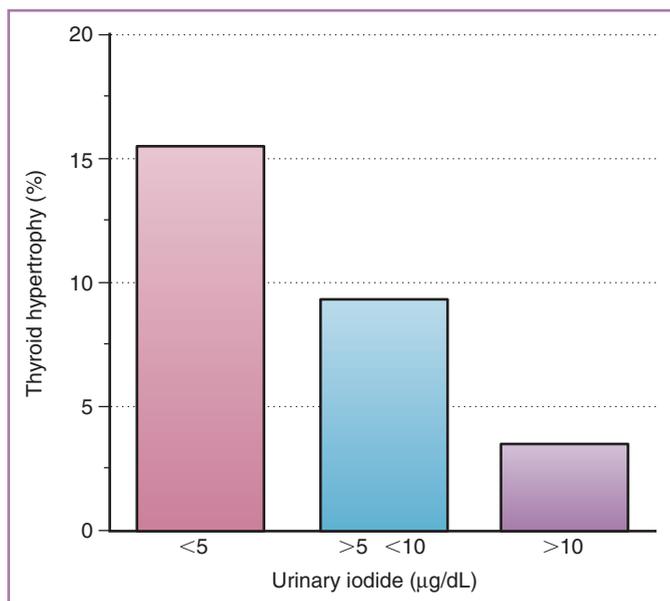

FIGURE 47-4 Iodine deficiency can manifest as thyroid hypertrophy. The percentage of maternal thyroid hypertrophy (thyroid volume > 18 mL) is plotted against the urinary iodine concentration measured during the first trimester of pregnancy. (Reprinted by permission from Caron P, Hoff M, Bassi S, et al: Urinary iodine excretion during normal pregnancy in healthy women living in the southwest of France: Correlation with maternal thyroid parameters. *Thyroid* 7:749, 1997.)

tional by weeks 10 to 12. Until mid-gestation, fetal TSH and T_4 concentrations remain low. At 18 to 20 weeks' gestation, the fetal thyroid gland's iodine uptake and serum T_4 concentrations begin to increase.²⁰ Concentrations of T_4 increase from 2 µg/dL at 20 weeks to 10 µg/dL at term, with increasing TBG concentrations contributing to this rise. Similarly, free fetal T_4 concentrations increase from 0.1 ng/dL at 12 weeks' gestation to 1.5 ng/dL near term. Increases in T_3 and free T_3 are smaller, presumably because of the availability of placental type III deiodinase, which converts T_4 rapidly to reverse T_3 . Fetal serum T_3 increases from 6 ng/dL at 12 weeks' gestation to 45 ng/dL near term. Fetal serum TSH increases from 4 to 8 mU/L between weeks 12 and term.^{21,22} In summary, most fetal T_4 is inactivated to reverse T_3 . The T_3 (from T_4 conversion or direct fetal thyroid secretion) has limited availability. Fetal tissues that depend on T_3 for development (e.g., brain structures) are supplied by local T_4 to T_3 conversion by means of deiodinase type II.²²

Placental Transfer of Thyroid Hormones

Although earlier studies suggested only limited T_4 and T_3 transfer through the placenta, later studies have shown that T_4 can be found in first-trimester celomic fluid by 6 weeks' gestation. Nuclear T_3 receptors can be identified in the brain of 10-week-old fetuses, and they increase tenfold by 16 weeks' gestation before the fetal thyroid becomes fully functional.²⁴ These studies suggest that maternal T_4 transfer occurs early in gestation and that low levels of T_4 are sustained in the fetus at this time.²⁵ Vulsma and colleagues²⁶ reported that cord serum T_4 levels in hypothyroid neonates with glandular agenesis represented as much as 30% of normal circulating values, a strong indication of maternal T_4 transfer, although this has not been a uniform finding.²⁷

It appears that the first phase of maximum growth velocity of developing brain structures—neuronal multiplication and organization occurring during the second trimester—corresponds to a phase during which the supply of thyroid hormones to the fetus is almost exclusively of maternal origin.²⁰ In the second phase of maximum fetal brain growth velocity, occurring from the third trimester to 2 to 3 years postnatally, the supply of thyroid hormone is of fetal and neonatal origin. Low maternal thyroxine concentrations in the second trimester can result in irreversible neurologic deficit in offspring. When it occurs later, the damage to the fetal brain is less and is partially reversible. The need for T_3 by mid-gestation for development of the human cerebral cortex was also demonstrated by Kester and associates.²⁸ Concentrations of TSH, T_4 , T_3 , and reverse T_3 are measurable in the amniotic fluid and correlate with the fetal rather than maternal serum.

Neonatal Thyroid Function

Immediately after birth, there is a surge of TRH and TSH that is followed by an increase in T_3 (from increased T_4 to T_3 conversion) and a moderate increase in T_4 .¹⁰ Within a few days, the increased TSH falls to adult levels through T_4 and T_3 negative-feedback inhibition. Neonatal T_4 and T_3 concentrations return to normal adult levels within 4 to 6 weeks.²⁹ The transient hyperthyroxinemia can be triggered by neonatal cooling and may represent an adaptation of thermogenesis to extrauterine life.^{30,31}

In premature neonates, free T_4 levels are low, TSH levels are normal (adult), and T_4 levels are related to gestational age. The clinical consequence of this transient hypothalamic hypothyroidism is unknown, but it has been associated with impaired neurologic and mental development.³²⁻³⁴

Placental Transfer of Drugs Affecting Thyroid Function

The potential influence of the placenta on fetal thyroid and neurologic development is evident by the ready transfer of several agents that affect thyroid function.^{35,36} These agents include the following:

- Iodine
- Thionamides
- β-Adrenergic receptor blockers
- Somatostatin
- Exogenous TRH
- Dopamine agonists and antagonists
- Thyroid-stimulating immunoglobulins and other antibodies

TSH does not cross the placenta. TRH and corticosteroid administered antenatally before 32 weeks' gestation stimulates T_4 release and decreases the frequency of chronic lung disease among neonates.³⁷ Intra-amniotic administration of T_4 in the preterm setting increases fetal maturation, as reflected by an increase in the lecithin-to-sphingomyelin ratio and decrease in respiratory distress syndrome of the newborn.³⁸

Pregnancy, the Immune System, and Thyroid Disease

Chapter 6 offers a detailed review of pregnancy immunology. The fetus, with its complete set of paternal antigens, survives because of

adjustments in the maternal-placental-fetal immune systems. This immunologic compromise of pregnancy is orchestrated primarily by the placental tissues and passaged fetal cells that are able to modulate the local and systemic maternal immune responses.^{39,40} Autoimmune responses are usually reduced in pregnancy, as evidenced by amelioration of Graves disease, rheumatoid arthritis, and multiple sclerosis.⁴¹⁻⁴³ Although there is a shift from proinflammatory T_H1 cytokines to T_H2 cytokines, driven perhaps by progesterone,⁴⁴ it is occurring against a background of reduced B-cell reactivity. The reduced B-cell responses are likely orchestrated by placental sex steroids, which are powerful negative regulators of B-cell activity. Whereas most of the immune changes in pregnancy return to normal by 12 months after delivery, there is a marked increase after most pregnancies in many different types of autoantibody secretion and an exacerbation of autoimmune disease. In most studies, total immunoglobulin G and autoantibody levels rise above pre-pregnancy levels during the first 6 months after delivery, suggesting continuing nonspecific immune stimulation.³⁹

Laboratory Evaluation of Thyroid Function during Pregnancy

Thyrotropin and Thyroid Hormones

Total T₄ and total T₃ are elevated because of increased TBG production and reduced clearance induced by the hyperestrogenic state of pregnancy.⁴⁵ The normal reference range for total T₄ should be adjusted by a factor of 1.5 for pregnant patients.² The T₃ resin uptake (i.e., indirect laboratory measure of available TBG binding sites) is reduced in pregnancy because increased TBG binding sites take up more of the added T₃, leaving less to bind to resin. The free thyroxine index, which is a product of the total T₄ and T₃ resin uptake, usually falls to within the normal range in pregnancy. Because free T₄ can be determined, however, third-generation TSH and free T₄ assessments are the best ways to evaluate thyroid function in pregnancy. However, automated free T₄ assays are sensitive to alternations in binding proteins as occurs in pregnancy. Because these proteins change, they can falsely elevate or lower the free T₄ assay result. The free T₄, as measured by equilibrium dialysis, is not affected by these protein changes. Trimester-specific normative data for iodine-sufficient women using specific commercially available assays is not available. This topic is discussed further in the section on Subclinical Hypothyroidism and Hypothyroxinemia.

If the TSH is suppressed, suggesting overproduction of thyroid hormones, free T₃ can be determined. The third-generation TSH assays can differentiate profound from marginal suppression. Trimester-specific TSH concentrations were obtained by Dashe and colleagues,⁴⁶ who determined these concentrations at each point during gestation in singleton and twin pregnancies. They constructed nomograms for both using regression analysis and showed significantly lower TSH concentrations in the first trimester. These levels were lower in twin pregnancies, as would be expected from the known effects of hCG. Values were converted to multiples of the median for singleton pregnancies at each week of gestation, and they suggested that values expressed this way might facilitate comparison across laboratories and populations. In another study, using sensitive TSH assays, 9% of non-symptomatic first-trimester women were found to have TSH values higher than 0.05 mU/L (i.e., lower limit of assay detection) but less than 0.4 mU/L, and another 9% had TSH values below the detection limit.⁸ Free T₃ and T₄ concentrations can be in the high-normal range

TABLE 47-1 FACTORS INFLUENCING THYROXINE-BINDING GLOBULIN

Factors Increasing TBG Levels	Factors Decreasing TBG Levels
Oral contraceptives	Testosterone

Inherited defect	Inherited defect

TBG, thyroxine-binding globulin.

early in pregnancy because of the stimulatory effects of hCG. Free T₄ levels tend to fall through the rest of pregnancy and occasionally to levels below those of nonpregnant women.² Free hormone levels then fall through the rest of the pregnancy but usually not below the lower limit of normal.⁴⁷ Table 47-1 outlines factors that influence TBG and therefore total hormone concentrations.

Resistance to thyroid hormone is a rare condition encompassing a number of different defects. The pituitary and other peripheral tissues can manifest this resistance. These patients present with an increased free T₄ concentration along with an inappropriately elevated or non-suppressed TSH, and they may have goiters. Whereas patients with thyroid hormone resistance have normal α -subunit concentrations, patients with TSH-secreting tumors (i.e., differential diagnosis of thyroid hormone resistance) often have elevated serum α -subunit levels.⁴⁸ In a case reported by Anselmo and colleagues,⁴⁹ transient thyrotoxicosis occurred during pregnancy in a woman with resistance to thyroid hormone caused by a mutation in the thyroid receptor β gene. This thyrotoxicosis manifested clinically by hypermetabolic features and paralleled the rise and peak of hCG concentrations. Symptoms ameliorated and thyroid hormone concentrations declined as pregnancy progressed and hCG concentrations fell.

Concern has been raised regarding unaffected fetuses of mothers with thyroid hormone resistance. Outcomes of pregnancies in an extended Azorean family with resistance to thyroid hormone were analyzed; miscarriages were found to be more common, and unaffected infants born to affected mothers had lower birth weights, demonstrating a direct toxic effect of thyroid hormone excess on the fetus.⁵⁰

Thyrotropin Receptor Antibodies

Several functional types of TSH receptor antibodies are recognized. Some antibodies promote gland function (i.e., thyroid-stimulating immunoglobulins [TSIs]), some inhibit binding of TSH to its receptor (i.e., thyroid-binding inhibitory immunoglobulins [TBIs]), and some enhance or inhibit thyroid growth. These antibodies can be measured by a variety of bioassays and receptor assays. For example, maternal production of TSIs causes maternal Graves disease, is transferred across the placenta, and can lead to neonatal Graves disease. Excess TBIs can cause maternal and neonatal hypothyroidism.

Antithyroid Antibodies

Patients with autoimmune thyroid disease commonly develop antibodies to thyroid antigens. The two most commonly determined antibodies are those to thyroglobulin and to thyroid peroxidase (anti-TPO).⁵¹ Among nonpregnant women, the incidence of anti-TPO

antibodies is about 3%, with the incidence ranging from 5% to 15% among pregnant women. A substantial proportion of women with positive anti-TPO antibodies in early pregnancy develop postpartum thyroiditis.^{52,53}

Drugs and Thyroid Function

Table 47-2 outlines drug effects on thyroid function and metabolism, absorption of thyroid hormones, and interpretation of thyroid function tests. Iodine and lithium inhibit thyroid function. Propranolol and iodate block T₄ to T₃ conversion, as do glucocorticoids; however, glucocorticoids also reduce release of TSH from the pituitary, as do dopamine, dopamine agonists, and somatostatin. The antiseizure medication phenytoin reduces total T₄ levels (up to 30%) by inhibiting the binding of thyroid hormones to binding proteins and increasing T₄ clearance. Ferrous sulfate, aluminum hydroxide, and sucralfate may inhibit thyroid hormone absorption substantially—an important interaction in pregnant women who are taking both iron and thyroid hormones.

Amiodarone, an iodine-rich drug, has been used in pregnancy for maternal or fetal tachyarrhythmias. Amiodarone and the iodine are transferred across the placenta, exposing the fetus to the drug and iodine overload. This iodine overload can cause fetal or neonatal hypothyroidism and goiter, because the fetus acquires the capacity to escape from the acute Wolff-Chaikoff effect (i.e., decrease in peroxidase activity and organification that follow iodine excess) only late in gestation. Among 64 pregnancies in which amiodarone was given to the mother, 17% of progeny developed hypothyroidism (goitrous and nongoitrous). Hypothyroidism was transient, although a few of the infants were treated

short term with thyroid hormones. Only two newborns had transient hyperthyroxinemia. Although breastfeeding resulted in substantial infant amiodarone ingestion, it did not cause major changes in neonatal thyroid function. The study authors concluded that amiodarone should be used only when tachyarrhythmias are unresponsive to other drugs and are life threatening and that hypothyroid neonates (and perhaps the fetus in utero) should be treated. It is prudent to monitor the infants of breastfeeding mothers who continue to use the medication.⁵⁴

Nonthyroidal Illness and Thyroid Function

Nonthyroidal illness has been the topic of various reviews and commentaries.^{4,5,55} Severely ill patients can manifest thyroid function test abnormalities that may correlate with functional inhibition of the hypothalamic-pituitary-thyroid axis, impaired T₄ to T₃ conversion (a constant accompaniment of nonthyroidal illness), and abnormalities in binding and clearance of thyroid hormone. Reverse T₃ levels are substantially elevated because of increased T₄ to reverse T₃ conversion and impaired metabolic clearance of reverse T₃. TSH concentrations can be low, normal, or elevated, although seldom higher than 20 mU/L.⁵⁵ The more severe the illness, the lower the T₄ values, and this relationship has been used as a prognostic indicator, because a high correlation has been found between a low T₄ value and a fatal outcome.⁵⁶ The best test for assessing thyroid function in severely or chronically ill patients is the free T₄ concentration. Despite the low T₃ and total T₄ state, this situation does not represent true hypothyroidism, but rather an adaptation to stress, and it should not be treated.

Thyroid Dysfunction and Reproductive Disorders

Thyroid hormones are important for normal reproductive function. Deficiency of thyroid hormone can result in delayed sexual development. As reviewed by Winters and Berga⁵⁷ and Krassas,⁵⁸ all women with infertility and menstrual disturbances should have thyroid function tests, usually T₄, T₃, and TSH. Women with type 1 diabetes, who have a relatively high incidence of hypothyroidism, should probably undergo screening before conception. This topic has been reviewed by Trokoudes and coworkers.⁵⁹

Hyperthyroidism

Hyperthyroidism has been linked to oligomenorrhea, hypomenorrhea, amenorrhea, and infertility, although many thyrotoxic women remain ovulatory. In one survey, only 21.5% of 214 thyrotoxic patients had menstrual disturbances, compared with 50% to 60% in older series.⁶⁰ Thyroxine upregulates the production of sex hormone-binding globulin. Elevated levels of circulating testosterone and estrogen may be observed, and the clearance of testosterone is reduced. Gonadotropin concentrations can be tonically elevated.^{61,62} The substantial weight loss seen in some hyperthyroid patients can affect the hypothalamic-pituitary-gonadal axis and can contribute to the infertility of severe hyperthyroidism.

Hypothyroidism

Hypothyroidism in fetal life does not affect the development of the reproductive tract, but during childhood, it leads to sexual immaturity

and usually a delay in puberty, followed by anovulatory cycles. Almost 25% of women with untreated hypothyroidism have menstrual irregularities. Menorrhagia occurs frequently and can reflect interference with the endometrial maturational process and response to ovarian steroids; it usually responds to thyroxine treatment.⁶³ The increased miscarriage rate seen in hypothyroid patients may reflect disrupted endometrial maturation. Hypothyroidism, through increased TRH, can be associated with hyperprolactinemia, which itself can disrupt reproductive function and menstrual cyclicity,⁶⁴ leading to oligomenorrhea or amenorrhea. Galactorrhea can sometimes be seen in this setting, as can elevated levels of luteinizing hormone, possibly through diminished dopamine secretion.⁶⁵

Women with hypothyroidism have diminished rates of metabolic clearance of androstenedione and estrone and an increase in peripheral aromatization. Whereas plasma concentrations of testosterone and estradiol are decreased because of diminished binding activity, their unbound fractions are actually increased. Several studies have suggested increased risk of miscarriage in the presence of thyroid antibodies, even in the face of a euthyroid status. Although previous studies did not demonstrate benefit in using T₄ to treat euthyroid women with recurrent spontaneous abortions,⁶⁶⁻⁶⁸ benefit was shown by Negro and colleagues⁶⁹ in a group of 115 antibody-positive women, one half of whom received thyroxine. Treatment decreased miscarriages and prematurity by 75% and 69%, respectively. In a thoughtful accompanying editorial, Glinoe⁷⁰ stated that the statistical strength of the association between miscarriages and autoimmune thyroid disease has been largely confirmed, with a threefold increase in the overall miscarriage rate. Because there is no reason to believe that thyroxine treatment altered autoimmunity, it was thought that the subtle deficiency in thyroid hormone concentration or reduced ability of maternal thyroid function to adapt adequately in women with autoimmune thyroid disease was the main reason for the beneficial effects of thyroid hormone administration.

Radioiodine and Gonadal Function

The prevalence of infertility, premature births, miscarriage, and genetic damage in the offspring of women treated with radioactive iodine for thyrotoxicosis does not seem to be increased.^{71,72} Although thyroid cancer doses of ¹³¹I may be associated with subsequent menstrual irregularities, exposure to radioiodine does not appear to reduce fecundity.⁷³ In a study of 32 women who conceived after ¹³¹I treatment for thyroid cancer (resulting in 60 term deliveries), two children conceived within a year of ¹³¹I therapy had birth defects, but no anomalies were seen in the remaining 58.⁷⁴ Contraception has been recommended for 1 year after ¹³¹I treatment. In a large study, Schlumberger and associates⁷⁵ obtained data on 2113 pregnancies conceived after exposure to 30 to 100 mCi of radioiodine given for thyroid cancer. The incidences of stillbirths, preterm labor, low birth weight, congenital malformations, and death during the first year of life were not significantly different between pregnancies conceived before or after radioiodine therapy. Miscarriages were more common for the women treated with ¹³¹I in the year preceding conception (40%).

All women need pregnancy tests before ¹³¹I treatment. Treatment late in the first trimester and in the second trimester may result in irreversible hypothyroidism in the fetus. Lactating mothers who have received diagnostic or therapeutic doses of ¹³¹I should not breastfeed their infants. These topics are reviewed by Gorman⁷⁶ and Berlin.⁷⁷

Hyperthyroidism and Pregnancy

Signs and Symptoms

The prevalence of hyperthyroidism in pregnant women ranges from 0.05% to 0.2%.⁷⁸ The signs and symptoms of mild to moderate hyperthyroidism—heat intolerance, diaphoresis, fatigue, anxiety, emotional lability, tachycardia, and a wide pulse pressure—can be mimicked by the hypermetabolic state of normal pregnancy. However, weight loss, tachycardia greater than 100 beats/min, and diffuse goiter are features that may suggest hyperthyroidism. Graves ophthalmopathy can be helpful but does not necessarily indicate active thyrotoxicosis.⁷⁹ Gastrointestinal symptoms such as severe nausea and excessive vomiting can accompany thyrotoxicosis in pregnancy, as can diarrhea, myopathy, lymphadenopathy, and congestive heart failure.

Diagnosis

Biochemical confirmation of the hyperthyroid state can be obtained through laboratory measurement of free T₄, free T₃, and TSH. Typically, elevated values of free T₄ and T₃ and greatly suppressed TSH values are found, but a normal free T₄ level can be seen in cases of T₃ toxicosis. Other laboratory features include normochromic, normocytic anemia; mild neutropenia; elevated levels of liver enzymes and alkaline phosphatase; and mild hypercalcemia. Patients may test positive for anti-thyroid antibodies (i.e., antithyroglobulin and antithyroid peroxidase), but they are not specific to Graves disease. TSIs are considered to be the antibodies specific to Graves disease and can be measured by bioassays or receptor assays.⁸⁰

Differential Diagnosis

Causes of hyperthyroidism are outlined in Table 47-3. Approximately 90% to 95% of hyperthyroid pregnant women have Graves disease, and this can be diagnosed with certainty in a thyrotoxic pregnant woman who has diffuse thyromegaly with a bruit and ophthalmopathy. Whereas excess circulating thyroid hormones cause lid retraction and lid lag, proptosis and external ocular muscle palsies reflect infiltrative ophthalmopathy of Graves disease. Graves disease is an autoimmune disease mediated by antibodies (i.e., TSIs) that activate the TSH recep-

tor and stimulate the thyroid follicular cell. It affects 3% of women of reproductive age.⁸¹

Treatment

The outcome of treatment before pregnancy is better than that of treatment in pregnancy,⁸² and hyperthyroidism is therefore best treated before conception. If untreated or treated inadequately, women may have more complications during pregnancy and delivery. Very mild cases of hyperthyroidism, with adequate weight gain and appropriate obstetric progress, may be followed carefully, but moderate or severe cases must be treated. In a retrospective study of 60 thyrotoxic pregnant women, preterm delivery, perinatal mortality, and maternal heart failure were significantly increased among women who remained thyrotoxic. Thyroid hormone status at delivery correlated directly with pregnancy outcome.⁸² In another study by Momotani and Ito,⁸³ hyperthyroidism at conception was associated with a 25% rate of abortion and 15% rate of premature delivery, compared with 14% and 10%, respectively, for euthyroid patients. Preeclampsia has also been associated with uncontrolled hyperthyroidism.⁸⁴

Thionamide Therapy

Thionamide therapy has been reviewed by Cooper⁸⁵ and Clark and associates.⁸⁶ The thionamides inhibit the iodination of thyroglobulin and thyroglobulin synthesis by competing with iodine for the enzyme peroxidase. Propylthiouracil (PTU) is more frequently prescribed in the United States. Carbimazole (a drug metabolized to methimazole) and methimazole itself are used often in Europe and Canada. PTU (but not methimazole) also inhibits the conversion of T_4 to T_3 . The goal of therapy is to control the hyperthyroidism without causing fetal or neonatal hypothyroidism.⁸⁷ Maternal free T_4 should be maintained in the high-normal range. PTU is given every 8 hours at doses of 100 to 150 mg (300 to 450 mg total daily dosage) according to thyrotoxicosis severity. The occasional patient may require higher doses (e.g., 600 mg or more) because the risk of uncontrolled maternal hyperthyroidism is greater than that of high-dose PTU.⁸² It can take 6 to 8 weeks for major clinical effects to manifest. After the patient is euthyroid (reflected by monthly free T_4 and free T_3 values), the dose of PTU should be tapered (e.g., halved), with further reduction as the pregnancy progresses. For many patients, PTU can be discontinued by 32 to 36 weeks' gestation, because remission of Graves disease during pregnancy is commonly observed, often with relapse after delivery. It has been suggested that a change from stimulatory to blocking antibody activity may contribute to this remission.⁸⁸

Maternal side effects of PTU treatment can include rash ($\approx 5\%$), pruritus, drug-related fever, hepatitis, a lupus-like syndrome, and bronchospasm. An alternative thionamide can be used, although cross-sensitivity occurs in 50% of patients. Agranulocytosis, which is the most serious side effect, develops in only 0.1%, occurring especially in older women and those receiving higher doses.⁸⁹ All patients experiencing fever or unexpected sore throat on therapy should discontinue the drug and have white blood cell count monitoring. Agranulocytosis is a contraindication to further thionamide therapy; the blood count gradually improves over days or weeks.

Methimazole is not used in the United States. Although the transplacental passage is similar,⁹⁰ methimazole may cause cutis aplasia, a scalp deformity.⁹¹⁻⁹³ Although rare, there are reports of methimazole and carbimazole embryopathy, with choanal atresia, tracheoesophageal fistula, and facial anomalies.⁹⁴⁻⁹⁷

The risks of untreated hyperthyroidism need to be considered in relation to the risk of antithyroid medications. They appear to relate

directly to the control and severity of the hyperthyroidism. In a study of hyperthyroid pregnant women, the odds ratio for low birth weight was 2.4 for those treated during pregnancy and 9.2 for those uncontrolled during pregnancy compared with a group who was euthyroid and remained so. Similarly, prematurity was more common in the hyperthyroid group; the odds ratio was 2.8 for the controlled group and 16.5 for the uncontrolled group. Similar findings related to preeclampsia, with an odds ratio of 4.7 for the controlled group.⁸⁴ This was confirmed by a later study.⁹⁸ In other reports, higher frequencies of small-for-gestational-age births, congestive heart failure, and stillbirths have been found.^{82,99} It is uncertain whether untreated Graves disease is associated with a higher frequency of congenital malformation.^{87,100}

Infants of mothers receiving thionamides should be evaluated ultrasonographically for signs of hypothyroidism, such as goiter, bradycardia, and intrauterine growth restriction. If needed, cordocentesis may be performed and fetal thyroid function determined; reference ranges have been reported.¹⁰¹ Doses of PTU should be adjusted to keep free T_4 level in the upper normal range and TSH level less than 0.5 mU/L during pregnancy to avoid hypothyroidism in the fetus. PTU often can be stopped in late gestation.

PTU is not significantly concentrated in breast milk (10% of serum) and does not appear to affect the infant's thyroid hormone levels in any major way. Methimazole also does not appear to affect subsequent somatic or intellectual growth in children exposed to it during lactation.^{87,102,103} Antithyroid medication should be taken just after breastfeeding, allowing a 3- to 4-hour interval before the woman lactates again.

β -Blockers

β -Blockers are useful for the control of adrenergic symptoms, particularly maternal heart rate. Propranolol is commonly used in doses of 20 to 40 mg two or three times daily, and it inhibits T_4 to T_3 conversion. Alternatively, atenolol (50 to 100 mg daily) may be used, and in an emergency, esmolol, an ultra-short-acting cardioselective intravenous β -blocker, has been used successfully.¹⁰⁴ Prolonged therapy with β -blockers can be associated with intrauterine growth restriction, fetal bradycardia, and hypoglycemia.

Iodides

Iodides decrease circulating T_4 and T_3 levels by up to 50% within 10 days by acutely inhibiting the release of stored hormone. Their use is appropriate in combination with thionamides (which should be started before the iodide) and β -blockers in patients with severe thyrotoxicosis or thyroid storm. Potassium iodide (SSKI, 5 drops every 8 hours) is given. Sodium ipodate, a radiographic contrast agent, is an alternative and has the added benefit of inhibiting conversion of T_4 to T_3 . Its safety in pregnancy has not been documented.

Because iodides cross the placenta readily, they should be used for no longer than 2 weeks, or fetal goiter can result. Inadvertent use of iodides also follows use of Betadine cleansing solutions, iodine-containing bronchodilators, and the drug amiodarone.

¹³¹I thyroid ablation is contraindicated in pregnancy because the radioactive iodine is concentrated in the fetal thyroid after 10 to 12 weeks' gestation. If a woman inadvertently receives ¹³¹I during pregnancy, SSKI should be given immediately, along with PTU, to block organification and reduce radiation exposure to the fetal thyroid by a factor of 100 and to the fetal whole body by a factor of 10. To be of benefit, SSKI and PTU treatment must be given within 7 to 10 days of exposure.⁷⁶

Surgery

In select cases of thyrotoxicosis with severe complications or noncompliance, surgery can be performed in the pregnant patient. Two weeks of low-dose iodine therapy, such as one or two drops of SSKI daily, can reduce gland vascularity preoperatively. Surgery is best performed in the second trimester, although it can be done in the first or third trimester.¹⁰⁵ The risks are those of anesthesia, hypoparathyroidism, and recurrent laryngeal nerve paralysis.

Thyroid Storm

Thyroid storm is a life-threatening exacerbation of thyrotoxicosis. Criteria for its diagnosis have been introduced,¹⁰⁶ and the classic findings are various degrees of thermoregulatory dysfunction, central nervous system effects (e.g., agitation, delirium, coma), gastrointestinal dysfunction, and cardiovascular problems manifesting as tachycardia or heart failure. For example, a patient with a temperature of 102°F who is agitated and tachycardic with a pulse rate exceeding 130 beats/min would be diagnosed with thyroid storm. Although rare in pregnancy, it may be seen and can be precipitated by labor and delivery, cesarean section, infection, or preeclampsia.¹⁰⁷ Thyrotoxic cardiomyopathy may also lead to heart failure in pregnancy.¹⁰⁸ Intensive care treatment with fluid and nutritional support is necessary for thyroid storm and heart failure. A loading dose of PTU of 600 mg may be given orally or through a nasogastric tube, and 200 to 300 mg of PTU is continued every 6 hours. An hour after the initial dose of PTU, iodine is given as five drops of SSKI every 8 hours (or 500 to 1000 mg of intravenous sodium iodide every 8 hours) to inhibit thyroid hormone release. If the patient is iodine allergic, lithium (300 mg every 6 hours) is an alternative. Dexamethasone (2 mg every 6 hours) is also given to block T₄ to T₃ conversion. For tachycardia exceeding 120 beats/min, β-blockers such as propranolol, labetalol, or esmolol may be used.¹ Table 47-4 summarizes the management of thyroid storm.

Subclinical Hyperthyroidism

Subclinical hyperthyroidism, as defined by suppressed TSH and normal free T₄ and free T₃ levels, is also seen in pregnancy. In a study by Casey and associates,¹⁰⁹ 1.7% of women screened had subclinical hyperthyroidism, which they defined as TSH values at or below the 2.5th percentile for gestational age and a free T₄ level of 1.75 ng/dL or less. Pregnancy complications, morbidity, and mortality were not increased

among these women, and it was recommended that treatment in pregnancy was unwarranted.

Fetal and Neonatal Hyperthyroidism

The topic of fetal and neonatal hyperthyroidism has been reviewed by Zimmerman.¹¹⁰ Hyperthyroidism in fetuses and neonates is usually produced by transplacental passage of TSIs. Although they are a common component of active Graves disease, the antibodies can continue to be present in the maternal circulation after surgical (Fig. 47-5) or radioactive iodine ablation or even in patients with Hashimoto thyroiditis. Fetal hyperthyroidism occurs when TSIs cross the placenta and activate the fetal thyroid; this occurs in 1% of infants born to these women.

Maternal TSI levels in excess of 300% of control values are predictive of fetal hyperthyroidism⁹⁹ and should be measured at 28 to 30 weeks. The assay used should be a functional one, because TSH-receptor antibodies are heterogeneous and can stimulate or block the TSH receptor.^{99,111} Neonatal syndromes have been caused by transplacental passage of stimulating and blocking antibodies.¹¹²

Fetal Thyrotoxicosis

Features of fetal thyrotoxicosis include a heart rate greater than 160 beats/min, growth retardation, advanced bone age, and craniosynostosis, all of which can be detected by ultrasound examination.¹¹³ Occasionally, nonimmune fetal hydrops and fetal death occur with associated diminished subcutaneous fat and thyroid enlargement. In utero, most cases are likely treated by the PTU given to the mother. This problem can arise if the mother is euthyroid but has elevated levels of TSIs.¹¹⁴ Cordocentesis can be used for diagnosis and for monitoring therapy. A combination of PTU and T₄ treats the fetal hyperthyroidism while keeping the mother euthyroid.

Neonatal Thyrotoxicosis

Features of thyrotoxicosis in the neonate include hyperkinesis, diarrhea, poor weight gain, vomiting, exophthalmos, arrhythmias, cardiac failure, hypertension (systemic and pulmonary), hepatosplenomegaly,

TABLE 47-4 TREATMENT OF THYROID STORM

Treatment	Rationale and Cautions	Dosage
General care	Intensive management achieved with intravenous fluid hydration and nutritional support	
Propylthiouracil		Initial: 600 mg orally or crushed and given by NG tube Maintenance: 200-300 mg every 6 hr given orally or by NG tube
Iodide	Initial dose to be given 1 hr after start of PTU	5 drops of supersaturated solution of potassium iodide every 8 hr or 500-1000 mg of intravenous sodium iodide infusion every 12 hr
Lithium carbonate	Used if patient is allergic to iodine	300 mg every 6 hr
Dexamethasone	Given to block T ₄ to T ₃ conversion	2 mg every 6 hr for four doses
β-Blockers	Given to control tachycardia ≥ 120 beats/min (use cautiously if patient in heart failure)	IV propranolol at 1 mg/min up to several doses until blockade is achieved and concurrent 60 mg of propranolol (PO or NG tube) every 6 hours <i>or</i> IV loading dose of 250-500 μg/kg of esmolol, followed by infusion at 50-100 μg/kg/min

IV, intravenous; NG, nasogastric; PO, orally; PTU, propylthiouracil.

FIGURE 47-5 Graves disease. **A**, Hypothyroid 21-year-old woman who developed Graves disease at age 7 was treated by subtotal thyroidectomy. She was given maintenance therapy with thyroid hormone (0.15 mg of Synthroid) throughout pregnancy. **B**, Her daughter was born at term with severe Graves disease, goiter, and exophthalmos that persisted for 6 months. **C**, The child was normal at 20 months old.

thrombocytopenia, and craniosynostosis. The infant should be examined immediately after birth. Cord blood reflects the in utero environment, and by day 2 of life, the maternal antithyroid drug effects have receded. Affected neonates are treated with PTU, β -blockers, iodine, and glucocorticoids and digoxin, as needed. Iodate may be preferable because it blocks T_4 to T_3 conversion. Remission by 20 weeks is common, and it usually occurs by 48 weeks; occasionally, there is persistent disease when there is a strong family history of Graves disease.

Other mechanisms of fetal and neonatal hyperthyroidism include activating mutations of the stimulatory G protein in McCune-Albright syndrome and activating mutations of the TSH receptor.^{115,116}

Hyperthyroidism Related to Human Chorionic Gonadotropin

When hyperthyroidism is diagnosed during the first trimester, the physician has a challenging differential diagnosis, usually that of Graves disease versus hCG-mediated hyperthyroidism. The hCG has TSH-like stimulatory activity, which can result in overproduction of thyroid hormone when the concentrations are high or when there is a change in its molecular structure. Molecular variants of hCG with increased thyrotropic potency include basic molecules with reduced sialic acid content, truncated molecules lacking the C-terminal tail, or molecules in which the 47-48 peptide bond in the β -subunit loop is nicked.¹¹⁷ This relationship is further complicated by differences in clearance rates of different hCG glycoforms.¹¹⁸ In vivo thyrotropic activity is regulated by the glycoforms and the plasma half-life.

The hCG concentrations peak at 6 to 12 weeks and then decline to a plateau after 18 to 20 weeks. The stimulation of thyroid hormone

production can suppress the TSH to low or suppressed values in up to 20% of normal pregnancies. Twin pregnancies can be associated with biochemical hyperthyroidism,⁹ as may pregnancies complicated by trophoblastic disease. Several clinical scenarios can arise and are described in the following sections.

Gestational Transient Thyrotoxicosis

Gestational transient thyrotoxicosis (GTT) occurs in the first trimester in women without a personal or family history of autoimmune disease. It results directly from hCG stimulation of the thyroid. Glinoe and colleagues⁸ found an overall prevalence of GTT in 2.4% in a prospective cohort study between 8 and 14 weeks' gestation. Symptoms compatible with thyrotoxicosis were often present, and elevated free T_4 concentrations were found. The GTT was transient, paralleled the decline in hCG, and usually did not require treatment. The thyroid gland was not enlarged. Occasionally, β -blockers were used. GTT was not associated with a less favorable outcome of pregnancy.

Hyperemesis Gravidarum

Hyperemesis gravidarum is a serious pregnancy complication associated with weight loss and severe dehydration, often necessitating hospitalization.¹¹⁹ Biochemical hyperthyroidism is found in most women with this condition.^{120,121} Whereas Goodwin and colleagues^{120,121} found that the severity of disease varied directly with the hCG concentration, Wilson and associates¹²² did not find such a correlation. As in the case of GTT, certain hCG fractions may be more important than total hCG as thyroid stimulators.¹²³ The duration of the hyperthyroidism varies widely from 1 to 10 weeks but is usually self-limited. Vomiting and normalization of T_4 levels occur by 20 weeks, though TSH may remain suppressed a little longer. Treatment is usually supportive, with correction of dehydration, antiemetics, and occasionally, parenteral nutrition. The vomiting may not be controlled by normalization of

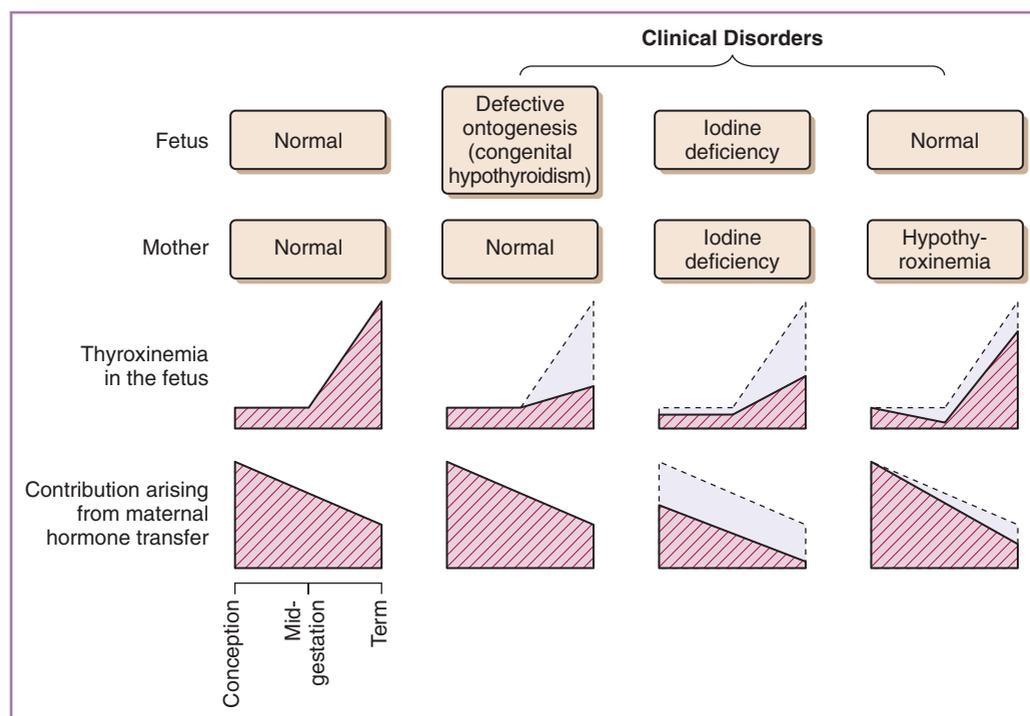

FIGURE 47-6 Thyroid function disorders. Schematic representation of the three sets of clinical conditions that can affect thyroid function in the mother alone, in the fetus alone, or in the fetomaternal unit shows the relative contributions of impaired maternal or fetal thyroid function that may eventually lead to alterations in fetal thyroxinemia. (Reprinted by permission from Glinoe D, Delange F: The potential repercussions of maternal, fetal and neonatal hypothyroxinemia on the progeny. *Thyroid* 10:871, 2000.)

thyroid hormones. In patients who require treatment, PTU therapy can be attempted if tolerated; methimazole suppositories can also be used.

Gestational Trophoblastic Disease

Both hydatidiform mole and choriocarcinoma can be associated with hCG levels that are greater than 1000 times normal and thus can cause hyperthyroidism (biochemically seen in approximately 50% of such women). The thyroid is usually not enlarged. Treatment of the hydatidiform mole or choriocarcinoma restores thyroid function to normal. Treatment with antithyroid drugs and β -blockers is frequently necessary, however, before surgical treatment of the mole.¹²⁴

Recurrent Gestational Hyperthyroidism

Cases of recurrent gestational hyperthyroidism have been described.^{125,126} In the case described by Rodien and colleagues,¹²⁶ the hyperthyroidism was caused by a mutant TSH receptor that was hypersensitive to hCG.

Other Causes of Hyperthyroidism

Much less common causes of hyperthyroidism include thyrotoxicosis factitia (i.e., ingestion of exogenous hormone surreptitiously); in such cases, serum thyroglobulin, which is produced by the thyroid, is suppressed.¹²⁷ Women with large nodular goiters may have hyperthyroidism from autonomously functioning nodules within such goiters. Alternatively, women can have hyperthyroidism from a single toxic

adenoma. If either of these entities is diagnosed during pregnancy, the correct treatment is control of hyperthyroidism with antithyroid drugs until definitive treatment (i.e., surgery or radioactive iodine) can be administered after delivery.

Even less common causes of hyperthyroidism in pregnancy are listed in Table 47-3. They include TSH-producing pituitary tumors, metastatic follicular thyroid cancer, viral (de Quervain) thyroiditis, and struma ovarii, which is an ovarian dermoid tumor in which more than 50% of the neoplasm consists of thyroid tissue.

Iodine Deficiency, Hypothyroidism, and Pregnancy

A schematic representation of the clinical conditions that can affect thyroid function in the mother, fetus, or fetomaternal unit is provided in Figure 47-6. Although iodine deficiency is rare in the United States, it is a common cause of maternal, fetal, and neonatal hypothyroidism in the world, where 1 to 1.5 billion are at risk and 500 million live in areas of overt iodine deficiency. Worldwide, it is the most common cause of mental retardation.

In the past few decades, the physiology of maternal and fetal iodine metabolism, thyroid hormone metabolism, and fetal brain development and the pathophysiology of iodine deficiency have been unraveled. These findings have revealed a fascinating aspect of pregnancy physiology. Iodine deficiency and hypothyroidism in pregnancy con-

continue to be a worldwide problem worthy of resolution. This topic also has been a subject of numerous reviews.¹²⁸⁻¹³¹ Even in the United States, iodine intake has declined, and 15% of women of childbearing age and 7% of pregnant women were found to have urinary iodine excretions below 50 µg/L, indicative of moderate iodine deficiency.¹³²

Pregnancy is an environmental trigger for the thyroid machinery, inducing changes in people who live in geographic areas that have iodine deficiency. Four biochemical markers are useful for following the changes induced:

1. Relative hypothyroxinemia
2. Preferential T₃ secretion as reflected by an elevated T₃/T₄ molar ratio
3. Increased TSH after the first trimester, progressing until term
4. Supranormal thyroglobulin concentrations correlating with gestational goitrogenesis

Goitrogenesis also occurs in the fetus, indicating the exquisite sensitivity of the fetal thyroid gland to the consequences of maternal iodine deficiency. This process can start during the earliest stages of fetal thyroid development. It occurs against a background of low initial maternal intrathyroidal iodine stores, the increased need for iodine after pregnancy occurs, and the insufficiency of iodine intake throughout the gestation.

It appears that maternal thyroxine, traversing the placenta during the first trimester and subsequently, is necessary for fetal brain development. Even before fetal thyroid hormone synthesis, T₃ receptors are found in fetal brain tissues, and local conversion of T₄ to T₃ can occur. Iodine deficiency perpetuates the process, because the fetus is less able to synthesize thyroid hormones even when the fetal thyroid has developed.

In severe iodine deficiency (intake of 20 to 25 µg/day), a condition known as endemic cretinism occurs, with a prevalence up to 15% in severely affected populations. These infants are characterized by severe mental retardation with a neurologic picture including deaf-mutism, squint, and pyramidal and extrapyramidal syndromes. There are few clinical signs of thyroid failure. A remarkable exception to this picture has emerged from Africa, where the cretins have less mental retardation and less in the way of neurologic deficits. The clinical picture is that of severe thyroid failure with dwarfism, delayed sexual maturation, and myxedema. Thyroid function is grossly impaired.

The consensus is that the neurologic picture of endemic cretinism results from insults to the developing brain, occurring perhaps during the first trimester (in the case of deafness) and mostly during the second trimester, with the cerebellar abnormalities resulting from postnatal insult. This is supported by the observation that the full picture can be prevented only when the iodine deficiency is corrected before the second trimester and, optimally, even before conception.¹³³ In Africa, iodine deficiency is complicated by selenium deficiency. The deficiency of selenium leads to accumulation of peroxide, and excess peroxide leads to destruction of thyroid cells and hypothyroidism.¹³⁴ Selenium deficiency also induces monodeiodinase I (a selenoenzyme) deficiency, resulting in reduced T₄ to T₃ conversion and increased availability of maternal T₄ for the fetal brain. This protective mechanism may prevent the development of neurologic cretinism, and the combined iodine-selenium deficiency prevalent in Africa may help explain the predominance of the myxedematous type observed there.

The neurologic abnormalities and mental retardation depend ultimately on the timing and severity of the brain insult. Endemic cretinism constitutes only the extreme expression of the spectrum of physical and intellectual abnormalities. In a meta-analysis of 18 studies in areas

of iodine deficiency, it appeared to be responsible for an IQ loss of 13.5 points.¹³⁵ Even borderline iodine deficiency, as seen in Europe, can be accompanied by impaired school achievements by apparently normal children, as reviewed by Glinioer.¹²⁹

Actions taken to eradicate iodine deficiency have prevented the occurrence of mental retardation in millions of infants throughout the world. In a study by Xue-Yi and coauthors¹³⁶ of a severely iodine-deficient area of the Xinjiang region of China, iodine was administered to pregnant women. The prevalence of moderate or severe neurologic abnormalities among 120 infants whose mothers received iodine in the first or second trimester was 2%, compared with 9% (of 952 infants) when the mothers received iodine in the third trimester ($P = .008$). Although treatment in the third trimester did not improve neurologic status, head growth and developmental quotients improved slightly.

The importance of thyroid hormone to fetal and neonatal well-being and development was highlighted by a remarkable case of an infant born to a mother with strongly positive TSH receptor-blocking antibodies. The mother was profoundly hypothyroid when tested after delivery. The infant was delivered by cesarean section because of bradycardia. She was also profoundly hypothyroid and required intubation. Her brain size was reduced, and her auditory brainstem response was absent at age 2 months. The audiogram at age 4 years revealed sensorineural deafness. At age 6 years, motor development was the same as at age 4 months. She required T₄ for 8 months until the antibody effect had worn off. Her physical growth was normal. The outcome of severe thyroid hormone deficiency in utero was fetal distress, permanent auditory deficit, brain atrophy, and severely impaired neuromotor development despite adequate neonatal treatment.¹³⁷

The Institute of Medicine of the National Academy of Sciences has set the iodine requirement as 110 µg for infants 0 to 6 months, 130 µg for infants 7 to 12 months, 90 µg for children 1 to 8 years, 120 µg for those 9 to 13 years, and 150 µg for those older than 13 years. The recommended intake for pregnancy and lactation is 200 µg/day. Even higher intakes (300 to 400 µg/day) have been suggested.¹³⁸

Hypothyroidism

Signs and Symptoms

Hypothyroidism occurs with a frequency of 1 case in 1600 to 2000 deliveries.⁶⁷ Population screening studies have revealed a higher incidence. In a study in the United States, serum TSH levels were determined in 2000 women between gestational weeks 15 to 18; 49 (2.5%) had TSH levels greater than or equal to 6 mU/L, and positive thyroid antibodies were found in 58% of these 49 women, compared with 11% of control euthyroid pregnant women.¹³⁹ In a Japanese study, only 0.29% had an elevated TSH level.¹⁴⁰ In another U.S. study, 1 infant in 1629 deliveries had hypothyroidism.¹⁴¹

Women with hypothyroidism have higher pregnancy complication rates. As well as miscarriages, complications include preeclampsia, placental abruption, low birth weight, prematurity, and stillbirths.¹⁴² These outcomes can be improved with early therapy. Gestational hypertension is also more common.¹⁴¹

The symptoms of hypothyroidism are insidious and can be masked by the hypermetabolic state of pregnancy. Symptoms can include modest weight gain, decrease in exercise capacity, lethargy, and intolerance to cold. In moderately symptomatic patients, constipation, hoarseness, hair loss, brittle nails, and dry skin also can occur. Physical signs may include a goiter, a thyroidectomy scar, and delay in the relaxation phase of deep tendon reflexes.

Laboratory confirmation is obtained from an elevated TSH level, with or without suppressed free T_4 . Test results for thyroid autoantibodies (antithyroglobulin and antithyroid peroxidase) may be positive. Other laboratory abnormalities can include elevated levels of creatine phosphokinase, cholesterol, and carotene and liver function abnormalities. Patients may have macrocytic or normochromic, normocytic anemia. Hypothyroidism may occur more frequently in pregnant women with type 1 diabetes, and T_4 replacement therapy can increase insulin requirements.¹⁴³

Differential Diagnosis

Hashimoto thyroiditis, also known as chronic lymphocytic thyroiditis, an autoimmune disease, is the most common cause of hypothyroidism and can occur in 8% to 10% of women of reproductive age. It is characterized by the presence of antithyroid antibodies, and the patient may have a goiter. Titers of antithyroglobulin are elevated in 50% to 70% of patients, and almost all have antithyroid peroxidase antibodies.⁵³ The goiter is firm and diffusely enlarged and painless, and the gland is infiltrated by lymphocytes and plasma cells. Many patients with Hashimoto thyroiditis are actually euthyroid but can subsequently develop hypothyroidism. The thyroid gland can be atrophic and the test result for antibodies negative—so-called idiopathic hypothyroidism. Patients with other autoimmune disease also can develop Hashimoto thyroiditis.

Other important and common causes of hypothyroidism include ^{131}I therapy, ablation for Graves disease, and thyroidectomy (e.g., for thyroid cancer). Of patients who receive ^{131}I therapy, 10% to 20% are hypothyroid within the first 6 months, and 2% to 4% become hypothyroid each year thereafter.¹⁴⁴ Hypothyroidism can result from subacute viral thyroiditis and, much less commonly, from suppurative thyroiditis.

Drugs known to inhibit the synthesis of thyroid hormones include thionamide, iodides, and lithium. Carbamazepine, phenytoin, and rifampin can increase thyroid clearance. Aluminum hydroxide, cholestyramine, and, most important, ferrous sulfate and sucralfate can interfere with the intestinal absorption of thyroxine.

Hypothyroidism resulting from hypothalamic or pituitary disease is rare but can occur in the setting of pituitary tumors, after pituitary surgery or irradiation, and in Sheehan's syndrome and lymphocytic hypophysitis, an autoimmune disease with a predilection for women, especially in the setting of pregnancy (see Chapter 48). In secondary hypothyroidism, the TSH level may be low or normal, but the free T_4 level is low.

Treatment

Hypothyroidism must be treated promptly, and a dose of 0.1 to 0.15 mg of T_4 per day, should be initiated. The dose is adjusted every 4 weeks until the TSH concentration is in the lower end of the normal range. In women with little or no functioning thyroid tissue, a dose of 2 $\mu\text{g}/\text{kg}/\text{day}$ may be required. Women who are euthyroid on T_4 need to be checked as soon as pregnancy is established; the dose should be adjusted and rechecked in 4 to 8 weeks,¹⁴⁵ because the requirements for thyroid hormone increase as early as the fifth week of gestation. Alternatively, the patient can be instructed to increase her dose by one extra dose per week and be checked a few weeks later. The amount of dose increase may depend on the cause. For example, women who have had total thyroidectomy may need a greater increase than women with mild hypothyroidism. Increased dosage requirements may plateau by the 20th week,¹⁴⁵ but the need for increased dosage may be seen as late as

the third trimester in about one third of patients.² In a study of 12 pregnant women with hypothyroidism, 9 required a higher T_4 dose, with a mean dose increase of 45%.¹⁴⁶ In a review of 77 pregnancies in 65 hypothyroid women, serum TSH levels became abnormal in 70% of women with prior ^{131}I ablation therapy and in 47% of women with chronic thyroiditis. When data from other studies were pooled, overall, TSH levels increased above normal in 45% with a mean daily thyroxine dose of 146 μg .^{147,148} It was estimated that the increment in dose could be predicted according to the TSH value at the first evaluation. The TSH concentration should be determined again 4 to 6 weeks after dose adjustment.

The causes of increased T_4 requirements include a real increased demand for T_4 in pregnancy¹⁴⁹ in patients whose thyroid reserve is compromised and, in some cases, iron therapy. Ferrous sulfate interferes with T_4 absorption and should be taken at a different time of day from thyroxine therapy.¹⁵⁰ Patients with thyroid cancer whose target TSH concentration is below the normal range almost uniformly require an increased dose to maintain their suppressed TSH levels, and they should be followed closely.¹⁵⁰ After delivery, the dose should be reduced to pre-pregnancy levels in all patients, and the TSH concentration should be measured 6 to 8 weeks later.

The topic of thyroid hormone and intellectual development has received widespread publicity and has been the subject of articles and reviews in the past few years.^{128,151,152} In 1969, Man and Jones¹⁵³ studied a cohort of 1349 children and concluded that mild maternal hypothyroidism alone was associated with lower IQ levels in the offspring. In 1990, Matsuura and Konishi¹⁵⁴ documented that fetal brain development is affected adversely when both mother and fetus have hypothyroidism caused by chronic autoimmune thyroiditis. With the background of this information and the associations of iodine deficiency, its consequent maternal hypothyroxinemia, and abnormal fetal brain development, Haddow and associates¹⁵¹ conducted a study measuring TSH levels from stored samples in more than 25,000 pregnant women. They located 62 women with high TSH levels and 124 matched women with normal values. Their 7- to 9-year-old children, none of whom had hypothyroidism as newborns, underwent 15 tests relating to intelligence, attention, language, reading ability, school performance, and visual-motor performance. The full-scale IQ in children of hypothyroid women was 4 points lower ($P = .06$); 15% had scores of 85 or less compared with 5% of controls. The IQ of the children of 48 women whose hypothyroidism was not treated averaged 7 points lower than the 124 controls ($P = .005$), and 19% had scores of 85 or lower. The researchers concluded that undiagnosed hypothyroidism can affect fetuses adversely and recommended screening for hypothyroidism in pregnancy. Fukushi and coworkers¹⁵⁵ reported on such screening in Japan and found hypothyroidism in 1 of 692 pregnancies.

In a study by Pop and colleagues,¹⁵⁶ even the presence of antithyroid peroxidase antibodies in the maternal circulation was shown to have deleterious effects on child development. In two similar studies, thyroid antibody-positive women had lower free T_4 levels, and lower scores on psychomotor tests were found in children of mothers whose free T_4 value was below the 5th and 10th percentiles as measured at 12 weeks' gestation.^{157,158}

Subclinical Hypothyroidism and Hypothyroxinemia

Subclinical hypothyroidism is defined as an elevated TSH level when the free T_4 level is in the normal range. More than 90% of hypothyroid-

ism diagnosed in pregnancy is subclinical. Its estimated prevalence in the general population is between 4% and 8.5%. The prevalence in pregnancy was 2.3% in a study of more than 17,000 women enrolled for prenatal care at 20 weeks' gestation or less.¹⁵⁹ In this study, pregnancies in patients with subclinical hypothyroidism were three times more likely to be complicated by placental abruption, and the rate of preterm birth (i.e., delivery at or before 34 weeks) was almost twofold higher.

Hypothyroidism has been associated with impaired neurodevelopment of the fetus.¹⁵¹ However, most of the patients in this study had a TSH level of 10 mU/L or greater, and most had a low free T₄ level; that is, they had overt rather than subclinical hypothyroidism. Nonetheless, this study has prompted rigorous debate on the merits of universal screening of all pregnant women. The nuances of this debate were carefully addressed by Casey.¹⁶⁰ Although a panel from the American Thyroid Association, the Endocrine Society, and the American Association of Clinical Endocrinologists did not find sufficient evidence to recommend routine screening in pregnancy in 2003, leaders of the same societies later published a consensus statement, recommending screening and treatment.¹⁶¹ The American College of Obstetricians and Gynecologists (ACOG) suggests it is premature to recommend universal screening for hypothyroidism, because efficacy of treatment has not been demonstrated. The ACOG and the various endocrine associations recommend TSH measurements in women with a family history of thyroid disease, prior thyroid dysfunction, symptoms of hypothyroidism, an abnormal thyroid gland, type 1 diabetes, or personal history of autoimmune disease. However, targeting high-risk cases may miss significant numbers with hypothyroidism, as was shown by Vaidya and coworkers.¹⁶² The investigators evaluated more than 1500 consecutive pregnancies and found increased TSH levels in 40 women (2.6%). Although the prevalence of high TSH levels was higher in the high-risk group (6.8% versus 1% in low-risk patients), 30% of women with high TSH levels were in the low-risk group.

Isolated maternal hypothyroxinemia (i.e., low free T₄ and normal TSH levels) during early pregnancy has been associated with impaired neurodevelopment of the fetus.^{158,163} The issue of detecting and treating isolated maternal hypothyroxinemia is an area of equal uncertainty. Unfortunately, assays of true free T₄ (e.g., equilibrium dialysis, ultrafiltration, gel filtration) are expensive and labor intensive. Clinical laboratories use a variety of tests that estimate the free hormone concentrations in the presence of protein-bound hormone, and they are binding protein dependent to some extent. This negatively affects the accuracy of free hormone assays.¹⁶⁴ Free T₄ assays usually result in lower values in late pregnancy.^{165,166} Nonetheless, in a "Clinical Perspectives" article in the *Journal of Clinical Endocrinology and Metabolism*, Morreale de Escobar and colleagues¹⁶⁷ made a compelling case for screening pregnant women for hypothyroxinemia, pointing out that maternal T₄ (as opposed to T₃) is the required substrate for the ontogenetically regulated production of T₃ in the amounts needed for optimal temporal and spatial development in different brain structures. This issue is important for women with relative iodine deficiency, because T₃ is preferentially synthesized.

To address these dilemmas, the National Institute of Child Health and Human Development Maternal-Fetal Medicine Units Network initiated a randomized trial of T₄ treatment for subclinical hypothyroidism or hypothyroxinemia diagnosed during pregnancy. The primary end point is the intellectual function of the children and secondary end points include determination of the frequency of pregnancy complications, including preterm delivery, preeclampsia, abruption, and stillbirth.

What do we do in the meantime? In an editorial by Brent⁶⁷ accompanying the paper on low-risk versus high-risk case finding, it was felt

that until the results of large, randomized trials become available, the extant evidence supports the benefits of T₄ therapy, at least to reduce pregnancy loss and preterm delivery.⁶⁹ This view was also held and previously stated by Larsen.¹⁶⁸ I recommend screening at least high-risk women (as defined by ACOG and others) for TSH and free T₄ levels. Subclinical hypothyroidism should be treated with thyroxine. Adequate iodine intake should be ensured in those with isolated hypothyroxinemia and treatment with thyroxine initiated if the hypothyroxinemia does not resolve. I also recommend screening patients who have delivered or had a miscarriage within 1 year of the index pregnancy, because postpartum or postmiscarriage thyroid disease is commonly found in the general population.

Fetal and Neonatal Hypothyroidism

The relationship between iodine deficiency and fetal development was previously discussed. Severe neurologic deficits also occur in children with congenital deficiency of thyroid hormone unrelated to iodine deficiency. Neurologic development is impaired if infants are untreated before they are 3 months old. Screening of neonates for thyroid hormone deficiency is mandatory in some states, and with early therapy, their development is reasonably normal.²⁹ Causes include thyroid agenesis and inborn errors of metabolism, such as peroxidase deficiency. Congenital pituitary and hypothalamic hypothyroidism also occur but are rare. Thyroid hormone deficiency can result from maternal blocking antibodies that are transferred to the fetus and that block TSH action or thyroid growth and development.^{169,170}

Gruner and associates¹⁷¹ reported a case of fetal goitrous hypothyroidism in which fetal TSH levels were determined on three occasions by cordocentesis to monitor weekly intra-amniotic administration of T₄. This therapy was initiated to reduce the fetal goiter and polyhydramnios (which it did) and to aid in fetal neurologic development. They also reviewed other reported cases of such therapy and concluded that the optimal dose of T₄ necessary to correct hypothyroidism could more accurately be determined by cordocentesis than by measurement of amniotic fluid hormone concentrations.

Thyroid Nodules, Malignant Tumors, and Nontoxic Goiter in Pregnancy

Thyroid tumors are the most common endocrine neoplasms. Most nodules are benign hyperplastic (or colloid) nodules, but between 5% and 20% are true neoplasms, which are benign follicular adenomas or carcinomas of follicular or parafollicular (C) cell origin. Nodular thyroid disease is common, especially in women. A prospective study found that the incidence of incipient thyroid nodules increased from 15% in the first trimester to 24% after delivery, with an increase in the growth of existing nodules.¹⁷² There is no evidence that thyroid cancer arises more frequently in pregnancy.

When a solitary or a dominant nodule is found within the thyroid, biopsy is recommended. Cytopathologic diagnosis of fine-needle aspiration biopsy (FNAB) in women between the ages of 15 and 40 years seen at the Mayo Clinic revealed benign findings in 64% and suspicious findings in 12%; FNAB was positive for cancer in 7% and nondiagnos-

tic in 17%.¹⁷³ The topic of nodular thyroid disease in pregnancy was also reviewed. During a 10-year period, 40 pregnant women were evaluated at the Mayo Clinic, and 39 had FNAB, 95% of which were diagnostic.¹⁷⁴ Most (64%) were benign. Three (8%) were positive for papillary thyroid cancer, and nine (23%) were suspicious for papillary cancer or a follicular (Hurthle cell) neoplasm. Comparable findings were reported by others.¹⁷⁵

The principles of nodular thyroid disease diagnosis in pregnancy resemble those for nonpregnant women. Serum TSH and free T₄ levels should be obtained, and an FNAB should be performed on dominant nodules. Radionucleotide scanning is contraindicated, but ultrasound is often performed and can demonstrate other nodules, lymphadenopathy, or abnormal calcification. FNAB is safe in pregnancy and can be performed at any stage. If a nodule is benign, ultrasound can monitor growth of the nodule during pregnancy. If the nodule is suspicious for a follicular or Hurthle cell neoplasm, it usually represents a 10% to 15% risk of malignancy. It is generally recommended that surgery be performed after delivery, but if a malignancy is diagnosed in early pregnancy, surgery may be performed in the second trimester for the patient needing reassurance. If the FNAB result is positive or suspicious for papillary thyroid cancer, the risk is high (50% for suspicious and 100% for positive), and neck exploration should be performed at the soonest safe date. Figure 47-7 outlines the decision-making process.

The impact of pregnancy on papillary thyroid cancer was evaluated by Moosa and Mazzaferri.¹⁷⁶ They compared outcomes in pregnant and nonpregnant women and found no difference in the rates of recurrence, distant spread, or cause-specific mortality. Outcomes were similar when neck surgery was performed during or after pregnancy. A similar conclusion was reached in a study of thyroid cancer cases from the New Mexico Tumor Registry.¹⁷⁷ If medullary thyroid cancer is suspected, early surgery is advised.

Postpartum Thyroid Disease

Autoimmune thyroid disease, which is suppressed during pregnancy, is exacerbated in the postpartum period. New-onset autoimmune thyroid disease occurs in up to 10% of all postpartum women.³⁹ Up to 60% of Graves patients in the reproductive years give a history of postpartum onset.¹⁷⁸ Most of the immune changes of pregnancy gradually return to normal in the 12-month postpartum period. Unlike pregnancy, the major immune changes in T and B cells in the postpartum period are overall T-cell deactivation, enhanced T_H1-type T-cell function, loss of tolerance for fetal alloantigens, enhanced IgG secretion, and autoantibody secretion. Possible mechanisms explaining postpartum autoimmune exacerbation suggested by Davies³⁹ include a reduced number of fetal cells, leading to loss of maternal tolerance to remaining microchimeric cells, and a loss of placental major histocompatibility complex-peptide complexes, which were inducing T-cell anergy during pregnancy.

Postpartum Graves Disease

The onset of Graves disease after delivery correlates with the development of TSIs. Peak antibody production is observed 3 to 6 months after delivery. Almost all patients with persisting TSIs at the end of pregnancy have a recurrence of Graves if antithyroid drugs are withdrawn. The prevalence of postpartum Graves disease, which can be transient or persistent, is estimated at 11% of those with postpartum thyroid dysfunction.¹⁷⁹

Postpartum Thyroiditis

The topic of postpartum thyroiditis (PPT) has been the focus of numerous reviews.^{39,179-183} For the diagnosis of PPT, there must be a documented abnormal TSH level (suppressed or elevated) during the first postpartum year in the absence of a positive result for TSIs (excluding Graves) or a toxic nodule.

Classically, PPT manifests with a transient hyperthyroid phase of 6 weeks to 6 months after delivery. A hypothyroid phase follows and can last up to 1 year after delivery. Figure 47-8 schematically demonstrates this and the accompanying changes in serum thyroid antibody concentrations. A review of 11 studies of PPT¹⁸⁴ revealed that only 26% of patients presented in this classic manner. Most patients present with hyperthyroidism alone (38%) or hypothyroidism alone (36%). The incidence of PPT is 6% to 9%. It is an autoimmune disorder, and patients with type 1 diabetes have an increased incidence, which was found to be approximately 25% in two North American studies.^{185,186} Women with a history of PPT in a prior pregnancy had a 69% recurrence rate in the subsequent pregnancy.

Symptoms of the hyperthyroid phase of PPT include fatigue, palpitations, heat intolerance, and nervousness. This destructive hyperthyroid phase always has a limited duration (a few weeks to a few months). Although β -blockers may reduce symptoms, antithyroid medications have no role to play.

The hypothyroid phase can be marked by fatigue, hair loss, depression, impairment of concentration, and dry skin. The hypothyroid phase frequently requires treatment, but it is reasonable to wean the patient off therapy 6 months after initiation. Some authorities recommend maintaining T₄ therapy in these patients until the childbearing years are over and then attempting to wean them off the therapy a year after the last delivery.

FIGURE 47-8 Postpartum thyroiditis and changes in thyroid antibody concentrations. **A**, Postpartum thyroiditis manifests with a transient hyperthyroid phase, during which serum levels of thyroxine (T_4) are elevated. A hypothyroid phase follows. **B**, Serum thyroid antibody levels fluctuate during and after pregnancy. (From Smallridge RC, Fein HC, Hayship CC: Postpartum thyroiditis. *Bridge Newsletter Thyroid Found Am* 3:3, 1988.)

The thyroid gland is enlarged in PPT, and thyroid hypoechogenicity appears to be the characteristic ultrasonographic finding.¹⁸⁷ PPT is an autoimmune disorder, and there is an association between it and HLA-DR3, HLA-DR4, and HLA-DR5 status. The lymphocytic infiltration is similar to that seen in Hashimoto thyroiditis. Stagnaro-Green¹⁸² reported that 33% of women who were antithyroid antibody positive in the first trimester of pregnancy had PPT, compared with 3% of women who were antibody negative.

The laboratory hallmarks of PPT, which is a destructive process, are positive test results for antithyroid antibodies (i.e., antithyroglobulin and antithyroid peroxidase), suppressed TSH levels, and high T_4 levels (released from destroyed thyroid cells) in the hyperthyroid phase, along with a profoundly suppressed radioactive iodine uptake (contraindicated in a breastfeeding woman). The absence of TSIs usually rules out Graves disease, which can also be distinguished by high radioactive iodine uptake.

Depression and Postpartum Thyroiditis

Depression and PPT are common postpartum events.¹⁸⁸ Four large-scale studies have been performed to evaluate their association. Harris and colleagues¹⁸⁹ evaluated 147 women (65 were thyroid antibody positive, and 82 were negative) at 6 to 8 weeks after delivery for thyroid status and depression. Although there was a positive correlation between PPT and postpartum depression, there was no association between antibody positivity and depression.

Pop and associates¹⁹⁰ evaluated 293 women during the third trimester and then every 6 weeks up to 34 weeks after delivery. They found that 38% of women with PPT experienced depression compared with 9.5% of women in a matched control group, and the difference was highly significant. Status of antibodies was not reported.

Harris and coauthors¹⁹¹ investigated the association between depression and PPT in 232 women (110 were thyroid antibody positive). The women had psychiatric assessment five times during the first 28 weeks after delivery. No association was found between PPT and depression, but an association was found between depression and antibody positivity. They concluded that 4% of women experience postpartum depression that has an autoimmune origin.

Pop and colleagues¹⁹² performed a further analysis of the same 293 women in their earlier study; antibody status was determined during the pregnancy, but only a slightly increased association between the

presence of antibody and depression was found, and they concluded that antibody status during pregnancy was an important predictor of PPT but not of depression. In a subsequent study, Pop and associates¹⁹³ reported an association between thyroid antibodies and depression in postmenopausal women.

In summary, the data suggest some association for PPT, thyroid antibodies, and depression. Of the four clinical trials, two demonstrated an association between PPT and depression, whereas two demonstrated an association between thyroid antibodies and depression. The role of potential interventions such as T_4 therapy has not been evaluated systematically.

Hypothyroidism and Postpartum Thyroiditis

Recovery of thyroid function in women with PPT is not universal, and some women remain permanently hypothyroid. In a study of 44 women with PPT with a mean follow-up of 8.7 years after delivery, Tachi and associates¹⁹⁴ reported that 77% of the women recovered during the first postpartum year and remained euthyroid. Permanent hypothyroidism developed in the other 23%; one half of these never recovered euthyroid function after the initial postpartum insult, and the other half developed hypothyroidism during the years of follow-up. A 23% incidence of permanent hypothyroidism at long-term follow-up (mean, 3.5 years) was also reported by Othman and coworkers.¹⁹⁵ It is recommended that women with a history of PPT be evaluated annually for the possible development of hypothyroidism.

Thyroiditis after Abortion

Several studies have described cases of thyroiditis occurring after an abortion.^{196,197} Neither the incidence nor clinical sequelae are known. In the case of Stagnaro-Green,¹⁹⁶ the patient developed transient hypothyroidism after a spontaneous miscarriage. After a subsequent term delivery, the patient became severely hypothyroid, and this condition remained permanent.

Prevention and Screening of Postpartum Thyroiditis

Levothyroxine (0.1 mg daily) or iodide (0.15 mg daily) was administered for 40 weeks after delivery to women who were thyroid antibody positive during pregnancy. A control group of antibody-negative women received no treatment. The incidence of PPT was similar in all

three groups, and the degree of postpartum elevation of thyroid peroxidase antibodies was indistinguishable in the three groups.¹⁹⁸

Whether screening for PPT is worthwhile is a contentious issue. A “Therapeutic Controversy” article in the *Journal of Clinical Endocrinology and Metabolism* addressed this topic.¹⁷⁹ Arguments for and against screening were presented. It was suggested that screening and treatment of symptomatic hypothyroidism would improve the quality of life of the mother, and the importance of recognizing postpartum depression was stressed. Contradicting arguments posited that the optimal screening strategy was undefined and that no cost-benefit analysis has been performed. It is agreed that women who present with symptoms should have a TSH assay performed. High-risk women (i.e., women with a history of PPT and women with type 1 diabetes) should be screened.^{186,199}

Chapter 48

Other Endocrine Disorders of Pregnancy

Shahla Nader, MD

The staggering advancements made in endocrinology over the past few decades have delineated both normal physiology and pathophysiology. In tandem, technologic and pharmaceutical advances have followed that allow correction and management of prevailing problems with a precision that is lacking in many other fields of medicine. When pregnancy is superimposed on abnormal endocrine function in the mother, the consequences for the mother and the fetus can be adverse and sometimes disastrous. Awareness of this danger, combined with the knowledge that accurate diagnostic and therapeutic measures are often available, places a substantial burden on the obstetrician caring for the pregnant patient. This chapter summarizes the normal maternal endocrine adaptation to pregnancy (see also Chapters 8, 9, 46, and 47) and outlines maternal disorders, some of which are almost specific to pregnancy.

Hypothalamus and Pituitary

The sella turcica of the sphenoid bone, which is lined by dura mater, is occupied by the pituitary gland. The dura covering the roof, called the diaphragm sella, is perforated centrally by the pituitary stalk. Directly above this diaphragm and anterior to the stalk lies the optic chiasm. The gland consists of an anterior lobe (i.e., adenohypophysis) and a posterior lobe (i.e., neurohypophysis); the former accounts for more than 80% of the gland's volume. The pituitary stalk comprises the direct neural connections between the hypothalamic nuclei and the posterior lobe, and it is the vascular link between the hypothalamus and the anterior lobe, enabling hypothalamic neurohumoral secretions to influence the activity of the anterior lobe cells. Paired superior hypophyseal arteries arising from the internal carotids anastomose around the upper part of the stalk. These terminate within elongated coiled capillary loops into which the hypothalamic hormones are discharged. The capillary bed drains into portal veins that empty into sinusoids of the anterior lobe (Fig. 48-1). Paired inferior hypophyseal arteries supply the posterior lobe. The venous drainage of both lobes flows into the cavernous sinuses.

Figure 48-2 is a diagram of the interrelationships and feedback mechanisms of the higher brain centers, hypothalamus, pituitary, and target endocrine glands in normal, nonpregnant women. The adenohypophysis produces gonadotropins (e.g., luteinizing hormone [LH], follicle-stimulating hormone [FSH]), growth hormone (GH), thyrotropin or thyroid-stimulating hormone (TSH), prolactin, and adrenocorticotropin or adrenocorticotrophic hormone (ACTH) and its related peptide β -lipotropin, from which melanocyte-stimulating hormone (β -MSH) is derived.

Since the 1940s, when the concept that control of the anterior pituitary is exerted through a neurohumoral mechanism was formulated, several peptides have been isolated from the hypothalamus that function in this capacity. Thyrotropin-releasing hormone (TRH) causes release of TSH (and prolactin); growth hormone-releasing hormone (GHRH) releases GH; gonadotropin-releasing hormone (GnRH) allows release of LH and FSH; and corticotropin-releasing hormone (CRH) releases ACTH. Substances with an inhibitory rather than a stimulatory influence have been identified. Somatostatin inhibits the release of GH (and many other hormones), and dopamine inhibits the release of prolactin. This inhibition of the lactotroph is clinically important; disturbances of the stalk or vascular dissociation of the hypothalamus from the anterior pituitary results in deficiency of all anterior pituitary hormones with the exception of prolactin. The lactotroph is normally under predominantly inhibitory control.

Physiologic Changes during Pregnancy

During pregnancy and in the immediate postpartum period, the anterior lobe of the pituitary can double or triple in size because of hyperplasia and hypertrophy of lactotrophs. This is evident at 1 month and continues throughout gestation. At delivery, involution of pregnancy cells occurs for a period of several months but seems to be retarded by lactation.¹ Magnetic resonance imaging (MRI) studies of normal primigravid patients have confirmed progressively increasing pituitary volumes during gestation²; at the end of pregnancy, there is an overall increase in pituitary gland size of 136% compared with control nulliparous subjects. Similar results have been obtained by Dinc and colleagues,³ who found changes in pituitary gland volume of 40%, 75%, and a maximum of 120% in the second, third, and immediate postpartum periods, respectively. The major accompanying physiologic change is a progressive increase in serum prolactin concentrations,⁴ with an approximately tenfold increase during gestation (Fig. 48-3).

Placental estrogens stimulate lactotroph DNA synthesis, mitotic activity, and prolactin secretion. Prolactin prepares the breasts for initiation and maintenance of lactation (see Chapter 9). Despite this dramatic increase, the lactotroph maintains its ability to respond to TRH, its releasing hormone (unlike prolactinomas, in which this response is usually blunted or absent).

Other physiologic changes during pregnancy include the following⁵:

1. Gonadotropin concentrations decline, with a progressively diminishing response to GnRH.

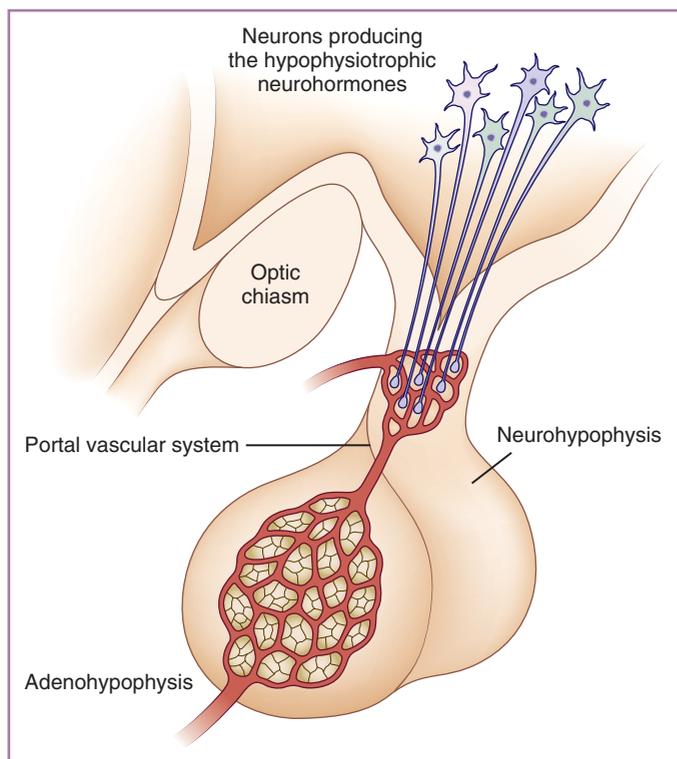

FIGURE 48-1 Neural and vascular connections of the hypothalamus and pituitary. Schematic illustration of the hypothalamus and pituitary gland indicates the neurohumoral mechanism controlling the anterior pituitary. (From Halasz B: Introduction to neuroendocrinology. In Fluckiger E, Muller EE, Thorner MO: Basic and Clinical Aspects of Neuroscience: The Dopaminergic System. Berlin, Springer-Verlag, 1985, p 1; courtesy of Sandoz, East Hanover, NJ.)

- Pituitary GH levels decline, with an increase of a placental variant of GH. This variant has similar somatogenic but less lactogenic bioactivity than pituitary GH, with increases in insulin-like growth factor 1 (IGF-1 or somatomedin-C) commensurate with elevated levels of the GH variant. Pituitary GH is the only detectable form during the first trimester. Thereafter, the amount of placental GH increases progressively.
- The levels of CRH of placental origin increase during the second and third trimesters.
- A twofold to fourfold increase in ACTH concentrations occurs, despite elevations of bound and free plasma cortisol. The placenta provides an alternative source of ACTH.

The diurnal variation of cortisol, although blunted, is preserved during pregnancy (discussed in the Adrenal Glands section). Thyrotropin, decreasing slightly in the first trimester, is otherwise essentially unchanged.

The posterior pituitary is a storage terminal for the neurohypophysial hormones oxytocin and vasopressin. Produced by the supraoptic and paraventricular hypothalamic nuclei along with their respective binding proteins or neurophysins, these hormones are transported as neurosecretory granules along the supraopticohypophysial tract to the pituitary, and from there, they find their way into the circulation. Vasopressin plays a central role in osmolarity and volume

regulation. Osmoreceptors are located in the anterior hypothalamus, and vasopressin release increases when plasma osmolality rises (Fig. 48-4).

Early in pregnancy, plasma osmolality decreases to values of 5 to 10 mOsm/kg below the normal mean of 285 mOsm/kg in nonpregnant women.⁶ Plasma levels of vasopressin and its response to water loading and dehydration, however, are normal in pregnancy, indicating a resetting of the threshold—that is, vasopressin is secreted at a lower plasma osmolality (see Fig. 48-4). Similarly, the plasma osmolality at which thirst is experienced is lower in the pregnant state. Along with these changes, the metabolic clearance of vasopressin increases markedly between gestational week 10 and mid-pregnancy. This is paralleled by the appearance and increase of circulating vasopressinase.⁷

Oxytocin is involved in the process of parturition⁸ and in suckling. Although the role of oxytocin in the initiation of labor is unclear, there is significant preterm increase in plasma concentrations of oxytocin. During nursing, nipple stimulation initiates a neurogenic reflex that is transmitted to the hypothalamus, triggering oxytocin release from the posterior pituitary. Oxytocin then induces contraction of the myoepithelial cells and mammary duct smooth muscle, resulting in milk ejection.

Fetal Hypothalamic and Pituitary Development

The development of the structural and functional aspects of the neuroendocrine system in the fetus occurs as follows.⁹ By 10 to 13 weeks' gestation, fetal pituitary and hypothalamic tissues can respond *in vitro* to stimulatory or inhibitory stimuli. By mid-gestation, the fetal hypothalamic-pituitary axis is a functional and autonomous unit subject to feedback control mechanisms. The posterior lobe of the fetal pituitary serves as a storage depot for neuropeptides.

Disorders of the Hypothalamus

Disorders of the hypothalamus can be congenital (e.g., Lawrence-Moon-Bardet-Biedl syndrome) or acquired inflammatory (e.g., meningitis, encephalitis), space occupying (e.g., tumors, cysts), vascular, or degenerative. For many women with these conditions, reproduction is impossible or undesirable. Among female patients with the autosomal recessive Lawrence-Moon-Bardet-Biedl syndrome of polydactyly, obesity, retinitis pigmentosa, and mental retardation, 45% to 53% are hypogonadal, but several pregnancies have been reported in such patients.¹⁰ Craniopharyngiomas are derived from vestigial remnants of the Rathke pouch or craniopharyngeal anlage. Manifestations can include headaches, visual disturbances, and hypothalamic dysfunction, including diabetes insipidus. Seven craniopharyngiomas have been reported during pregnancy. In two, the tumor recurred, and its enlargement resulted in loss of vision in a subsequent pregnancy.¹¹ Two of the case reports of craniopharyngiomas, previously undiagnosed, said that patients presented with diabetes insipidus in pregnancy.¹² One of these patients also had visual field disturbances and symptoms of raised intracranial pressure. Surgery was performed 3 days after delivery at 34 weeks' gestation because of deteriorating visual acuity. Craniopharyngiomas may require surgery during pregnancy. It has even been suggested that the hormonal stimulation of pregnancy may potentiate growth of this congenital tumor. Craniopharyngioma was diagnosed in a pregnant woman who had had a normal MRI result 4 years earlier.¹³

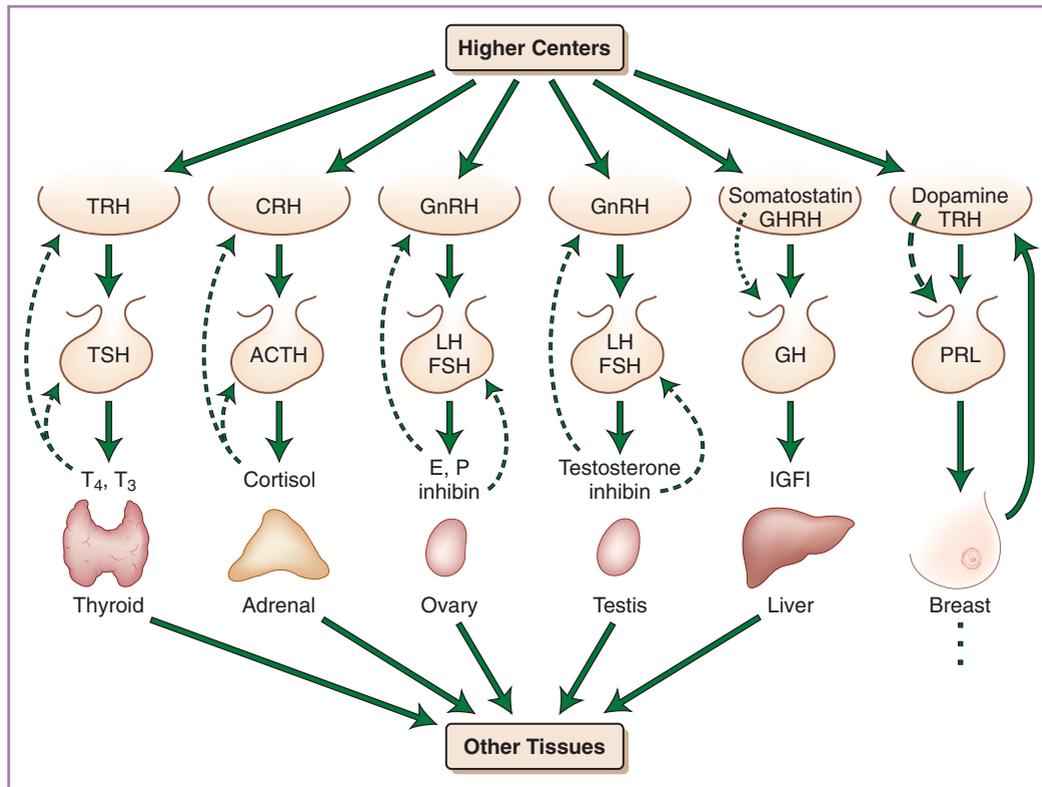

FIGURE 48-2 Relationships and feedback mechanisms of the neuroendocrine and endocrine systems. The components shown in the schematic drawing include the central nervous system, hypothalamus, anterior pituitary gland, and target glands and tissues. *Solid lines* indicate hormone secretion through stimulatory pathways; *dotted lines* indicate an inhibitory effect. ACTH, adrenocorticotropin; CRH, corticotropin-releasing hormone; E, estradiol; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; IGF-1, insulin-like growth factor 1; LH, luteinizing hormone; P, progesterone; PRL, prolactin; TRH, thyrotropin-releasing factor; TSH, thyroid-stimulating hormone; T₃, triiodothyronine; T₄, thyroxine.

Basal serum prolactin (HPr) levels increase throughout a normal gestation. *Points* represent the mean \pm standard error of the mean (SEM); *solid lines* represent the range of prolactin levels found during pregnancy. (From Tyson JE, Hwang P, Guyden A, et al: Studies of prolactin secretion in human pregnancy. *Am J Obstet Gynecol* 113:14, 1972.)

Disorders of the Pituitary

Anterior Lobe Disorders

Most commonly, tumors and, less commonly, vascular mishaps and inflammatory changes affect the anterior lobe. In their evaluation, the physician must consider anatomic derangements and the effects of excess or deficient hormones that can accompany these disorders. Because of the additional physiologic changes in pregnancy outlined previously, the combination of pregnancy and pituitary disorders poses a challenge to the obstetrician and endocrinologist in their endeavors for a safe outcome for the mother and fetus.

PITUITARY TUMORS

The topic of pituitary tumors in pregnancy has been reviewed by Molitch⁵ and Gillam and colleagues.¹⁴ Pituitary tumors can be classified as hormonally functioning or functionless lesions. Examples of the former include GH-producing tumors resulting in acromegaly, ACTH-producing tumors giving rise to Cushing disease, and prolactinomas. Prolactinoma is by far the most common pituitary tumor encountered in pregnancy. Hormonally functionless pituitary tumors are less common (although some of these produce subunits of pituitary hormones, they are clinically hormonally functionless). Because they are functionless, these pituitary tumors are relatively asymptomatic in

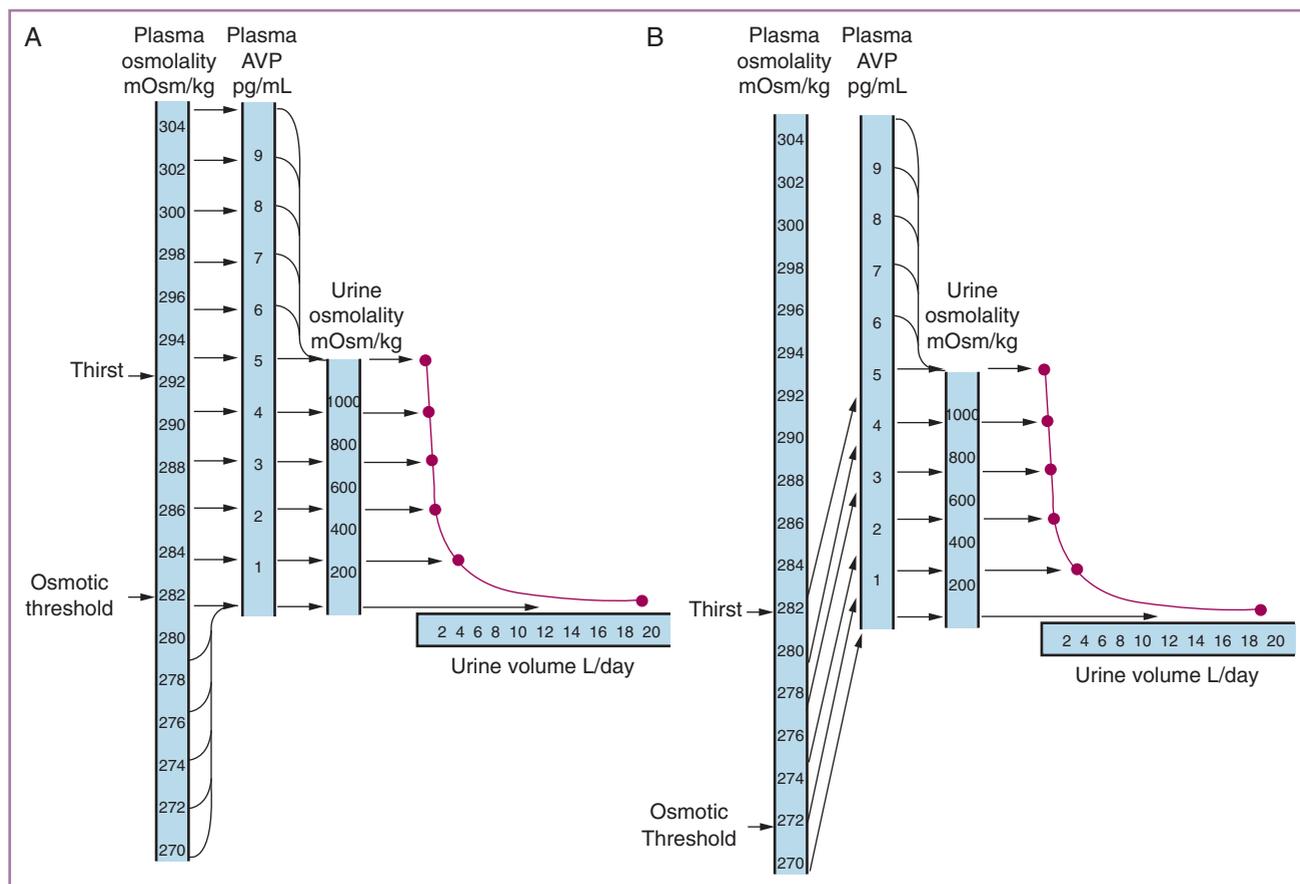

FIGURE 48-4 Osmolarity and volume regulation. **A**, Idealized schematic diagram of normal physiologic relationships shows the direct associations between plasma osmolality and plasma vasopressin and between plasma vasopressin and urine osmolality. The osmotic threshold is illustrated as a floor for plasma osmolality below which the plasma osmolality does not normally fall because of excretion of a high volume of dilute urine. Thirst is illustrated as a physiologic ceiling for plasma osmolality, because, above this level, thirst is sensed and water imbibed to avoid further elevation of plasma osmolality. **B**, Idealized schematic diagram shows the reset osmostat, as occurs in pregnancy. For the patient to function normally with a lower osmolality, thirst and the osmotic threshold must be lowered and maintain their relative relationships with one another. Urine osmolality and urine volume follow appropriately for the level of vasopressin in plasma. Subjects experience extreme thirst if the osmolality is raised into the normal range. (From Robinson AG: Disorders of antidiuretic hormone secretion. *Clin Endocrinol Metab* 14:55, 1985.)

their early stages and tend to be larger at the time of diagnosis. If diagnosed, the patient should undergo appropriate surgical treatment before becoming pregnant. Tumor expansion with visual field defects during pregnancy has been reported.^{15,16} In the case reported by Masding and coworkers,¹⁶ there was prompt response to bromocriptine, and this response presumably was related to shrinkage of lactotroph hyperplasia.

PROLACTINOMA

The advent of prolactin radioimmunoassay in the early 1970s permitted the correct diagnosis of prolactinomas in many patients previously thought to have functionless pituitary tumors. Because of the negative effect of excess prolactin on the hypothalamic-pituitary-gonadal axis, most of these women, who were in their childbearing years, presented with amenorrhea and, consequently, with infertility. Parallel with the development of the prolactin assay and improved radiologic techniques for diagnosing these tumors came the development and refinement of transsphenoidal microsurgical techniques and a powerful new drug, bromocriptine mesylate, which can suppress elevated prolactin concentrations to normal levels. Numerous preg-

nancies resulted from restoring normal gonadal function in these women, and in the 1980s, information concerning these pregnancies was consolidated. Because of the physiologic changes that occur in the pituitary in a normal pregnancy—enlargement of the gland and hyperplasia of the lactotrophs with a tenfold increase in serum prolactin—concerns about women with prolactinomas becoming pregnant were reasonable.

Effects of Prolactinoma and Bromocriptine Treatment on Pregnancy and the Fetus. Bromocriptine mesylate is an ergot derivative with potent dopamine receptor agonist activity. Administered orally, it is a potent inhibitor of prolactin secretion, with effects usually lasting only for the duration of treatment. Numerous accounts of the use and safety of bromocriptine in pregnancy are available, but they are best summarized by Krupp and Monka¹⁷ (from the Drug Monitoring Center, Clinical Research, Sandoz, Basel, Switzerland). They collected data from 2587 pregnancies in 2437 women treated with bromocriptine during some stage of gestation. The results showed that its use was not associated with an increased risk of spontaneous abortion, multiple pregnancy, or congenital malformation in their progeny.

These investigators followed 546 children postnatally up to the age of 9 years and found no adverse effect on postnatal development. In most women treated, bromocriptine was discontinued on confirmation of pregnancy. These results are important insofar as investigations indicate that bromocriptine crosses the placental barrier and can be found in dose-related concentrations in fetal blood and in the amniotic fluid.¹⁸ The use of bromocriptine throughout pregnancy was limited to approximately 100 patients; one infant had an undescended testicle, and another a talipes deformity.⁵ The newer synthetic dopamine agonist, cabergoline, is also approved for treatment of prolactinomas. As with bromocriptine, the drug should be discontinued after pregnancy is established. Its twice-weekly administration and reduced side-effect profile makes it more palatable for some patients.¹⁹ The experience with cabergoline use in pregnancy, albeit in fewer patients, appears to be similar to that with bromocriptine.^{20,21} Given the longer safety record of bromocriptine, it is the drug of choice in patients desiring pregnancy. There have been reports of cardiac valvular defects in patients using cabergoline in large doses for Parkinson disease.²² Although the doses used in prolactinoma patients is much smaller and the relevance of these studies to its use in such patients is unknown, caution should be exercised, and the patient should be informed.

Effects of Pregnancy on Prolactinomas. Prolactinomas are subclassified according to size as microadenomas (<10 mm in diameter) (Fig. 48-5) and macroadenomas (≥10 mm in diameter). In a review of the subject with data collected and combined from many studies, Albrecht and Betz²³ found that of 352 pregnant patients with untreated microadenomas, 8 (2.3%) experienced visual disturbances, 17 (4.8%) experienced headaches, and 2 (0.6%) had diabetes insipidus. The corresponding figures for 144 pregnant women with macroadenomas were visual disturbances in 22 (15.3%), headaches in 22 (15.3%), and diabetes insipidus in 2 (1.4%).

In the same review, the outcomes of 318 pregnancies in patients with microadenomas and macroadenomas treated (i.e., surgery, radiation therapy, or both) before pregnancy were analyzed. There were visual disturbances in 10 (3.1%), headaches in 12 (3.8%), and diabetes

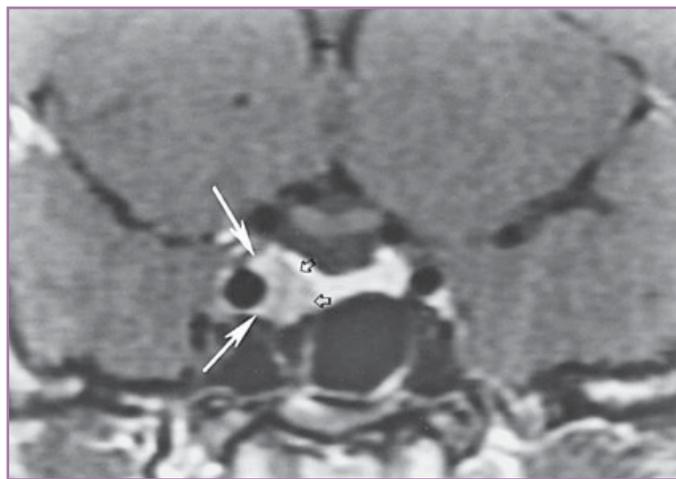

FIGURE 48-5 Prolactinoma in a 26-year-old woman. Coronal magnetic resonance imaging (SE = 600/25) after injection of gadolinium-DTPA reveals a 9 × 8 mm, solid mass (*open arrows*) of intermediate signal intensity involving the right side of the pituitary gland. The mass is abutting the dura (*solid arrows*), which surrounds the right internal carotid artery. The gadolinium-DTPA has increased the signal intensity of normal pituitary tissue, enhancing the contrast between normal and adenomatous areas.

insipidus in 1 (0.3%). In a further compilation of series published in the world literature,¹⁴ of 457 patients with microadenomas, 12 (2.6%) had symptomatic tumor enlargement, but none required surgery. Of 140 macroadenomas previously treated by surgery or radiation, 7 (5%) had symptomatic enlargement, and none required surgery. In contrast, of 142 macroadenomas not previously treated by surgery or radiation, 45 (31%) had symptomatic enlargement, and 12 (8.5%) had surgical treatment. Symptoms related to a pregnancy-induced increase in the size of a pituitary tumor can begin as early as the first trimester, with a mean time for the onset of visual symptoms at 14 weeks' gestation.²⁴ Headaches usually precede visual changes.

The data previously given can be used to counsel patients with prolactinomas who are planning pregnancy.^{14,25} Patients with microadenomas can safely be given bromocriptine. Visual field testing and MRI should be performed in patients with visual changes or symptoms suggestive of tumor expansion. For patients with small intrasellar or inferiorly expanding macroadenomas, bromocriptine may also be given as primary therapy. If tumor reduction is demonstrated, pregnancy should be allowed and the drug stopped when pregnancy is diagnosed. The rate of clinically serious complications is unlikely to be high in such cases. In patients with large macroadenomas with suprasellar extension, the risk of tumor expansion is significant when using bromocriptine to establish pregnancy. Pre-pregnancy tumor debulking can significantly reduce the risk of tumor expansion in pregnancy in these patients. Alternatively, bromocriptine may be administered throughout pregnancy as discussed previously and in the Management of Prolactinoma Complications during Pregnancy section. For patients with macroadenomas treated with bromocriptine or surgically, follow-up at 1- to 3-month intervals is recommended, along with visual field testing. Repeat MRI is performed for patients with symptoms or signs of tumor expansion. Recommendations for management of patients with prolactinomas are outlined in Tables 48-1 and 48-2.

Despite prior surgical intervention, complications can occur during pregnancy.²⁶ Monthly measurement of serum prolactin is not necessary. Prolactin concentrations measured in a group of patients with surgically untreated microadenomas were found to be elevated early in gestation but did not increase further with advancing gestation,²⁷ in contrast with normal pregnant controls (Fig. 48-6). A small subset of women appears to experience decrease or normalization of prolactin levels after delivery. Tumor necrosis might have occurred in some, and use of bromocriptine has been associated with tumor fibrosis.²⁸

Management of Prolactinoma Complications during Pregnancy. Bromocriptine (and cabergoline) has tumor-shrinking properties. It has been used successfully in the treatment of such complications and is the initial treatment of choice.⁵ It should be administered with food and the dose adjusted according to symptoms (e.g., 2.5 to 5 mg given two or three times daily). Glucocorticoids may also be given to expedite recovery of visual defects. Surgery is recommended only if there is no response to bromocriptine.

Most patients with microadenomas have uncomplicated pregnancies, whereas a disturbing number of patients with untreated macroadenomas have symptomatic tumor enlargement. Given the tumor-shrinking properties of bromocriptine, it is not surprising that the continuous use of bromocriptine in pregnancy has been advocated and carried out in patients with macroadenomas.²⁹ Experience with its use throughout gestation is limited to approximately 100 patients.⁵ Although the rates of abortion and perinatal mortality do not differ in women with pituitary tumors that are untreated or treated before or during pregnancy, there is a significant increase in prematurity among those treated (i.e., surgery, radiotherapy, or both) during pregnancy, compared with those not requiring such treatment or with those

TABLE 48-1 RECOMMENDATIONS FOR TREATMENT OF PATIENTS WITH PROLACTINOMAS WHO DESIRE PREGNANCY

Treatment	Microadenomas and Intrasellar Macroadenomas	Suprasellar Macroadenomas
Primary	Bromocriptine	Transsphenoidal surgery followed by bromocriptine
Alternative	Transsphenoidal surgery followed by bromocriptine (if necessary)	Radiotherapy plus bromocriptine <i>or</i> continuous bromocriptine

TABLE 48-2 MANAGEMENT OF PATIENTS HARBORING PROLACTINOMAS DURING GESTATION

Status of Patient	Microadenomas	Macroadenomas
Asymptomatic	Stop bromocriptine. Provide routine obstetric care with evaluation for symptoms of tumor expansion.	Stop bromocriptine. Perform monthly evaluation for symptoms of tumor expansion. Check visual fields every 1 to 3 months.
Symptomatic	Check visual fields. Measure the serum prolactin concentration. Obtain magnetic resonance imaging of the pituitary gland. Initiate bromocriptine with or without dexamethasone for visual complications. Perform transsphenoidal surgery if unresponsive to bromocriptine.	Check visual fields. Measure the serum prolactin concentration. Obtain magnetic resonance imaging of the pituitary gland. Initiate bromocriptine with or without dexamethasone for visual complications. Perform transsphenoidal surgery if unresponsive to bromocriptine.

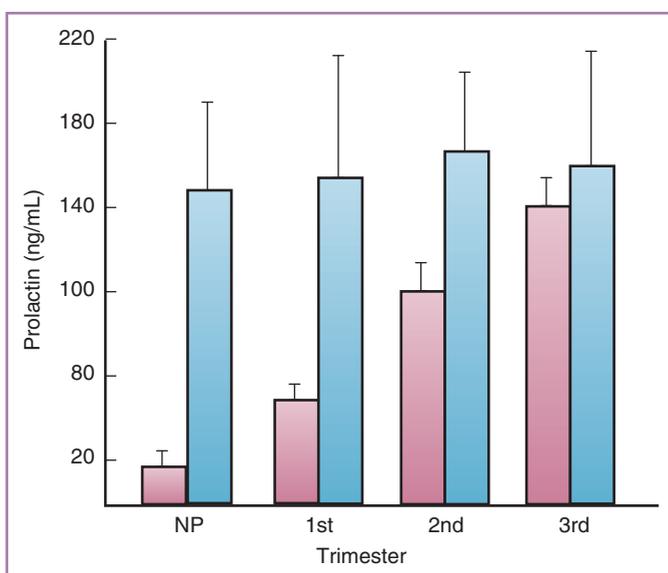

FIGURE 48-6 Prolactin concentrations. Maternal serum prolactin levels (mean \pm SEM) were measured in patients with microadenomas (blue bars, $n = 237$) and controls (purple bars, $n = 215$) while nonpregnant (NP) and during each trimester of pregnancy. (From Divers WA, Yen SSC: Prolactin producing microadenomas in pregnancy. *Obstet Gynecol* 62:425, 1983; reprinted with permission of the American College of Obstetricians and Gynecologists.)

treated before pregnancy.²⁴ Pituitary apoplexy, which is a rare event, has been reported in a patient with a macroadenoma in early pregnancy.³⁰

Breastfeeding and Postpartum Care. There is no reason to avoid breastfeeding when a patient with prolactinoma wishes to nurse her child. In a small study of 14 women with microadenomas who breastfed for 6 to 14 months, the level of serum prolactin was not sig-

nificantly higher than it was before pregnancy.³¹ In another study, the increase in prolactin associated with suckling was absent in women with pathologic hyperprolactinemia. For those wishing to inhibit lactation, bromocriptine is the treatment of choice in a dose of approximately 2.5 mg given three times daily with food.

Although occasional case reports have described seizures or strokes in women who used bromocriptine to inhibit postpartum lactation—and it should be kept in mind that suppression of lactation is no longer an approved indication for the use of this agent—a recent case-control study failed to link these events to the actual use of bromocriptine.³² Estrogen should not be used to inhibit lactation because the tumor can expand. Ophthalmologic and radiologic evaluation and determination of serum prolactin concentrations are in order 6–8 weeks after delivery. In most instances, the sella returns to its original size and prolactin decreases to previous levels. Further pregnancies are not contraindicated in patients with prolactinomas. Decreases in prolactin and tumor size have been reported in patients with multiple bromocriptine-induced pregnancies.³³

EXCESSIVE GROWTH HORMONE SECRETION: ACROMEGALY

Acromegaly is the result of excessive GH secretion in adults, and it is associated with acidophilic or chromophobic pituitary adenomas. About 60% of patients have macroadenomas. Women with acromegaly slowly develop coarse facial features, prognathism, and spadelike hands and feet. When clinical evidence exists, a glucose tolerance test is performed; lack of suppression of GH below 2 ng/mL during this test is in keeping with a diagnosis of acromegaly in nonpregnant patients. Because the biologic effect of GH is mediated through somatomedin-C, elevation of serum concentration of this growth factor is considered a useful confirmatory test and has been used to monitor the progression of the disease. In the context of pregnancy, however, somatomedin-C concentrations should be interpreted with caution because they can be elevated.³⁴ Because of the production of a placental variant of GH, special assays using antibodies that recognize specific epitopes on

the two hormones are necessary to differentiate normal from placental GH.³⁵ The placental variant is undetectable within 24 hours after delivery. TRH testing may distinguish pituitary from placental GH; 70% of patients with acromegaly experience a GH response to TRH, whereas the placental variant does not cause a response.³⁶ Pituitary GH secretion is pulsatile, with 13 to 19 pulses daily, as opposed to the placental variant, which is nonpulsatile.

Menstrual irregularity or amenorrhea is an extremely common finding in acromegalic women. Nonetheless, pregnancy can occur in women with acromegaly and has been reported in 70 patients.³⁷ It can be accompanied by tumor expansion in approximately 10%, necessitating hypophysectomy. Despite other soft tissue changes, no major changes occur in the genital tract that would complicate delivery. Definitive treatment before conception is the treatment of choice in acromegalic women desiring children. Carbohydrate intolerance occurs in up to 50% and overt diabetes in up to 20% of acromegalic women, and the insulin resistance of pregnancy is additive. Hypertension occurs in 25% to 35% of acromegalic women, and cardiac disease is common. An additional six cases with favorable outcomes have been reported.³⁸

An algorithm for the management of acromegaly in pregnancy has been presented by Herman-Bonert and colleagues.³⁷ Management was also reviewed by Molitch.⁵ The observation that levodopa (L-dopa) causes a paradoxical decrease in GH in acromegaly led to the use of dopaminergic agonists in the treatment of acromegaly. In two reported cases, pregnancy occurred in acromegalic women during bromocriptine therapy. Continuation of treatment during pregnancy did not lead to tumor expansion.³⁹ Tumor expansion resulting in visual field defects, however, has been reported in one of two patients with acromegaly and macroadenomas during pregnancy.¹⁵

If acromegaly is diagnosed in a pregnant patient, management depends on the activity of the disease, the tumor size, and the stage of pregnancy. Active disease during pregnancy may respond to bromocriptine until fetal lung maturation is documented. If signs and symptoms related to suprasellar extension do not abate with bromocriptine, transsphenoidal surgery could be necessary.

In a case reported by Yap and associates,⁴⁰ acromegaly was diagnosed in the second trimester. Bromocriptine corrected visual field defects and suppressed prolactin secretion but did not reduce fasting GH levels. It was suggested that suppression of physiologic lactotroph hyperplasia by bromocriptine might permit noninvasive management of the pituitary adenoma in pregnancy. The somatostatin analogues octreotide and lanreotide have been used in at least 10 patients.^{41,42} In three patients, the drug was continued throughout pregnancy without reported ill effects on the fetus, despite documented transplacental passage.⁴³ Somatostatin analogues should be discontinued in acromegalic patients contemplating pregnancy, but they may be considered an alternative to transsphenoidal surgery in pregnancy for an expanding tumor if the patient does not respond to dopaminergic agonists such as bromocriptine. The maternal-fetal transfer of GH is thought to be negligible, and apart from the effect of glucose intolerance, the fetus is not thought to be affected by acromegaly.

THYROTROPIN-SECRETING TUMORS

Three cases of TSH-secreting tumors and pregnancy have been reported. One patient was treated with octreotide before pregnancy, stopped the medication with the pregnancy diagnosis, but developed symptomatic growth at 6 months. The second, whose pregnancy was uncomplicated, received octreotide throughout gestation. The third had tumor enlargement and visual loss despite bromocriptine, necessitating transsphenoidal surgery.⁴⁴

CUSHING SYNDROME

The hypothalamic-pituitary-adrenal axis in pregnancy was the subject of a review by Lindsay and Nieman⁴⁵ and Cushing syndrome in pregnancy the subject of a specific review by Lindsay and associates.⁴⁶ Cortisol secretion is controlled by the hypothalamic-pituitary axis. Cushing syndrome is a state of hypercortisolism that can arise from excess ACTH produced by the pituitary or an ectopic ACTH source such as a tumor, both of which can lead to bilateral adrenal hyperplasia. An adrenal lesion (i.e., adenoma or carcinoma) may be the direct source of excess cortisol.

Pregnancy is uncommon in patients with Cushing syndrome because of its association with a high incidence of menstrual disturbances and anovulation. Pituitary-dependent Cushing syndrome, also called Cushing disease, gives rise to bilateral adrenal hyperplasia and a state of hypercortisolism. Although pituitary-dependent Cushing syndrome is the most common cause in nonpregnant patients, it is relatively less commonly associated with pregnancy, because hyperfunctioning adrenal tumors are relatively more common in pregnant patients with this syndrome. A possible explanation for this discrepancy is the greater degree of ovulatory disturbance in patients with pituitary-dependent Cushing syndrome.⁴⁷

In 136 pregnancies in 122 women,⁴⁵ the mean gestational age at diagnosis was 18 weeks. Adrenal adenomas accounted for almost one half of the cases (compared with 15% in nonpregnant women), with adrenal carcinomas occurring in 10%. Pituitary-dependent Cushing syndrome (i.e., Cushing disease) was less common, occurring in a third of the 122 women, compared with 70% in the general population. Ectopic ACTH occurred in four patients. Exacerbation of Cushing syndrome in pregnancy with amelioration or remission after pregnancy has been reported.^{48,49}

Diagnosis. The diagnosis of Cushing syndrome in pregnancy can be rendered more difficult because weight gain, hypertension, striae, edema, and pigmentation may occur in normal pregnancy. More specific signs, such as thinning of the skin, spontaneous bruising, and muscle weakness, should be sought. The laboratory diagnosis is complicated by the changes in adrenal function that occur during normal pregnancy. These include an increase in bound and free serum cortisol levels, increased levels of urinary free cortisol, and a lack of adequate suppression of cortisol after low-dose dexamethasone treatment.

Urinary free cortisol excretion is less than 50 µg/24 hours in nonpregnant women with the use of mass spectroscopy assays. Excretion is increased during normal pregnancy. The mean 24 urinary free cortisol level is increased at least 180% during gestation. Levels of total and free plasma cortisol increase twofold to threefold, with a wide range of normal variation in morning cortisol ranging from 16.3 to 55 µg/dL.⁴⁵ The diurnal variation is blunted. The suppressibility of cortisol was shown to be 40% after 1 mg of dexamethasone in second- and third-trimester normal pregnancies, compared with 80% in non-gravid controls; loss of suppression increased with increasing gestation. In a collected series and review of the literature with 136 cases of Cushing syndrome in pregnancy in 122 women, the following features were identified⁴⁵:

1. There was a mean eightfold elevation in urinary free cortisol (range, 2- to 22-fold).
2. Diurnal variation of cortisol was absent.
3. Midnight cortisol level was elevated (mean, 30.9 µg/dL).
4. Using 1 mg overnight or 2-day low-dose (2 mg daily) dexamethasone suppression testing, the median suppressibility of cortisol was approximately 30% in women with Cushing disease and 10% in those with adrenal Cushing syndrome; dexamethasone suppress-

ibility was not considered a sensitive test for Cushing syndrome in pregnancy.

5. In the differential diagnosis of Cushing syndrome, 8 of 16 with the adrenal form or ACTH-independent hyperplasia had ACTH assay results below the detection limit of 10 pg/mL. Conversely, of 18 patients with Cushing disease, 2 had ACTH values below 10 pg/mL (i.e., inappropriately low).
6. Using high-dose dexamethasone (8 mg daily) and a criterion of 80% suppression as indicative of pituitary-dependent Cushing syndrome, all patients with ACTH-independent Cushing syndrome failed to suppress. However, 3 of 7 with pituitary-dependent Cushing syndrome did not have suppression.
7. MRI of the pituitary identified an adenoma in 5 of 8 subjects.
8. Adrenal imaging correctly identified the lesion in 11 of 15 by ultrasound; MRI or computed tomography were uniformly successful in identifying the lesion. Bearing these changes in mind, urinary free cortisol excretion of more than three times the upper limit of normal in the second or third trimesters may suggest Cushing syndrome.

To distinguish pituitary-dependent Cushing disease from hyperfunctioning adrenal tumors, a high-dose dexamethasone suppression test is recommended (8 mg/day for at least 2 days). Significant ($\geq 50\%$) suppression of plasma cortisol is the rule in pituitary-dependent Cushing syndrome, and failure of suppression with high-dose dexamethasone, along with low or undetectable ACTH concentrations, strongly suggests an adrenal source. Because the placenta also produces ACTH, this test may not always be reliable. Ectopic ACTH syndrome also causes failure to suppress. In determining the differential diagnosis, high-dose dexamethasone suppression testing and plasma ACTH should be performed. The pituitary can be evaluated during pregnancy by means of MRI.^{2,49} CRH testing in pregnancy can also aid in the differential diagnosis. Although the ACTH response to CRH is blunted in the third trimester, a substantial rise in cortisol after CRH stimulation in Cushing syndrome is consistent with pituitary-dependent disease. One microgram of ovine CRH was given per kilogram of body weight (U. S. Food and Drug Administration [FDA] pregnancy category C drug), and a rise in cortisol (44% to 130%) was seen in those with pituitary disease confirmed surgically.⁴⁵ Pituitary disease can also be distinguished from ectopic ACTH by inferior petrosal sinus sampling combined with CRH stimulation. There is one report of such testing in pregnancy.⁵⁰

Maternal-Fetal Complications. Although congenital malformations are not more common in Cushing syndrome than in normal pregnancy,⁴⁸ maternal and fetal complications can occur. In the 136 pregnancies reported by Lindsay and Nieman,⁴⁵ maternal morbidity and mortality included hypertension (68%), diabetes or impaired glucose tolerance (25%), preeclampsia (14%), osteoporosis and fracture (5%), heart failure (3%), psychiatric disturbances (4%), wound infections (2%), and maternal deaths (2%). Fetal morbidity was also significant, with a prematurity rate of 43%, stillbirth rate of 6%, and spontaneous abortion rate of 5%, and there were two infant deaths. Intrauterine growth restriction is prevalent, occurring in approximately one half of reported cases.⁴⁷ Possible causes include hypertension and cortisol excess itself. Neonatal adrenal insufficiency has been reported and is presumably caused by suppression of the fetal hypothalamic-pituitary-adrenal axis from transplacental transport of excess maternal cortisol.

Therapy. Because of the poor fetal outcome, therapy aimed at controlling the hypercortisolism is recommended. In the 136 pregnancies discussed previously with outcomes available, when no

active treatment was given, there was a 76% rate of live births, compared with 89% among women treated at a mean gestational age of 20 weeks. The following recommendations for treatment have been suggested.⁴⁶

In the first trimester, pituitary surgery for pituitary-dependent Cushing syndrome and adrenal surgery for tumors of adrenal origin (especially to rule out carcinoma) should be performed. In the third trimester, early delivery of the fetus—preferably vaginal—may be attempted. Metyrapone therapy (to block cortisol secretion) may reduce hypercortisolism until fetal maturity is attained.⁵¹ In the second trimester, treatment should be individualized; the alternatives are definitive surgery or medical therapy aimed at ameliorating hypercortisolism. Successful transsphenoidal surgery has been reported in the second trimester.⁵² The risks of treatment with metyrapone, ketoconazole, and aminoglutethimide, all of which block cortisol secretion, are uncertain because transplacental passage occurs and fetal adrenal steroid synthesis may be affected.⁵³ The risk of teratogenicity, virilization of female fetuses (with aminoglutethimide) or inadequate masculinization of a male fetus (with ketoconazole) discourages the use of these two agents. Metyrapone is the drug of choice, although there is a potential for exacerbation of hypertension. Mitotane is teratogenic and should not be used.

Nelson Syndrome. When a patient with pituitary-dependent Cushing syndrome undergoes bilateral adrenalectomy as definitive treatment for hypercortisolism and the pituitary lesion is not adequately addressed, a syndrome of hyperpigmentation along with an expanding intrasellar ACTH-producing tumor can result. This is called Nelson syndrome. The association of this syndrome and pregnancy is rare. In a series involving 10 cases, 5 required postpartum treatment of their pituitary tumors, 5 were only observed, and 1 required surgical treatment during the pregnancy, with successful outcomes for the mother and child.⁵⁴ A later case documented an uncomplicated pregnancy and normal lactation.⁵⁵

HYPOPITUITARISM

Diminished or decreased production of anterior pituitary hormones results in inadequate activity of target organs, such as the thyroid, adrenals, and gonads. The deficiency can be partial—affecting trophic hormones in various degrees—or it can be complete, resulting in panhypopituitarism. The role of the obstetrician-gynecologist in this context is twofold: to be alert to and aware of the possibility of two disease processes that can affect the pregnant patient—Sheehan syndrome and lymphocytic hypophysitis—and to recognize and treat hypopituitarism in a pregnant patient, thereby avoiding undesirable consequences.

Sheehan Syndrome. In 1937, Sheehan⁵⁶ drew attention to the relationship between postpartum hemorrhage and anterior pituitary necrosis. Because the syndrome is distinctly uncommon, with other conditions associated with shock and vascular collapse, it is assumed that the hyperplastic gland in pregnancy is more vulnerable to an inadequate blood supply. In a retrospective survey by Hall,⁵⁷ pregnant patients admitted for hemorrhagic collapse were subsequently traced and evaluated for hypopituitarism; the incidence was approximately 3.6%. There is said to be no direct correlation between the severity of the hemorrhage and the occurrence of Sheehan syndrome, but the major part of the pituitary must be destroyed before symptoms become evident.⁵⁷ In one review, small sella size was suggested as a risk.⁵⁸

In a series of 25 cases,⁵⁹ 50% of patients had permanent amenorrhea, and the remainder had rare and scanty menses. Only one patient menstruated normally, and in most, lactation was poor or absent. There was a surprisingly long interval between the obstetric event and

diagnosis (>10 years) for more than one half of the patients. In a later series of 20 cases, the mean time between diagnosis and date of last delivery was 26.8 years. Amenorrhea and absent lactation occurred in 70%. Some degree of hypogonadism, GH deficiency, and low prolactin levels occurred in all; 90% were hypothyroid, and 55% had adrenal failure.⁶¹

Although pregnancy in hypopituitary patients is rare, the inability to establish the diagnosis and institute proper therapy can have lethal consequences for the mother and fetus. Grimes and Brooks⁶¹ reviewed the pregnancies of their patients with Sheehan syndrome. There was an 87% rate of live births, 13% rate of abortions, and no stillbirth or maternal death in 15 pregnancies among patients receiving hormonal therapy. In sharp contrast, in 24 pregnancies among 11 women in whom hormone replacement was not provided, there was a 58% rate of live births, 42% rate of abortions, one stillbirth, and three maternal deaths.

In nonpregnant patients thought to have Sheehan syndrome, the diagnosis and the extent of pituitary damage can be determined by tests of target organ function (e.g., thyroid function tests, cortisol concentration) and tests of pituitary reserve.⁶² An ongoing pregnancy does not constitute evidence against the diagnosis of Sheehan syndrome, and it should be considered for all patients with a history of postpartum hemorrhage, especially if the patient is currently symptomatic. The finding of a low serum thyroxine level and low TSH level is in keeping with secondary hypothyroidism; low cortisol concentrations (compared with those of normal pregnant women) and failure of cortisol and ACTH to increase during times of stress are in keeping with diminished ACTH reserve. Imaging studies are likely to reveal an empty sella turcica.⁶³

Treatment of pituitary insufficiency during pregnancy does not present special problems. Oral L-thyroxine (0.1 to 0.2 mg/day) and cortisol (20 mg in the morning and 10 mg in the evening) or prednisone (5 mg in the morning and 2.5 mg in the evening) are administered. There is no need for mineralocorticoids. The dose of L-thyroxine required in pregnancy is likely to be higher, and free thyroxine concentrations should be kept in the mid-normal range. TSH is not useful for monitoring treatment. As in the nonpregnant state, glucocorticoid requirements may increase during episodes of intercurrent illness. During labor, a good state of hydration should be maintained and parenteral glucocorticoids administered. This is most easily achieved by the intravenous infusion of hydrocortisone (cortisol). The dose can be adjusted as appropriate for the patient's state, ranging from 25 to 75 mg every 6 hours. After delivery, parenteral glucocorticoids should be continued in smaller doses for a few days along with intravenous fluids.

Pituitary Necrosis. Spontaneous pituitary necrosis and hypopituitarism can occur in pregnant diabetic patients, possibly related to diabetic vascular changes and the general susceptibility of the anterior pituitary to ischemia in pregnancy. It is manifested by severe, midline headaches and vomiting during the third trimester, followed by a decrease in insulin requirements. In three of eight patients reported, the condition was associated with fetal death followed by maternal death.⁶⁴ Early recognition and prompt management are essential. Pituitary apoplexy in a nondiabetic patient presenting during pregnancy with headaches and circulatory collapse has also been reported.⁶⁵

Lymphocytic Adenohypophysitis. In 1962, Goudie and Pinkerton⁶⁶ described the case of a 22-year-old woman who died of circulatory collapse 8 hours after appendectomy. This occurred 14 months after a normal pregnancy and delivery, but she had developed secondary amenorrhea after delivery. Autopsy revealed lymphocytic infiltra-

tion of the pituitary and of the thyroid; the investigators postulated an autoimmune mechanism to explain both.

Lymphocytic adeno hypophysitis (LAH) was the subject of a review.⁶⁷ As was previously known, there is a striking temporal association of LAH with pregnancy. Of a total of 245 cases of LAH reported, 210 occurred in women, and of these women, 120 (57%) presented during pregnancy or after delivery, most in the last month of pregnancy or within the 2 months after delivery. There were no fetal complications, but one patient died in labor. Sixteen women had subsequent pregnancies. Release of pituitary antigens during pregnancy-related changes and alterations in pituitary blood supply have been suggested as links to altered immunity. Anti-pituitary antibodies have been demonstrated in a significant number of cases.^{67,68} Exacerbation of the disease after delivery, even when it initially manifests in pregnancy, has been described.⁶⁹

Table 48-3 inventories the characteristics of patients with LAH. Hypocortisolism is the most important hormone deficiency, followed by TSH, gonadotropin, and prolactin. Hyperprolactinemia may also occur, manifesting as amenorrhea or galactorrhea. Stalk compression, an inflammatory process in the lactotroph inducing release of prolactin, and antibodies stimulating prolactin synthesis are potential mechanisms leading to hyperprolactinemia.

The association of this disease with pregnancy was highlighted in an immunohistochemical study performed on pituitary material obtained at autopsy of 69 women who were pregnant or who had undergone delivery; among these were five cases of mild LAH.¹ In four of the five cases, the patients died at 38 to 41 weeks' gestation.

This is a potentially life-threatening condition, but it is a treatable disease affecting young women during or after pregnancy. The diag-

TABLE 48-3 CHARACTERISTICS OF 245 PATIENTS WITH LYMPHOCYTIC ADENOHYPOPHYSITIS

Characteristic	Quantity or Percent
Mean age of women (<i>n</i> = 210)	35 yr
Mean age of men (<i>n</i> = 35)	45 yr
History of onset in pregnant or postpartum women (120 women)	57%
Hypocortisolism	42%
Hypothyroidism	18%
Hypogonadism	12%
Inability to lactate	11%
Hyperprolactinemia	23%
Polyuria or polydipsia	1%
Headaches	53%
Visual disturbances	43%
Association with other autoimmune disease*	18%
Median duration of symptoms with diagnosis outside pregnancy	12 mo
Median duration of symptoms with diagnosis associated with pregnancy	4 mo
Required long-term hormonal treatment	56%
Deaths	8.6%
Disease resolved spontaneously	4.5%

*Includes 131 patients with infundibulo-neurohypophysitis and panhypophysitis and 245 patients with lymphocytic adenohypophysitis.

nosis should be considered in women of reproductive age presenting with signs and symptoms of anterior pituitary hormone deficiencies (isolated or combined) before or after delivery, especially in the absence of significant bleeding during labor. The diagnosis should also be considered in pregnant or postpartum women with visual symptoms and changes. In the absence of a threat to vision, such patients should be treated medically with hormone replacement and their progress observed. MRI should be used to delineate and follow the anatomic defects. It typically shows a symmetrically enlarged gland and a thickened stalk, and in contrast to macroadenomas, MRI shows strong and homogeneous enhancement after gadolinium contrast.

The use of steroids has been associated with amelioration of visual symptoms,^{70,71} and the sellar mass has been shown to regress spontaneously. In another reported case,⁷¹ partial hypopituitarism resolved after delivery in a biopsy-diagnosed case of LAH. Glucocorticoids should be the first line of treatment for the pituitary mass. Other immunosuppressive drugs, such as azathioprine and methotrexate, have also been used. Decompressive surgery is indicated only for progressive visual deficit. Although considered a disease of the anterior pituitary, LAH can manifest as diabetes insipidus with thickening and prominence of the pituitary stalk.⁷² LAH has recurred in a subsequent pregnancy in a case of histologically documented hypophysitis.⁷³ One case was associated with postpartum cardiomyopathy.⁷⁴

Posterior Lobe Disorders

DIABETES INSIPIDUS

Vasopressin and oxytocin, produced in the supraoptic and paraventricular nuclei of the hypothalamus, are released into the posterior lobe and then into the circulation. No disease process with oxytocin deficiency or excess has been described. Lack of vasopressin results in diabetes insipidus, however, and this can occur as a primary or idiopathic disorder ($\approx 30\%$ of cases) or can be acquired secondary to a variety of pathologic lesions, including cranial injuries (16%), infections, sellar and suprasellar tumors (25%), and vascular lesions. The main symptoms are polyuria, polydipsia, and low urinary specific gravity. The diagnosis is confirmed by water deprivation. During this test, increasing serum osmolality in the face of low urine osmolality is diagnostic of diabetes insipidus; a return toward normal after vasopressin administration confirms vasopressin deficiency.

Effect of Diabetes Insipidus on Pregnancy. In a comprehensive review, Hendricks⁷⁵ concluded that the prior existence of diabetes insipidus in a woman did not appear to alter her fertility, the course of pregnancy, the effectiveness of labor, or lactation. Because oxytocin is also produced in the same hypothalamic nuclei, diabetes insipidus is of particular interest in managing the pregnant woman because of the possible relationship of decreased oxytocin with decreased uterine contractions during labor. Despite one report of uterine atony,⁷⁶ it appears that labor is normal in most patients with diabetes insipidus.

Effect of Pregnancy on Diabetes Insipidus. The effect of pregnancy on diabetes insipidus has been reviewed by Durr and Lindheimer.⁷⁷ Diabetes insipidus during pregnancy appears to be characterized by several distinct clinical entities: pregnancy in patients with diabetes insipidus antedating gestation; transient arginine vasopressin (AVP)-resistant but L-deamino, 8-D-arginine vasopressin (DDAVP)-responsive diabetes insipidus; transient diabetes insipidus during pregnancy in patients with acquired or hereditary latent diabetes insipidus; diabetes insipidus after a complicated delivery; and transient de novo nephrogenic diabetes insipidus, resistant to AVP and DDAVP.

For pregnancy in patients with diabetes insipidus antedating gestation, the effect of pregnancy on established diabetes insipidus varies.

In a review of the subject, Hime and Richardson⁷⁸ found that 58% of patients deteriorated, 20% improved, and 15% remained the same. The metabolic clearance of vasopressin markedly increases between gestational week 10 and mid-pregnancy, and it is associated with parallel increases in circulating vasopressinase. Placental inactivation of vasopressin with the production of large quantities of vasopressinase by the placenta may contribute to this increase in clearance rate.⁷ In a few patients in whom preeclampsia developed, the diabetes insipidus improved. The decreased contribution of the placenta to destruction of vasopressin is thought to explain this improvement.⁷⁹

Transient AVP-resistant but DDAVP-responsive diabetes insipidus is attributable to excessively high quantities of circulating vasopressinase.⁸⁰ It is often associated with liver abnormalities in the mother, such as acute fatty liver or HELLP syndrome (*hemolysis, elevated liver enzymes, low platelets*). Vasopressinase isoenzymes are proteins that are cleared by the liver, and under these circumstances, excessive amounts are made available. Two cases were reported by Brewster and Hayslett⁸¹ that were unassociated with liver disease. An accompanying commentary stated that a sodium level of 140 mEq/L should be considered hyponatremia in most pregnant women, and early recognition and treatment were advised.⁸² A case of transient diabetes insipidus in pregnancy showed absence of the hyperintensity of the posterior pituitary lobe on MRI during pregnancy with restoration after delivery, presumably reflecting depletion and restoration of neurosecretory granules.⁸³
